QUALISYS

www.qualisys.com

We turn motion into science.

Qualisys is proud to support the biomechanics community by being a Sapphire sponsor of ISB 2023. For more than 30 years, we have been supplying motion capture systems for researchers, coaches, and clinicians. Visit *Qualisys Booth B* as our staff members below host various hands-on demonstrations.

MONDAY 30 JULY

Digital Integrations - Bertec Force Plates

Learn how to digitally integrate Bertec force plates with QTM. We will demonstrate the workflow live using our Functional Assessment module to display force integration within our web reporting platform.

TUESDAY 31 JULY

Scripting in QTM

In this interactive demonstration, we will show you how to leverage the flexibility of Python or Lua scripts in QTM to add functionality, automate pipelines, create custom tools, and more!

WEDNESDAY 1 AUGUST

OpenSim

Learn how to simplify your simulation workflow with QTM and OpenSim. We will present a streamlined workflow to prepare data recorded with QTM and to load it into OpenSim software.

Welcome

from the Congress Chair

Dear Scholars,

Please accept my sincere welcome to the XXIX Conference of the International Society of Biomechanics (ISB) and the XXIX Conference of the Japanese Society of Biomechanics (JSB).

After a long, difficult time, we finally have a chance to exchange our latest findings, ideas and recent advances with friends and colleagues in person. This is exactly what I had hoped I could do as the ISB/JSB2023 conference host. I am so happy with this. My first time at an ISB conference was in Tokyo in 1997. The leader of our laboratory at the University of Tokyo, Professor Miyashita organized the conference as the congress chair. At that time, I had just started my academic career as a research associate at Nagoya University. I was overcome by the scale and the level of science at the ISB conference. I never imagined that I would have a chance to one day organize the ISB conference myself! If I had a chance to go back to that time, I would tell myself “Keep staying in academics because you will organize this conference in the future”. But who can believe it? Anyway, throughout my career, the ISB always shown me the path I have walked.

Also, it is my great pleasure to organize the JSB conference as a joint conference with the ISB conference. Since 1957, JSB continues to enhance academic research on human movement and promotes academic interactions among scientists in order to promote research in biomechanics as a leading scientific society in Japan. Throughout ISB’s history, JSB scholars have actively promoted the ISB’s mission. It is worth noting, JSB scholars successfully organized ISB conferences twice in history and the organizers achieved an excellent reputation from participants for their heart-warming and well-organized conference management. This is the third time for JSB, and I aim to ensure that you will come to have the exact same feeling during the current conference.

Fukuoka University kindly gave me the chance to host a conference in this charming city. Fukuoka is best known for its unique food, culture, beautiful beaches and islands. I am sure you will enjoy your stay. I can’t wait for the start on Sunday 31st July with The Wartenweiler Memorial Lecture. See you all very soon.

Welcome to ISB/JSB2023.

Hiro Nunome, PhD

Professor, Fukuoka University

Congress Chair

Welcome

from the ISB President

Dear Delegates,

On behalf of the International Society of Biomechanics Executive Council and the Congress organizers, I welcome you to Fukuoka, Japan, for the XXIX Congress of the International Society of Biomechanics (ISB2023) to be held in conjunction with the XXIX Congress of the Japanese Society of Biomechanics (JSB2023). Many thanks to the Congress Chair Prof. Hiroyuki Nunome, Fukuoka University, and Congress co-Chair, Dr. Hiroaki Hobara, Tokyo University of Science. Thanks also to the JSB president Prof. Shinji Sakurai, Chukyo University. The Organizing and the Scientific committees have worked very hard for securing this memorable event.

In the past few years, biomechanics has continued to grow despite international crisis and the pandemic. Rather, biomechanics always contributes to bring together professionals from a variety of scientific and technical disciplines including anatomy, physiology, engineering, computer science, orthopaedics, sport science, rehabilitation medicine, kinesiology and others also from industry. They work together to understand the development of diseases on mechanical bases, and to devise products, programmes, devices for a better quality of life and better functional and sport performances. To achieve this, state-of-the-art technology is exploited, and novel tools are developed; we now look forward to take advantage also of AI for more comprehensive models and thorough knowledge of the complex biological systems of the human body.

In 2021, the XXVIII Congress of ISB was held in Stockholm, and, although over 1000 delegates participated digitally we only had about ten people attend in person, because of the terrible international situations. This year we expect two thousand participants, as in most of the Congresses before 2021. It is so important that the necessary contact between these scientists can have a physical space able to welcome, involve and introduce people of all ages and backgrounds. Japan is a perfect location, due to its long and superb history and the passion and competence of its people, presenting a clear example of a tight-knit community. Please take the chance to become acquainted with the Japanese biomechanists, and also to meet the people and to taste their fascinating cities and culture. By gathering in person again, we finally can better exchange ideas and projects, to get to know each other, to hear research stories with sympathy, and thus perhaps to strengthen friendships amongst people in the world.

The ISB wants to promote biomechanics internationally and to contribute to this spirit of collaboration. In addition to the biennial international Congresses, the Society has a number of initiatives in this respect, including publications, student awards and mentoring, honours, social media, educational series, specialised Technical Groups, local national communities, special supports for members in economically developing countries, recommendation papers etc. Please search and ask about these, the Council members and other seniors will be pleased to tell you. The Congress is also the time for the General Assembly, where these activities are reported and discussed all together.

To make this Congress even more memorable, we celebrate 50 years of the ISB with a number of special guests and surprise events!

Alberto Leardini, DPhil

Istituto Ortopedico Rizzoli, Bologna - Italy

President, International Society of Biomechanics

Welcome

from the JSB President

Dear Delegates,

As the president of the Japanese Society of Biomechanics (JSB), I am honored to welcome you to our joint conference with the International Society of Biomechanics (ISB). This marks the third time that the ISB conference is being held in Japan, following the 8th conference in Nagoya in 1981 and the 16th conference in Tokyo in 1997.

The JSB was founded in 1957, and this year's conference marks our 29th meeting, coinciding with the 29th biannual conference of the ISB, which was established in 1973. We are thrilled to be hosting this esteemed event in Fukuoka.

2020 saw the World Health Organization declare a global emergency due to the COVID-19 pandemic. After more than three years of uncertainty, we are finally able to gather in person for this conference. While online events have their advantages, there is nothing that can replace the value of face-to-face discussions and information exchange that takes place at such gatherings.

I am confident that this conference will provide a stimulating forum for the exchange of ideas and the presentation of cutting-edge research in biomechanics. I encourage all attendees to take full advantage of this opportunity to engage with fellow researchers, share knowledge, deepen friendship, and forge new collaborations.

In closing, I thank each of you for attending and contributing to what is sure to be an outstanding showcase and celebration of the field of biomechanics. On behalf of the JSB executive board, we wish all attendees an enjoyable and intellectually stimulating meeting.

Shinji Sakurai, PhD

Professor, Chukyo University

President, Japanese Society of Biomechanics

Organizing Committee

General Information

CITY OF FUKUOKA

Fukuoka is an extremely compact and well-organized city where places to live and work, as well as places of entertainment and leisure, are both temporally and geographically in close proximity. In fact, a short walk from the city center will bring you face-to-face with the expansive Hakata Harbour. Beautiful landscapes replete with water and greenery dot Fukuoka, which is that rare tourist city that offers the urban and the natural together. On your visit, be sure to enjoy Fukuoka's diverse natural environment and well-organized city area to the fullest.

CONGRESS VENUE

Fukuoka International Congress Center
2-1 Sekijo-machi, Hakata-ku, Fukuoka, 812-0032, Japan
TEL: +81-92-262-4111
Access from Fukuoka airport:
15 minutes by taxi / 30 minutes by subway & bus
www.marinemesse.or.jp/eng/congress/access/

GENERAL INFORMATION/REGISTRATION DESK

General information and registration desks are located at the entrance hall on the 1st floor. Participants are requested to complete the online registration in advance. QR code must be downloaded from the registration "My page" after completing the registration to receive the name badge and the certificate of attendance at the registration desk on-site.
Desks will be open during the following times:

Sunday, July 30th	09:30 – 18:00
Monday, July 31st	07:30 – 17:00
Tuesday, August 1st	07:30 – 17:00
Wednesday, August 2nd	07:30 – 17:00
Thursday, August 3rd	07:30 – 14:00

EXHIBITION

The exhibition will be held in the multi-purpose hall on the 2nd floor. It will be open at the following times:

Monday, July 31st	08:00 – 17:00
Tuesday, August 1st	08:00 – 17:00
Wednesday, August 2nd	08:00 – 17:00
Thursday, August 3rd	08:00 – 13:30

TRAVEL DESK

The travel desk will be located at the entrance hall on the 1st floor.

INTERNET

Wireless internet (Wi-Fi) will be available free of charge.

SSID: FCC_Free_WiFi *No password required

INSTRUCTIONS FOR CHAIRS

Chairs are requested to take their seats at the front-right row of each session room at least 15 minutes before the session starts. Chairs are asked to stay within the time allotted for the session and each presentation. During the Q&A, please ask the participants questions and/or comments to stand in line by the microphone in advance.

CORPORATE SUPPORT DISCLOSURE FOR ALL SPEAKERS

All presenters, regardless of format, must disclose within their presentations whether corporate support was provided for their research, including conference-related travel expenses. Example disclosure statements:

- "No corporate support was received for this research."
- "Company ABC funded subject recruitment and data collection. Other than funding no Company ABC employee was directly involved in this research in any way that could have influenced or biased the reported results."

INSTRUCTIONS FOR ORAL PRESENTATIONS

Session	Presentation	Discussion
Keynote	45 minutes	5 minutes
Symposium/Workshop/Others	Assigned individually	
Oral	8 minutes	3 minutes

- You must use congress PCs (Windows). Use of your own PC is not permitted.
- Screen ratio of 16:9 is recommended.
- Preferred file format: PPTX, PowerPoint 2010 or higher. If you create your PowerPoint file on a Mac please check your presentation on a Windows PC beforehand.
- Other file formats: PDF format is also possible.
- Presenter view is not allowed. Please bring your printed notes with you if necessary.
- Please bring your media (USB flash memory drive or CD-R).
- When writing onto a CD-R, use only the hybrid format (ISO 9660), as using special functions such as "Packet Write" may cause problems with data display.
- To avoid the possible spread of computer viruses, always scan your presentation files beforehand with updated anti-virus software.
- After saving your presentation file on the appropriate medium, do a test run on another PC to make sure it works properly.

- Please ensure you arrive at your presentation room and be seated at the next speaker seat at least 15 minutes prior to the start of the session.
- Any copies of your presentation data that the secretariat has received will be deleted after the congress.

SPEAKER READY ROOM

Speaker Ready Room is located on the 2nd floor. Each oral session speaker must report to the Speaker Ready Room to load their presentation on the laptop computer that will be used in their session room at least 1 hour prior to the start of the session. The Speaker Ready Room will be open during the following hours:

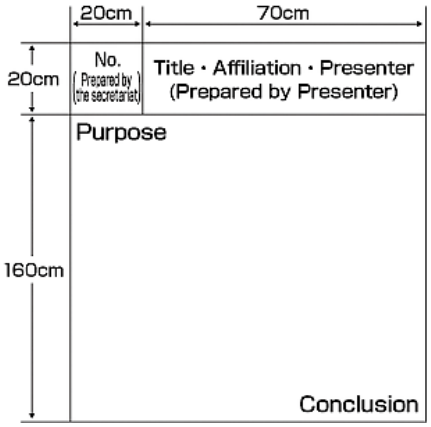
Sunday, July 30th	15:00 – 18:00
Monday, July 31st	07:30 – 17:00
Tuesday, August 1st	07:30 – 17:00
Wednesday, August 2nd	07:30 – 17:00
Thursday, August 3rd	07:30 – 15:00

INSTRUCTIONS FOR POSTER DISPLAY

All posters will be displayed during the general poster sessions. There will be no oral presentations, flash talks, or formal rotating audience panels for posters. Instead poster sessions will run in a free format. Each presenter is encouraged to engage with all attendees who are interested in your work.

Monday, July 31st	Install	07:30-
	Session	17:20-18:50
	Dismantle	18:50-19:10
Tuesday, August 1st	Install	07:30-
	Session	18:15-19:55
	Dismantle	19:55-20:15
Wednesday, August 2nd	Install	07:30-
	Session	18:10-19:40
	Dismantle	19:40-20:00

*If your poster is not removed by the relevant deadline, your poster will be removed and disposed of by the secretariat.
Poster size: H 180 cm (71 in) × W 90 cm (35 in).
Poster number: a 20 cm × 20 cm (8 in × 8 in) poster number will be provided at the congress venue on your allotted poster panel. Please place this number on the upper left corner of your poster (see figure below).



CATERING

Coffee will be offered at the posters/exhibition room on the 2nd floor and lobby on the 5th floor. Lunch will be offered on the 3rd and 4th Floors. For break times please refer to the day-at-a-glance pages of the program.

DRESS CODE

The dress code is smart casual.

DUPLICATION / RECORDING

No photography, videotaping or recording is allowed in oral or poster sessions except by the official society photographer or society-approved audio-visual vendor. This includes cameras, cell phones and all other devices.

SOCIAL PROGRAMS

Welcome Reception
18:00- , Sunday, July 30th

Pioneering Women of ISB: Tales from the Archives and Beyond

Julie Steele

Emeritus Professor, University of Wollongong, Australia

Julie Steele is an Emeritus Professor at the University of Wollongong, retiring in 2020 after 38 years at the University. With over 200 journal publications, Julie's research is focused on developing innovative strategies to decrease injury potential and optimize the quality of life of individuals of all ages. She has investigated lower limb injuries caused by high-impact landings; developed innovative wearable technologies for health applications; examined the effects of obesity, aging and occupational loading on lower limb structure and function; and investigated breast health biomechanics so women can exercise in comfort. A member of the World Council of Biomechanics and a Fellow of ISB, Julie served on the Executive Council of ISB for 14 years and as ISB President from 2009-2011. In 2019 Julie was awarded a Member of the Order of Australia (AM) for significant service to science in the field of biomechanics, higher education, and professional associations.

ISB President's Lecture

13:30-14:20, Thursday, August 3rd

Alberto Leardini

IRCCS Istituto Ortopedico Rizzoli – Bologna, Italy

He has been working at Istituto Ortopedico Rizzoli - Bologna (Italy) since 1990, where he is now Director of the Movement Analysis Laboratory, and Research Coordinator of the Line of Research "Innovative and prosthetic surgery".

He received the Doctor of Philosophy (DPhil) in Orthopaedic Engineering at the University of Oxford. His initial research focused on methodological issues and clinical applications of human motion analysis. His interests evolved to three-dimensional videofluoroscopy, radiostereometry, and ccomputer-assistedsurgery. He also made fundamental progress in the mechanical modelling and prosthesis design of the ankle joint, and his original total ankle replacement is implanted with successful clinical and functional outcomes. He is now exploiting medical imaging, including modern weight-bearing CT, and additive manufacturing for the custom-design of orthotics and implants in Orthopaedics. He is author of 241 papers in peer-review journals (H-index 47 and more than 13200 citations - SCOPUS August 2022) and of 4 international patents.

He has served in many national and international scientific communities: he has been President of the Società Italiana di Analisi del Movimento in Clinica (SIAMOC), of the Technical Group 3-D Analysis of Human Movement (3DAHM) and of the Italian Digital Biomanufacturing Network (IDBN), and in the Research Committee of the European Foot and Ankle Society (EFAS). He has been in the Steering Group of the International Foot & Ankle Biomechanics community (i-FAB) since the foundation, and more recently in the Scientific Board of the International Weight Bearing CT Society (IWBCTS). He is now the President of the International Society of Biomechanics (ISB).

Muybridge Award Lecture

15:10-16:10, Tuesday, August 1st

Born to Move: Embracing our Evolutionary Legacy

Irene S. Davis

The University of South Florida, USA

Dr. Irene Davis is a Professor in the School of Physical Therapy and Rehabilitation Science in the Morsani College of Medicine at the University of South Florida. Prior to this, she was the founding Director of the Spaulding National Running Center, Department of Physical Medicine and Rehabilitation, Harvard Medical School. Dr. Davis received her Bachelor of Science in Exercise Science from the University of Massachusetts, and in Physical Therapy from the University of Florida. She earned her Master's degree in Biomechanics from the University of Virginia, and her PhD in Biomechanics from Pennsylvania State University. She is a Professor Emeritus in Physical Therapy at the University of Delaware where she served on the faculty for over 20 years. Her research is focused on the relationship between lower extremity structure, mechanics and injury. Her research also extends to the development of interventions to alter faulty mechanics through gait retraining. She has been studying the use of wearable sensors in both the evaluation and treatment of injured runners. Her interests also include the effect of minimal footwear on mechanics and injury. Dr. Davis has received funding from the Department of Defense, and National Institutes of Health to support her research. She has given over 350 lectures both nationally and internationally and authored 160 publications on the topic of lower extremity mechanics during walking and running gait. She has been named one of the 50 Most Influential People in Running. She is a Fellow and Past President of the American Society of Biomechanics, and the 2019 ASB Borelli award winner. She is also a Fellow, past Vice President and current President-Elect of the American College of Sports Medicine. Finally, she is a Catherine Worthingham Fellow of the American Physical Therapy Association.

Keynote Lecture 1

09:40-10:30, Monday, July 31st

Animals as Machines: Robotic Approaches to Understanding Comparative Locomotor Mechanics

Bill Sellers

The University of Manchester, United Kingdom

Bill Sellers is a Professor of Natural Science at the University of Manchester where he researches the use of robotic simulation techniques for understanding animal biomechanics. His first degree was in zoology from the University of Cambridge, and he did his PhD on primate locomotion at the University of Liverpool. He uses machine learning to generate control systems that allow anatomically realistic digital twins to produce spontaneous gait patterns that match those recorded experimentally. He has used this approach to answer a range of questions about animal locomotion in both living and fossil animals including human and non-human primates, birds, turtles, spiders, dinosaurs, and plesiosaurs. He has also done a range of experimental and field studies on animal locomotion and vertebrate palaeontology.

Keynote Lecture 2

09:40-10:30, Tuesday, August 1st

Complementary Roles of Biomechanics and Machine Learning in Human Motion Monitoring

Sukyung (Sue) Park

Korea Advanced Institute of Science & Technology (KAIST), South Korea

Sukyung (Sue) Park is a professor in the department of Mechanical Engineering at KAIST, Korea. Her research interests are to understand human movement through the descriptive dynamics model that demonstrates movement mechanics and control, with an ultimate aim to develop wearable healthcare devices. Among a wide range of human movements, she is interested in walking, running, postural control, and sports activities including golf. Her recent studies focus on resolving the challenges of wearable devices for biomechanical variable prediction by integrating biomechanical knowledge with machine learning technology. She earned her BS. and MS. in Mechanical Engineering at KAIST and Ph.D. in Mechanical Engineering from the University of Michigan and was a post-doctoral fellow at the Massachusetts Eye and Ear Infirmary, Harvard Medical School. Recently she served as the Advisor to the President for Science and Technology at the Office of the President.

Keynote Lecture 3

09:40-10:30, Wednesday, August 2nd

Brain-Computer Interface Design: Thinking out of the box

Natalie Mrachacz-Kersting

The University of Freiburg, Germany

Prof. Dr. Natalie Mrachacz-Kersting member of IEEE received her Ph.D. degree in biomedical engineering from Aalborg University, in 2005, and currently holds a position as full Professor in Neuroscience at the Albert-Ludwigs University of Freiburg. She has previously held positions at Aalborg University, Denmark, FH Dortmund and at the University of Auckland, New Zealand. Natalie does research in Medical Technology, Biomedical Engineering and Neuroscience. She has authored over 80 articles in peer-reviewed journals, over 150 conference articles/abstracts, and ten book chapters. She is working on several projects specifically within the area of Brain-Computer-Interfaces (BCIs) involving patient populations such as those suffering from stroke or ALS. Dr. Mrachacz-Kersting received several awards including the international BCI award in 2017. She is on the board of the international society for Brain-Computer Interfaces (BCI Society) and has been voted on the Administrative Committee (AdCom) of the IEEE EMBS where she will commence her term from 1. January, 2023.

Keynote Lecture 4

13:30-14:20, Wednesday, August 2nd

The Mechanics of Running Fast and Jumping High: from small Differences in Ground Force to Big Differences in Performance

Peter Weyand

Southern Methodist University, USA

Dr. Peter Weyand is the Glenn Simmons Endowed Professor of Applied Physiology and Biomechanics and the Director of the Locomotor Performance Laboratory at Southern Methodist University. Prior to joining SMU, Dr. Weyand directed research efforts at Harvard University's Concord Field Station, a large animal facility specializing in terrestrial locomotion, and the Locomotion Laboratory of Rice University. Dr. Weyand's expertise on the mechanical basis of performance has led to him serving as a lead investigator on a number of high-profile projects at the intersection of biomechanics and sport policy. These include the mechanics of basketball flopping and the effects of artificial limbs on running and jumping performance. Dr. Weyand's past research subjects have included antelope, emus, rodents, and professional athletes with and without limb amputations.

Keynote Lecture 5

09:40-10:30, Thursday, August 3rd

Designing Treatment Strategies for Large Skeletal Defects by Combining in Silico, in Vitro and in Vivo Models

Liesbet Geris

The University of Liège and KU Leuven, Belgium

Liesbet Geris is professor in Biomechanics and Computational Tissue Engineering at the University of Liège and KU Leuven (Belgium). Her research focuses on the development of multi-scale and multi-physics in silico and in vitro models. Together with her team and their clinical and industrial collaborators, she uses these models to investigate the etiology of skeletal pathologies, design cell-based treatments, and optimize their manufacturing processes. She has received 2 prestigious ERC grants to finance her research and a number of young investigator and research awards. She is a member of the TERMIS-EU strategic alliance committee. She is the executive director of the VPH Institute, advocating the use of in silico modeling in healthcare through liaising with the clinical community, European Commission and Parliament, regulatory agencies, and patients. Besides her research work, she is often invited to give public lectures on the challenges of interdisciplinarity in research, women in academia, and digital healthcare.

Tutorials

Workshop 1

10:00-12:00, Sunday, July 30th

Machine Learning Applications in Movement Biomechanics

Marion Mundt (University of Western Australia, Australia)

This tutorial will provide an overview of different applications of machine learning to support movement biomechanics analysis. You will learn to use an off-the-shelf pose estimation model to determine anatomically-related landmarks in 2D videos and to code a simple artificial neural network to classify normal and abnormal gait from inertial sensor data. The pros and cons of machine learning in biomechanics will be discussed and opportunities and challenges explained using the two examples provided. All analyses will be undertaken using samples Python files.

Workshop 2

10:00-12:00, Sunday, July 30th

Power to the Foot! Understanding and Applying Distal Power Calculations in Biomechanics

Kota Takahashi (University of Utah, USA)
Eric C. Honert (BOA Technology Inc., USA)

'Distal power' calculation (also called unified deformable segment analysis in the literature) has a myriad of potential applications in biomechanics: (1) to understand energetic functions of the foot and ankle in various tasks (e.g., walking, running, and other sports-specific tasks), species or populations (e.g., individuals with and without pathologies) and (2) to quantify energy storage and return from assistive devices, such as prostheses, orthoses, and footwear. In this tutorial, we encourage participants from various specialties within ISB (e.g., sports or clinical biomechanics, orthopedics, comparative biomechanics, and orthotics & prosthetics) to learn and apply distal power calculations in their research areas. Sample data files from human walking will be provided during the tutorial, but attendees are highly encouraged to bring their unique data for an interactive discussion of the results and interpretations.

Workshop 3

13:00-15:00, Sunday, July 30th

Statistical Parametric Mapping - for MATLAB Users and SPM Novices

Todd Pataky (Kyoto University, Japan)
Mark Robinson (Liverpool John Moores University, UK)
Jos Vanrenterghem (KU Leuven, Belgium)

This tutorial will get you started with spm1d for MATLAB for the analysis of 1D data including forces, kinematics and EMG. We will begin with spm1d's implementations of 0D tests to help you become accustomed to the spm1d interface and its outputs. We'll then walk-through 1D t-tests, regression and ANOVA, highlighting important points regarding statistical outputs and their interpretations. We will also provide a conceptual overview of SPM theory by demonstrating the commonalities between 0D and 1D analysis. We will finish with slides regarding more advanced tests and future spm1d developments. Digital documentation and worksheets will be distributed to attendees; both MATLAB and Python files will be distributed but the workshop demonstrations will conducted in MATLAB only. MATLAB and basic statistics experience is expected but SPM experience is not. WARNING: there will be substantial overlap with our Online Workshop materials (https://spm1d.org/Workshops.html).

Workshop 4

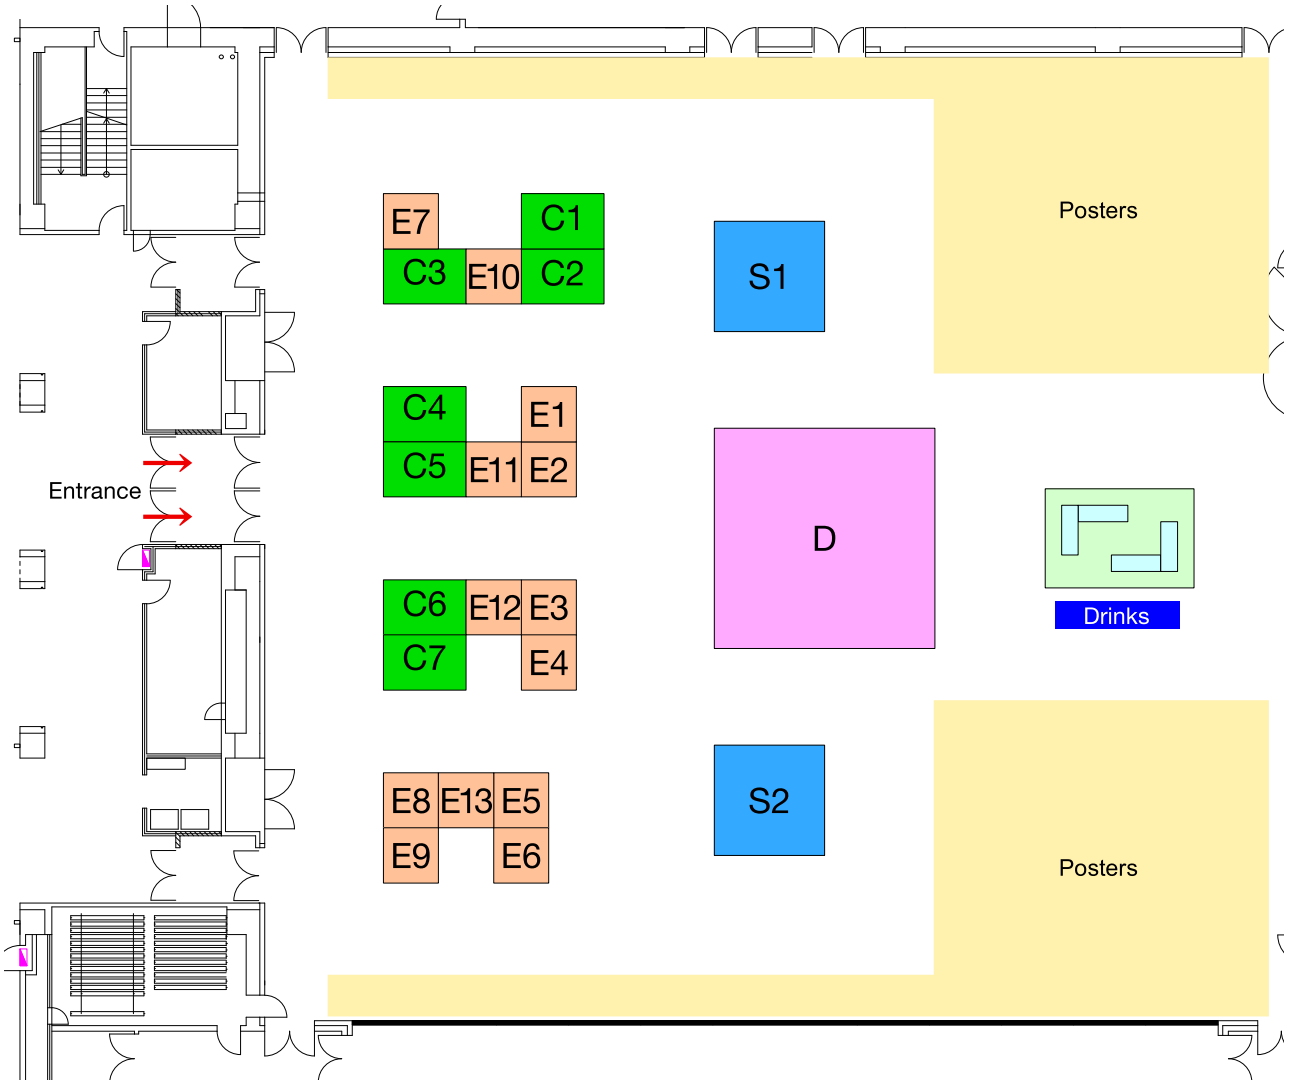
13:00-15:00, Sunday, July 30th

An Introduction to Time-frequency Low-pass Filter Methods in Biomechanics

Neal Smith (University of Chichester, UK)
Simon Augustus (Kingston University, UK)

In a variety of human movements, ranging from walking to running, landing to kicking, we will attempt to apply some kind of mathematical filter to our kinematic (and kinetic) data, reducing the inherent noise within the signal that propagates errors in further calculations. However, the extent to which these body collisions alter the frequency content of the signal has remained relatively unknown. Once this information is identified, it is plausible to optimise the use of contemporary low-pass filter techniques that vary the magnitude of noise reduction over different phases of a task (i.e., transitions from aerial to ground contact). This workshop will explore the theory of the frequency content of these types of collision, along with practical demonstrations, and involvement of the audience with pre-prepared data sets. Participants will require a working version of MATLAB to participate in the workshop.

Exhibitor Location Map (2F)



Booth Number	Company Name
C1	Archivetips(Cometa)
C2	BERTEC
C3	Sakai Medical Co.,Ltd.

Exhibitors

AMTI

Booth Number: E11
Web: www.AMTI.biz

Because Quality Matters... since over 45 years!

AMTI understands that the best research and testing in Orthopedics begins with the best equipment. For this reason, AMTI builds the most accurate Biomechanics Force Platforms, Instrumented Treadmills and state-of the art 6DOF Joint Simulators for your Biomechanical Research. We care about data quality for significant scientific conclusions, shouldn't you?

Archivetips(Cometa)

Booth Number: C1
Web: www.cometasystems.com

Cometa Systems is an Italian company producing and selling wireless EMG and inertial systems. Our systems have the smallest form factor on the market, and exclusive features such as fixed delay and configurable analog output, impedance check and waterproof coating for swimming applications. Our Mini Wave and Pico systems have been used worldwide by the most famous institutions for many years and a number of different applications. WaveX is our latest EMG development, with integrated IMU, wifi memory download, and IP68 certification for underwater use.

BERTEC

Booth Number: C2
Web: www.bertec.com

Thirty-five years of measurement excellence.

Bertec's products have represented a legacy of excellence in biomechanics for over thirty years. We provide solutions founded in accuracy and precision. Our engineering is trusted worldwide to enable a deeper understanding of human movement.
Bertec is a provider of the highest standard instrumented force plates, treadmills, stairs and other devices for the international research community.

BTS Bioengineering

Booth Number: E8
Web: www.btsbioengineering.com

BTS Bioengineering connects the world of healthcare and sport with cutting-edge motion capture technologies.
The ultimate goal of BTS Bioengeneering technologies is to help people overcome their restricted mobility and enhance their performance so that they can face life and competition to the best of their ability. We develop technologies as we are very familiar with the needs of the people for whom they are intended.
For patients and sports people, of course, but primarily for doctors, rehabilitators, physiotherapists, and athletic trainers, who need to find the same simplicity and fluidity in their use as someone who moves confidently.

Delsys/Inter Reha

Booth Number: C7
Web: www.delsys.com

Delsys is the worldwide leader in the design, manufacture, and marketing of a portfolio of high-performance electromyography (EMG) instruments. These include a range of wireless physiological and biomechanical sensors that are used in all types of human movement research and education. These products play a fundamental role in helping researchers, clinicians, and educators understand and solve complex questions surrounding human movement. Our EMG sensors contain a patented electrode design with several different form factors to choose from. Delsys develops its own software to support standalone use as well as a vast number of popular integrations.

4Assist, Inc.

Booth Number: C6
Web: www.4assist.co.jp

We deal with biomechanics such as Motion capture, Forceplate and other sports training science products.

h/p/cosmos sports & medical gmbh

Booth Number: E10
Web: www.hpcosmos.com

h/p/cosmos has been developing and building treadmills since 1988 in Germany for various fields including fitness, competitive sports, sports medicine, orthopaedic and neurological rehabilitation, sport science, biomechanics, uniformed services, performance diagnostics, cardiopulmonary diagnostics and rehabilitation. Over the time, the Traunstein based company has developed into the German specialists in manufacturing treadmill ergometers and systems and set up standards for innovation, technology, safety and support. Many developments and pioneering work from h/p/cosmos have significally influenced product design, functionality and methodologies.

Kistler Japan G.K.

Booth Number: E3
Web: www.kistler.com

As a global leader in dynamic measurement technology for measuring pressure, force, torque and acceleration, we support our customers in industry and science to improve their products and make their manufacturing processes more efficient. The piezoelectric sensor is at the heart of every measurement system from Kistler. To offer you sensors, measurement systems and services that are exactly tailored to your needs, we fully focus upon the complex current and future challenges in the areas of automobile development, industrial automation and in fields related to extreme environments and of course biomechanics and life sciences.

The MotionMonitor (Innovative Sports Training, Inc)

Booth Number: E13
Web: https://innsport.com/

The MotionMonitor makes a real-time biomechanics software for data collection, visualization and analysis. The MotionMonitor provides turn-key motion capture systems with all hardware and software included. Applications include finger, hand and upper extremity movement, gait, balance, sports-specific analysis including baseball, golf, basketball and more. The MotionMonitor team is excited about our recent integration of markerless motion capture, providing a research-grade hardware and software system that is optimized for flexibility and speed.

Movella

Booth Number: C4
Web: www.movella.com

Movella™ is a full-stack hardware, software, and data analytics company created by the consolidation of mCube, Xsens, and Kinduct. Movella is a global innovator of advanced technologies and products that sense, capture and analyze all aspects of movement. Movella serves the entertainment, sports, health, and industrial markets by capturing and transforming movement data into meaningful and actionable insights. Working with the leading global brands such as Electronic Arts, NBC Universal, Toyota, Siemens, and over 500 sports teams, we are creating extraordinary outcomes that move humanity forward.

Novel/Creact

Booth Number: E6
Web: www.novel.de

novel is the global leader in accurate and reliable load distribution measurement systems, with more than 40 years of experience. Our company has developed systems, that are able to measure contact forces between many surfaces,
Our world-wide customers include medical device manufacturers as well as world-class scientists and physicians. All novel systems operate with high quality, calibrated sensors and provide reliable and reproducible long term measurements.
Outstanding scientific software for the analysis of medical and industrial data allows our customers to be always one step ahead.

OptiTrack

Booth Number: S2
Web: www.optitrack.com

OptiTrack delivers the highest performing 3D motion capture hardware and software for both indoors and outdoors activities. With industry-leading 3D precision and accuracy, simpler workflows, on-site manufacturing enabling the best pricing, free and open developer access, and native integration of Force plates or EMG, OptiTrack is the favorite of key leaders in the movement science community. The OptiTrack product line includes motion capture software and world class high-speed tracking cameras ranging offering active markers, passive markers and markerless solutions.

PreciX Pte Ltd

Booth Number: E12

Web: https://precix.io/

PreciX is a Singapore based MedTech company, founded with a mission to revolutionize the approach to joint health and mobility assessment. Our flagship product, GATOR, is a non-invasive multi-sensor wearable platform that leverages automated pipelines and AI-powered data processing to enable the measurement of soft-tissue-corrected knee biomechanics with exceptional precision, eliminating the need for invasive bone pins or continuous X-rays. GATOR is designed for easy setup, without the requirement of body markers or cameras. By prioritizing simplicity, speed, and accessibility in joint assessment and data analysis, PreciX strives to advance and translate biomechanics research for improved patient care and outcomes.

Qualisys

Booth Number: S1

Web: www.qualisys.com

Qualisys is a leading provider of motion capture technology and has a long history of supplying research, animation, engineering and sports facilities with high-end camera systems and expertise in capturing and analyzing movements.

Qualisys offers a wide range of products and services and has offices in Gothenburg, Chicago and Shanghai. Our customers are found in the biomechanical research, sports biomechanics and medical sectors. Our systems are also used for engineering and specialized industrial purposes, along with entertainment applications such as virtual reality and animation.

Qualisys is certified according to ISO 9001:2015, our clinical products are compliant with Medical Device Directive 93/42/EEC and have FDA clearance (K171547), which demonstrates our commitment to provide highest possible quality products and services to our customers. The certifications reflect our ongoing investment in technology, process and people.

Sakai Medical Co.,Ltd.

Booth Number: C3

Web: www.noraxon.com

For over 30 years, Noraxon USA has been an industry leader in human movement metrics and biomechanics research solutions. Innovation is our number one goal and we are constantly hard at work to continue bringing valuable tools to the market for capturing biomechanics. Our system allows you to create a smarter workflow with reliable data by integration of electromyography, force, pressure, motion and high speed video. Whether you are in the lab, on the field, or in the clinic, we provide you with hardware and software solutions that are practical and flexible for all of your measurement applications.

Simi Reality Motion Systems GmbH

Booth Number: E5

Web: www.simi.com

Simi - Pioneers of Motion Capture and Analysis technology

Experts at the intersection of biomechanics and technology. Simi's not only been through the whole journey of motion capture since 1992; we've shaped it. Offering 30+ years of expertise in the field, we are one of the pioneers for markerless motion capture technology.

Simi delivers high-end 3D mocap technology using leading computer vision and machine learning algorithms to detect and quantify human movements in any condition.

We are establishing AI-powered technologies in all kinds of sports. Our solutions offer full 3D analytics, processing and visualization.
Go Markerless, go Simi: Choose experience.
www.simishape.com

Spice/Nobby Tech. Ltd.

Booth Number: E9
Web: mocap.jp

スパイスは30年以上の実績を持ったモーションキャプチャの老舗で、OptiTrackをはじめ多くの製品の日本総代理店です。
ノビテックは、モーションキャプチャやハイスピードカメラを取り扱う、画像計測を専門としたプロ集団です。
本学会では2社で共同出展をしております。

Sportip

Booth Number: E7
Web: www.sportip.jp

Sportip develops markerless 3D motion analysis technology using AI-based human pose estimation and 3D reconstruction. Sportip provides a wide range of products and services, mainly in the fitness, sports, and medical fields, using motion analysis as a solution that enables easy and quick analyzes.

Tec Gihan Co.,Ltd.

Booth Number: E1
Web: tecgihan.co.jp/en/

TEC Gihan is a leading manufacturer of measuring instruments, specializing in multi-axis small sensors, special load cells, and data loggers. We collaborate with cutting-edge companies, research institutes, and universities, supporting their research and development efforts. Our comprehensive range of products includes high-quality measuring instruments, measurement and control software, testing equipment, and inspection tools. With a focus on innovation and reliability, we deliver custom solutions tailored to our customers' unique needs. Through our consistent services and dedication to technological advancement, we strive to be the preferred partner in the field of measurement and instrumentation.

Tekscan INC

Booth Number: E2
Web: www.tekscan.com

Tekscan, Inc. is a leading manufacturer of tactile pressure and force measurement systems, which are used by researchers and clinicians around the world to aid in the diagnosis and treatment of pathomechanical disorders, and to ensure effective offloading of peak plantar pressure areas at increased risk for ulceration. Our in-shoe (F-Scan™) and modular platform and mat (Strideway™ and MobileMat™) systems accurately measure plantar pressure distribution, timing and Center of Force (CoF) trajectory during the stance phases of gait, giving you new information to help design better treatments. Enhance your ability to evaluate, substantiate and document your diagnosis with Tekscan pressure mapping systems. Learn more at www.tekscan.com/medical.

Vicon Motion Systems Ltd

Booth Number: D
Web: www.vicon.com

Vicon delivers highly accurate 3D movement analysis systems for use in dynamic injury assessment and evaluating therapy progress. Over 150 sports training department's world-wide use Vicon technology. Its flagship camera line, the Vicon Valkyrie, offers the highest resolution, frame rates and accuracy available, allowing detailed motion capture in almost any environment. Vero is Vicon's next generation camera, combining size, power, and price performance into one amazing solution.

Vicon was established in Oxford, UK, in 1984 and is now a subsidiary of the Oxford Metrics Group Plc. Some of Vicon's global clients include: University of Calgary's Running Injury Clinic; University of Brussels; Northumbria University; Imperial College, London; Loughborough University; University of Western Australia; Katholieke Universiteit Leuven; and University of New Brunswick. For more information please visit www.vicon.com

Zero C Seven Inc

Booth Number: E4
Web: www.0c7.co.jp

ゼロシーセブン株式会社センシング・ソリューション事業部は、Movella社XSENSモーションキャプチャ、Xsensor社足圧インソール、SIMI社マーカーレスモーションキャプチャなどを扱っています。

The Sensing Solutions Division of Zero C Seven Inc.. handles Movella XSENS motion capture, Xsensor foot pressure insoles, and SIMI marker-less motion capture.

XSENSOR Technology Corporation

Booth Number: C5
Web: www.xsensor.com

Reveal accurate gait and motion data, visualize in high-quality and get access to advanced, easy-to-use AI-powered analysis tools with Intelligent Dynamic Sensing.

Powered by leading-edge technology XSENSOR's Foot and Gait research-grade assistive tools provide access to key insights of the lower extremities, enabling you to augment Movement Research, optimize Athletic Performance, and aid Clinical Assessment.

Scientific Program

Day 1 Sunday, July 30th

Program-at-a-glance

	Room 1 3F Main Hall	Room 2 5F 501	Room 3 5F 502+503	Room 4 4F 401+402+403	Room 5 4F 409	Room 6 4F 410	Room 7 4F 411+412	Room 8 4F 413+414

10:00	9:40-10:30 **Keynote Lecture 3**	**"Brain-Computer Interface Design: Thinking out of the box"** Natalie Mrachacz-Kersting Chiar: Gregory Sawicki						
11:00	10:30-11:00 **Coffee Break (2F Poster & Exhibition Hall, 5F Lobby)**							
12:00	11:00-12:30 **Symposium 08** **Performance Enhancement Footwear in Running**	11:00-12:24 **Oral 45** **Locomotion: Clinical gait 3**	11:00-11:48 **Oral 46** **Methodologies and data analysis 2**		11:00-12:00 **Oral 47** **Prosthetics and orthotics 3**	11:00-12:30 **Hand & Wrist Symposium Slot 2**	11:00-12:24 **Oral 48** **Biomedical engineering**	11:00-12:00 **Oral 49** **Impact biomechanics 2**
13:00	12:40-13:30 **Lunch Break (3F/4F)**							
14:00	13:30-14:20 **Keynote Lecture 4**	**"The Mechanics of Running Fast and Jumping High: from small Differences in Ground Force to Big Differences in Performance"** Peter Weyand Chiar: Wolfgang Potthast						
15:00	14:30-16:00 **Symposium 09** **Wearable Intertial Sensors**	14:30-15:42 **Oral 50** **Sport biomechanics 5**	14:30-15:42 **Oral 51** **Balance and posture 2**	14:30-15:30 **Oral 52** **Running: Biomechanics 2**	14:30-15:18 **Oral 53** **Simulation techniques and applications 2**	14:30-16:00 **Hand & Wrist Symposium Slot 3**	14:30-15:54 **Oral 54** **Artificial intelligence and machine learning 3**	14:30-15:30 **Oral 55** **Prosthetics and orthotics 2**
16:00	16:00-16:30 **Coffee Break (2F Poster & Exhibition Hall, 5F Lobby)**							
17:00	16:30-18:00 **Symposium 10** **Ankle Injury Biomechanics**	16:30-17:42 **Oral 56** **Sport biomechanics 6**	16:30-17:54 **Oral 57** **Locomotion: General 3**	16:30-18:06 **Oral 58** **Wireless sensors and wearable devices 2**		16:30-17:20 **Hand & Wrist Symposium Slot 4**	16:30-17:42 **Oral 59** **Clinical biomechanics 3**	16:30-18:06 **Oral 60** **Musculoskeletal modeling 5**
18:00								
19:00	18:10-19:40 **Poster 22-31 (2nd floor, Poster Display #1)** **Poster 32-33 (5th Floor, Poster Display #2)** **Dismantle:** 19:40-20:00							
20:00								
21:00								

Scientific Program

Day 5 Thursday, August 3rd

Program-at-a-glance

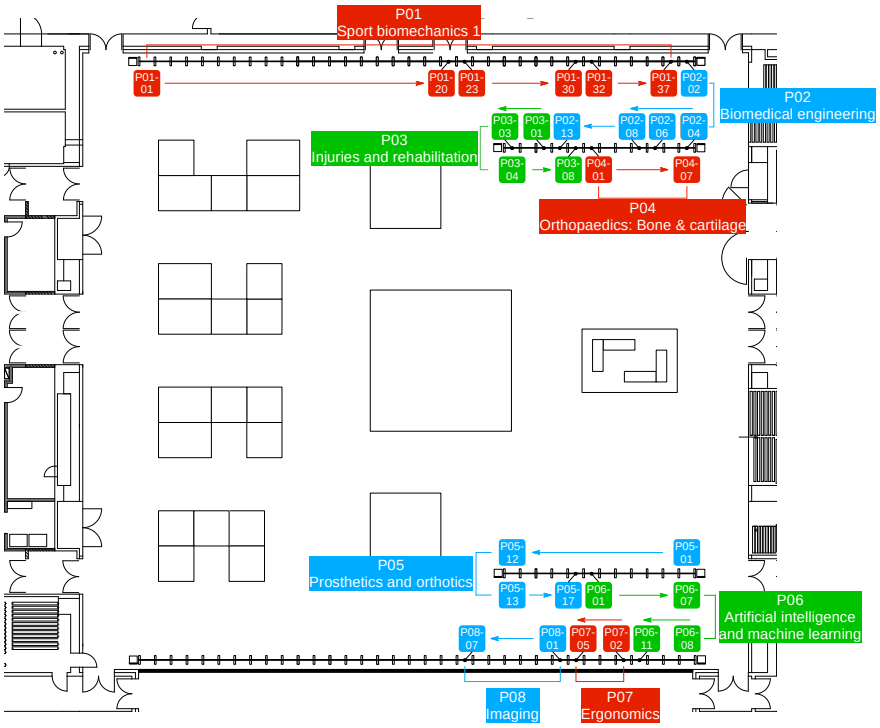
	Room 1 3F Main Hall	Room 2 5F 501	Room 3 5F 502+503	Room 4 4F 401+402+403	Room 5 4F 409	Room 6 4F 410	Room 7 4F 411+412	Room 8 4F 413+414
8:00	8:00-9:30 **Symposium 11** **ISEK: Lab and Clinic EMG Updates**	8:00-9:24 **Oral 61** **Balance and posture 3**	8:00-9:00 **Oral 62** **Rehabilitation technology: Biorobotics and exoskeletons 3**	8:00-9:12 **Oral 63** **Ergonomics**	8:00-9:12 **Oral 64** **Others 4**	8:00-9:12 **Oral 65** **Spine and trunk 2**	8:00-8:48 **Oral 66** **Orthopaedics: Surgeon guided biomechanics**	8:00-9:24 **Oral 67** **Upper extremity**
9:00								
10:00	9:40-10:30 **Keynote Lecture 5**	**"Designing Treatment Strategies for Large Skeletal Defects by Combining in Silico, in Vitro and in Vivo Models"** Liesbet Geris Chair: Eng Kuan Moo						
11:00	10:30-11:00 **Coffee Break (2F Poster & Exhibition Hall, 5F Lobby)**							
		11:00-12:12 **Oral 68** **Sport biomechanics 7**	11:00-12:24 **Oral 69** **Motor control 2**	11:00-12:24 **Oral 70** **Lower extremities 2**	11:00-12:12 **Oral 71** **Rehabilitation and neurorehabilitation**	11:00-11:48 **Oral 72** **Running: Biomechanics 3**	11:00-12:24 **Oral 73** **Musculoskeletal modeling 6**	11:00-12:12 **Oral 74** **Artificial intelligence and machine learning 4**
12:00								
13:00	12:40-13:30 **Lunch Break (3F/4F)**							
14:00	13:30-14:20 **ISB President's Lecture**	Alberto Leardini Chair: Shinji Sakurai						
15:00	14:20-16:20 **AGM** **Awards Presentations**							
16:00								
17:00	16:20-17:00 **Closing Ceremony**							
18:00								
19:00	19:00-21:00 **GALA Dinner (Kawabata Shopping Arcade)**							
20:00								
21:00								

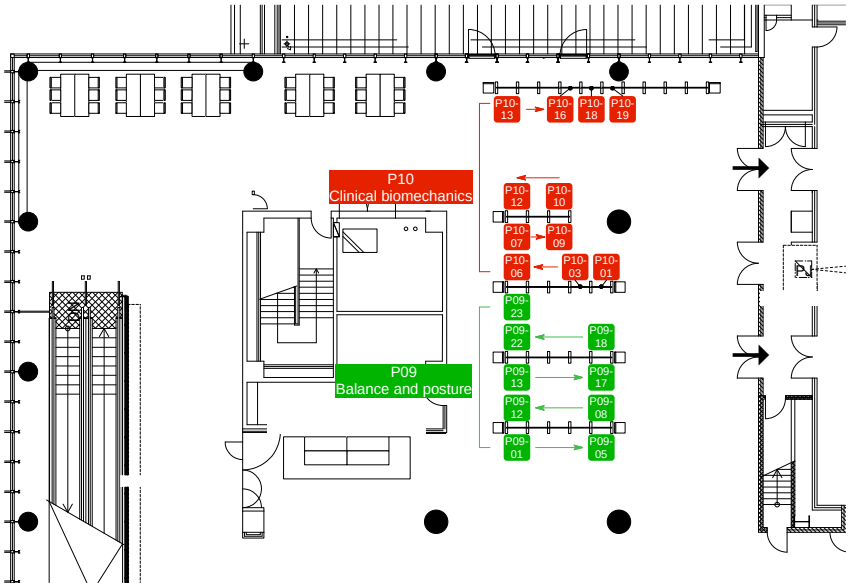
Poster Map

Monday, July 31st

Venue	Session		Presentation Number
2nd floor, Poster Display #1	Poster 01	Sport biomechanics 1	P01-01 → P01-37
	Poster 02	Biomedical engineering	P02-02 → P02-13
	Poster 03	Injuries and rehabilitation	P03-01 → P03-08
	Poster 04	Orthopaedics: Bone & cartilage	P04-01 → P04-07
	Poster 05	Prosthetics and orthotics	P05-01 → P05-17
	Poster 06	Artificial intelligence and machine learning	P06-01 → P06-11
	Poster 07	Ergonomics	P07-02 → P07-05
	Poster 08	Imaging	P08-01 → P08-07
5th Floor, Poster Display #2	Poster 09	Balance and posture	P09-01 → P09-23
	Poster 10	Clinical biomechanics	P10-01 → P10-19

2nd floor, Poster Display #1



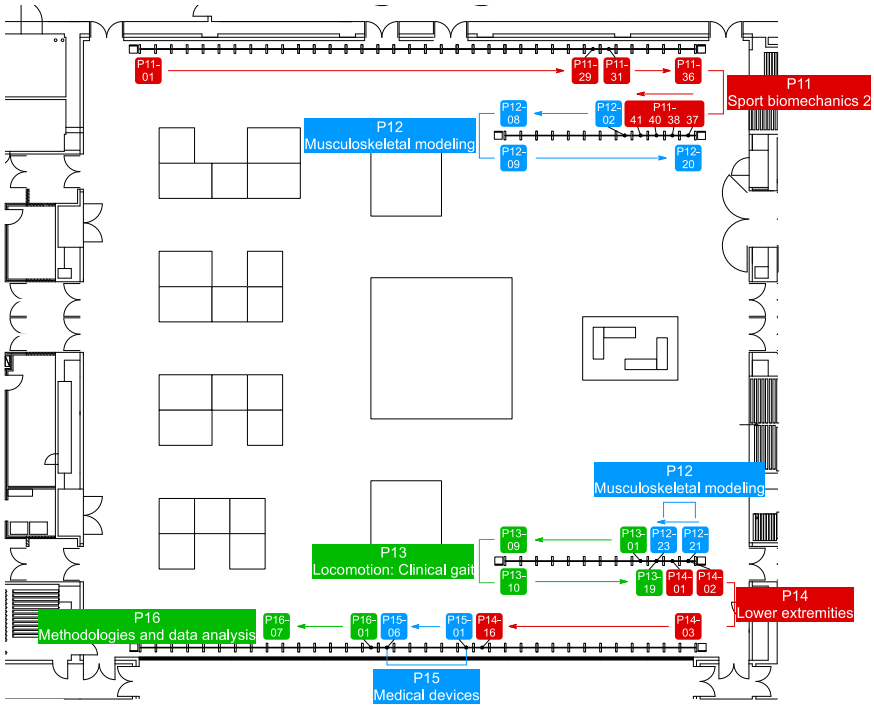


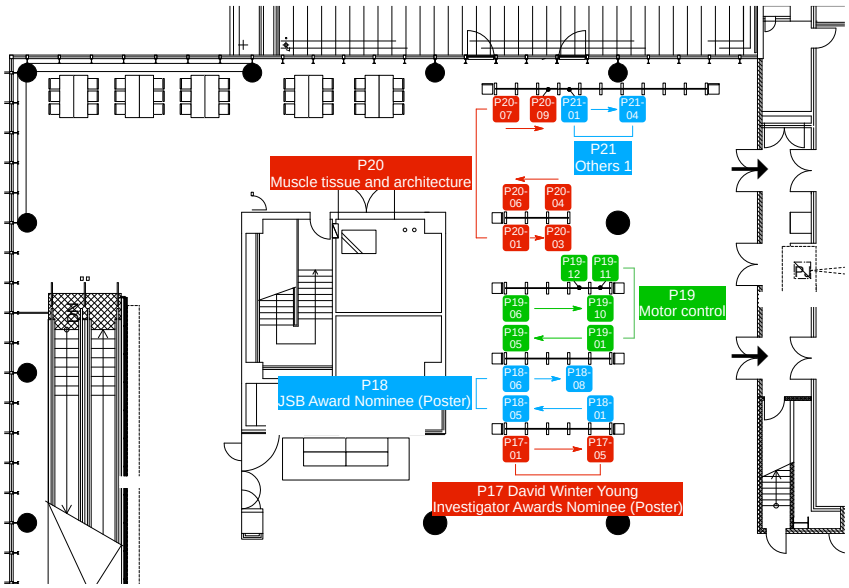
5th Floor, Poster Display #2

Tuesday, August 1st

Venue	Session		Presentation Number
2nd Floor, Poster Display #1	Poster 11	Sport biomechanics 2	P11-01 → P11-41
	Poster 12	Musculoskeletal modeling	P12-02 → P12-23
	Poster 13	Locomotion: Clinical gait	P13-01 → P13-19
	Poster 14	Lower extremities	P14-01 → P14-16
	Poster 15	Medical devices	P15-01 → P15-06
	Poster 16	Methodologies and data analysis	P16-01 → P16-07
5th Floor, Poster Display #2	Poster 17	David Winter Young Investigator Awards Nominee (Poster)	P17-01 → P17-05
	Poster 18	JSB Award Nominee (Poster)	P18-01 → P18-08
	Poster 19	Motor control	P19-01 → P19-12
	Poster 20	Muscle tissue and architecture	P20-01 → P20-09
	Poster 21	Others 1	P21-01 → P21-04

2nd floor, Poster Display #1



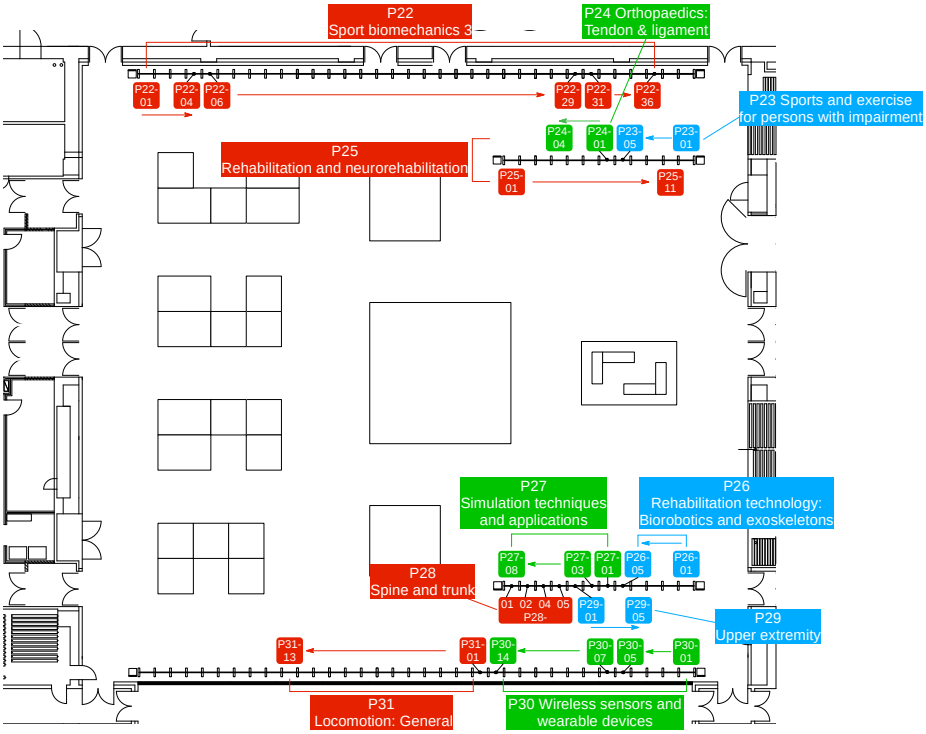


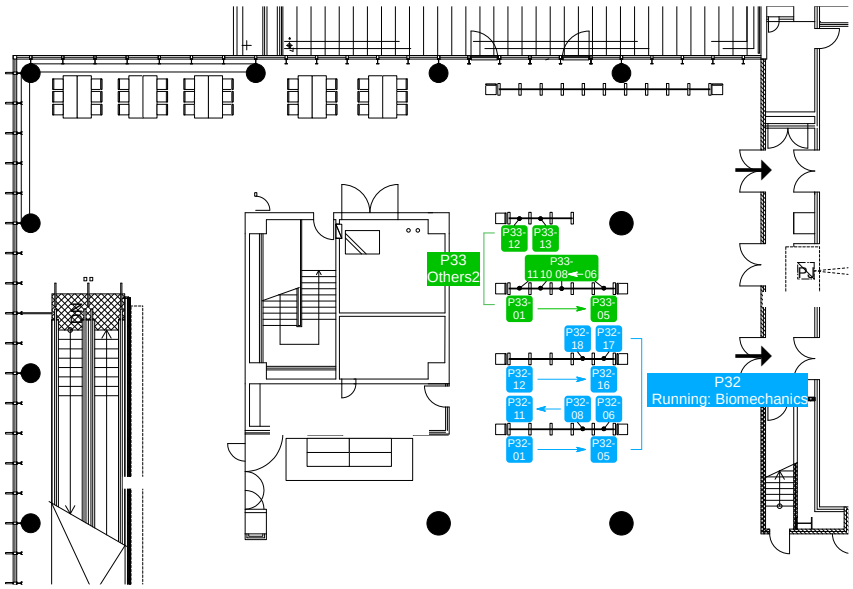
5th Floor, Poster Display #2

Wednesday, August 2nd

Venue	Session		Presentation Number
2nd Floor, Poster Display #1	Poster 22	Sport biomechanics 3	P22-01 → P22-36
	Poster 23	Sports and exercise for persons with impairment	P23-01 → P23-05
	Poster 24	Orthopaedics: Tendon & ligament	P24-01 → P24-04
	Poster 25	Rehabilitation and neurorehabilitation	P25-01 → P25-11
	Poster 26	Rehabilitation technology: Biorobotics and exoskeletons	P26-01 → P26-05
	Poster 27	Simulation techniques and applications	P27-01 → P27-08
	Poster 28	Spine and trunk	P28-01 → P28-05
	Poster 29	Upper extremity	P29-01 → P29-05
	Poster 30	Wireless sensors and wearable devices	P30-01 → P30-14
	Poster 31	Others 2	P31-01 → P31-13
5th Floor, Poster Display #2	Poster 32	Locomotion: General	P32-01 → P32-18
	Poster 33	Running: Biomechanics	P33-01 → P33-13

2nd floor, Poster Display #1





5th Floor, Poster Display #2

Detailed Program

Sunday, July 30th

1000-1200	**Workshop 1**	**Room 2**
WS1	Machine Learning Applications in Movement Biomechanics	Marion Mundt
1000-1200	**Workshop 2**	**Room 8**
WS2	Power to the Foot! Understanding and Applying Distal Power Calculations in Biomechanics	Kota Takahashi, Eric C. Honert
1300-1500	**Workshop 3**	**Room 2**
WS3	Statistical Parametric Mapping - for MATLAB Users and SPM Novices	Todd Pataky, Mark Robinson, Jos Vanrenterghem
1300-1500	**Workshop 4**	**Room 8**
WS4	An Introduction to Time-frequency Low-pass Filter Methods in Biomechanics	Neal Smith, Simon Augustus
1645-1745	**Wartenweiler Memorial Lecture** Chair: **Karen Mickle**	**Room 1**
WL	Pioneering Women of ISB: Tales from the Archives and Beyond	Julie Steele

Monday, July 31st

0800-0930	**Symposium 01 Standardizing Terminology, 3D Spatial Orientation, and Relative Positioning of the Foot and Ankle Bones** Chairs: **Amy Lenz, Lauren Welte**	**Room 1**
SY01-1	Standardizing terminology, 3D spatial orientation, and relative positioning of the foot and ankle bones: An expert consensus task force	Amy Lenz
SY01-2	Foot and ankle automatic anatomical coordinate system definition	Andrew Peterson
SY01-3	In vivo tarsal bone kinematics and the influence of articular talus morphology	Anja-Verena Behling
SY01-4	Weight-bearing CT in support of age-related 3D foot measurements	Claudio Belvedere
0800-0924	**Oral 01 Locomotion: General 1** Chairs: **Hannah Rice, Keitaro Seki**	**Room 2**
O01-1	The impact of body composition on stand-to-sit biomechanics and muscle activity of nurses - a quantitative-explorative study	Anna Brinkmann
O01-2	The effect of changing bicycle saddle position on submaximal cycling behaviour	Cristian Riveros-Matthey
O01-3	Effects of age-related muscle degeneration on dynamic stability during walking: A computer simulation study	Shoma Kudo
O01-4	Anatomical knee model for forward dynamics gait simulation	Beomsoo Shin
O01-5	The effect of changing gait parameters on tensor fascia latae, gluteus maximus, and the iliotibial band	Laura Hutchinson
O01-6	Walking symmetry is speed and index dependent	Gaspare Pavei
O01-7	Body center of mass to minimal moment axis distance is determinant of age-related evolution in stepping	Bruno Watier
0800-0912	**Oral 02 Musculoskeletal modeling 1** Chairs: **Masaki Ishikawa, Tetsuya Hirono**	**Room 3**
O02-1	Effectiveness of co-contraction in mitigating the effect of age-related increase in passive muscle stiffness	Tiina Murtola
O02-2	A composite reflexive and synergistic controller for predictive simulations of cycling	Giacomo Severini
O02-3	Investigating the effects of patellofemoral geometry incongruence on joint function using computational modelling	Annagh Macie
O02-4	A gradient-based method for automated muscle path calibration	Ziyu Chen
O02-5	Stabilization of the foot-ankle complex in response to perturbations	Michael Asmussen
O02-6	The influence of muscle injuries on the shoulder joint mechanics: A musculoskeletal modelling study and experimental validation	Melody Charlotte Labrune
0800-0912	**Oral 03 Cellular and molecular** Chair: **Walter Herzog**	**Room 4**
O03-1	High-fat diet induced vascular smooth muscle cell stiffening in apoe-/- mice	Zhongkui Hong
O03-2	Identification of collective mechanical traits of an injured muscle model	Tae Yoon Kwon
O03-3	Effects of solute molecular shapes on osmosis across fibrous membranes: An application to fluid transport in an endothelial glycocalyx layer	Panadda Dechadilok
O03-4	Contribution of titin to passive and active forces in single myofibrils	Seong-won Han

O03-5	The distinctive mechanical and structural signatures of residual force enhancement in myofibers	Anthony Hessel
O03-6	How collagen IX alters the micromechanical properties of collagen II arrays?	Fatemeh Jalali
0800-0912	**Oral 04 Orthopaedics: Bone & cartilage** Chairs: **Salvatore Federico, Genki Hisano**	**Room 5**
O04-1	An integrated finite element approach to simulate internal bone strain in response to joint loading	Timo van Leeuwen
O04-2	Effusion-synovitis mediates the association between quadriceps weakness and worsening knee pain	Ze Gong
O04-3	Ultrasonographic assessment of acute femoral cartilage response after running and cutting	Miyuki Hori
O04-4	3D MR analysis reveals sex-specific cam location differences in femoroacetabular impingmenent patients	Jessica Bugeja
O04-5	Timing and accuracy of 3D printed pelvic fracture plates	Dale Robinson
O04-6	Trochlear orientation of total knee designs is opposite to that of the natural femur	Nikhil Gattu
0800-0924	**Oral 05 Medical devices** Chairs: **Bing-Shiang Yang, Masataka Yamamoto**	**Room 6**
O05-1	Accelerometer based assessment of upper extremity movement in patients with obstetric plexus palsy	Catherine Disselhorst-Klug
O05-2	Differences in trochlear sulcus geometry of total knee designs	Shuyang Han
O05-3	Design and evaluation of a novel patient-specific, unloading knee brace	Michael Skipper Andersen
O05-4	Experimental validation of a knee implant damage prediction framework	Michael J. Dreyer
O05-5	Evaluation of plantar pressure redistribution in novel footwear for people with diabetes	Sarah Hemler
O05-6	Quantifying muscle tone of upper limb for stroke patients via an impedance-based arm circumference motor evaluation system (i-ACMES)	Chieh-Hsiang Hsu
O05-7	Novel arthrometer provides quantitative and objective measures of uniplanar and multiplanar knee laxity	Carl Imhauser
0800-0924	**Oral 06 Muscle tissue and architecture 1** Chairs: **Toni Arndt, Hiroto Shiotani**	**Room 7**
O06-1	Human lower leg muscles grow asynchronously	Brian V. Y. Chow
O06-2	Residual force depression during submaximal voluntary contractions is not simply related to the preceding positive muscle work	Brent James Raiteri
O06-3	Post-activation potentiation does not contribute to *in vivo* residual force enhancement	Daniel Hahn
O06-4	Understanding aging-related skeletal muscle weakness using shear wave elastography	Filiz Ates
O06-5	Shear modulus differs between regions of the tibialis anterior muscle during contraction	Patricio Pincheira
O06-6	Changes in biceps femoris long head fascicle length during sprinting	Mianfang Ruan
O06-7	How does the medial gastrocnemius and achilles tendon interplay contribute to the muscle-tendon unit during gait in cerebral palsy?	Francesco Cenni
0800-0912	**Oral 07 Injuries and rehabilitation 1** Chairs: **Yuki Sugimoto, Ayako Higashihara**	**Room 8**
O07-1	Passive muscle stiffness does not change after eccentric-only resistance training at long muscle lengths with a long duration	Raki Kawama
O07-2	Constant force muscle stretching induces greater acute deformations and changes in passive mechanical properties compared to constant length stretching	Guido Mirko Geusebroek
O07-3	Hamstring activation deficits during jumping and landing in athletes with hamstring strain injuries using time-frequency analysis method	Amornthep Jankaew
O07-4	The relationship between center of pressure position and knee extensor moment during double-leg squatting	Tomoya Ishida
O07-5	Inter-session reliability of markerless lower limb kinematics and kinetics in return-to-sport tasks often evaluated after serious knee injury	Jiaming Xu
O07-6	Effect of increasing walking cadence on impact loading in adults with knee osteoarthritis	Khara James
0940-1030	**Keynote Lecture 1** Chair: **Todd Pataky**	**Room 1**
KL1	Animals as Machines: Robotic Approaches to Understanding Comparative Locomotor Mechanics	Bill Sellers
1100-1230	**Symposium 02 ISB Motor Control Technical Group** Chairs: **Jim Richards, Walter Herzog**	**Room 1**
SY02-1	Development of a musculoskeletal model that estimates muscle tension from electromyography, joint torque, impedance, and equilibrium position	Yasuharu Koike
SY02-2	Interaction analysis between sEMG signals and cerebral dynamics in brain regions during isometric contraction of elbow joint	Le Li
SY02-3	Does a foot-eye coordination variable add value to the prediction of mild cognitive impairment?	Daniel Koska
SY02-4	Reflex modulation during gait with mechanical perturbations	Dana Lorenz

SY02-5	Embedding the control of balance into the muscle coordination for walking is associated with better walking function	Jessica Allen
SY02-6	Modelling patient-specific neural control in children with cerebral palsy	Miriam Febrer Nafria
SY02-7	Pre-programmed hamstring activation during sidecutting is associated with reflexive response during a single-legged pertubation test	Jesper Bencke
1100-1236	**Oral 08 Sport biomechanics 1** Chairs: **Kat Daniels, Takahiko Sato**	**Room 2**
O08-1	Relationship between countermovement jump and fastball velocity in adolescent baseball pitchers	Hui-Wen Hsiao
O08-2	Comparison between backward and forward propulsion in wheelchair badminton	Ilona Alberca
O08-3	Estimating distribution of mass between castor- and rear wheels using inertial sensors during manual wheelchair propulsion	Marit van Dijk
O08-4	Aerodynamics of dimple structure on soccer ball using 3D printer	Sungchan Hong
O08-5	The largest segmental components of energy directly contributing to height do not explain the variance of its total in the high jump	Natsuki Sado
O08-6	Hamstring muscle kinematics and activation during the acceleration phase in sprinting of soccer players	Van Thiet Le
O08-7	Sex-specific anthropometric and kinematic performance determinants in national elite javelin athletes	Chinedu Godwin Uzomba
O08-8	Classifying punch types and ranges in boxers: A machine learning approach with IMU sensor data	Saravanan Manoharan
1100-1212	**Oral 09 Musculoskeletal modeling 2** Chairs: **Luke Kelly, Satoru Hashizume**	**Room 3**
O09-1	A systematic review and evaluation of open-source transtibial amputee musculoskeletal models for use on female populations	Misha Hasan
O09-2	Complete 3D kinematics parameters of the temporo-mandibular joints using in vivo data fusion	Gaël Bescond
O09-3	Muscle contributions to the barbell back squat in trained females	William Goodman
O09-4	Predicting knee joint loading during different activities of daily living: A validation framework based on the CAMS-knee dataset	Enrico De Pieri
O09-5	Effect of the loading direction on the predicted local mechanical properties of the tibia in the ovariecto-mised mouse model	Saira Mary Farage-O'Reilly
O09-6	Automated tool for musculoskeletal finite element modeling of knee	Amir Esrafilian
1100-1212	**Oral 10 Locomotion: Clinical gait 1** Chairs: **Heng-ju Lee, Hiroaki Noro**	**Room 4**
O10-1	A CNN-based approach to classification of Parkinson's disease patients with and without freezing of gait during 360° turning task	Hwayoung Park
O10-2	Rotary spinal dynamics in gait - Reference data and functional descriptions based on surface topograpy	Ulrich Betz
O10-3	Gait and dynamic postural stability during obstacle crossing in the individuals with early-stage Parkinson's disease	Nok-Yeung Law
O10-4	Gait strategies identified by machine learning in older adults after spinal fixation	Naoto Mano
O10-5	Are adaptations in fall predictors following a 12-week mixed power training related to gait parameters in community-dwelling older men?	Aubertin-Leheudre Mylène
O10-6	Gait propulsion in patients with unilateral cerebral palsy when walking with and without an ankle foot orthosis	Jacqueline Romkes
1100-1236	**Oral 11 Balance and posture 1** Chairs: **Genevieve Williams, Sentarou Koshida**	**Room 5**
O11-1	Virtual reality skateboard balance training for improving balance stability in the elderly	Yi-Ching Tsai
O11-2	EMG normalization approaches show differing results in older adults during a stepping task	Marcel Bahia Lanza
O11-3	Adaptation in reactive balance control over repeated standing slips in ballet dancers	Caroline Simpkins
O11-4	Cortical involvement for postural control	Thomas Legrand
O11-5	The effect of applying external cutaneous tension on lower-limb movement and balance	Ning Tung
O11-6	Plantar tactile sensation, joint range of motion, and pain are unique fall risk factors for people with knee osteoarthritis	Peixin Shen
O11-7	Synthetic simulation of stepping maneuver using reinforcement learning	Yoshimori Kiriyama
O11-8	Human electrical brain and muscle activity during underwater standing balance	Seongmi Song
1100-1148	**Oral 12 Clinical biomechanics 1** Chairs: **Nahoko Sato, Hajime Ohtsu**	**Room 6**
O12-1	Muscle power and strength deficiencies in fallers with lower limb loss	Isabel Lin

O12-2	Initial changes in knee loading from a personalized gait modification are associated with changes in MRI metrics of cartilage health after 1 year	Kirsten Seagers
O12-3	Characterizing mechanical adaptation of muscles affected by myasthenia gravis using shear wave elastography	Manuela Zimmer
O12-4	Effects of small and normalized Q-Factor changes on knee biomechanics in stationary cycling	Songning Zhang
1100-1224	**Oral 13 Artificial intelligence and machine learning 1** Chairs: **Neil Cronin, Yoichi Iino**	**Room 7**
O13-1	Gait time series prediction using random forest model: A sensitivity analysis on IMU sensor location, window size, and number of features	Shima Mohammadi Moghadam
O13-2	Can computer vision be as good as multi-camera infra-red systems for motion analysis?	John Komar
O13-3	Comparison of the validity of ground reaction forces from two different sets of body landmarks during sidestepping via artificial neural networks	Yulin Zhou
O13-4	The estimation of ground reaction forces during stair walking	Marion Mundt
O13-5	Estimating knee arthroplasty patients' EQ-5D-5L VAS using IMUs and machine learning	Ted Yeung
O13-6	Using deep learning to personalize stroke rehabilitation	Sina David
O13-7	A machine learning approach to characterising rugby head impacts for laboratory recreation	Danyon Stitt
1100-1212	**Oral 14 Others 1** Chairs: **Mitsuo Otsuka, Kikwang Lee**	**Room 8**
O14-1	Brain tissue mechanics in postmortem interval estimation	Natalia Kabaliuk
O14-2	Degrading quality of proteoglycans in osteoarthritic cartilage	Eng Kuan Moo
O14-3	Skeletal muscle anisotropic mechanical properties quantification in vivo: Combining magnetic resonance elastography and diffusion tensor imaging	Zhongzheng Wang
O14-4	Brain stress measurements during biofidelic head surrogate impacts	Giuseppe Zullo
O14-5	A novel predict-update deep learning model for joint angle predictions from inertial measurement units	Vaibhav Shah
O14-6	A method to estimate the kinetics of a collective load carrying in ants	Jordan Drapin
1330-1500	**The 50th ISB Anniversary Session 1** **ISB 50 Years of International Biomechanics: History** Chair: **Veronique Feipel**	**Room 1**
AS1-1	Historical perspective of the founding of ISB	Joe Hamill Benno Nigg
AS1-2	History of the JSB-ISB relationship	Mitsumasa Miyashita
AS1-3	Muscle mechanics	Walter Herzog
AS1-4	Sports biomechanics and modeling	Jill McNitt Gray
AS1-5	Human motion and Gait analysis	Brian Davis
AS1-6	Neuromechanics	Daniel Hahn Catherine Disselhorst-Klug
1540-1710	**The 50th ISB Anniversary Session 2** **ISB 50 Years of International Biomechanics: Future** Chair: **Katherine Boyer**	**Room 1**
AS2-1	Muscles Alive-how far have we come since then?	Yasuo Kawakami
AS2-2	New perspectives in tendon biomechanics	Taija Finni
AS2-3	The future of Gait analysis and Human motion analysis	John Challis
AS2-4	Neuromusculoskeletal biomechanical modeling and Neuromechanics	Luca Modenese
AS2-5	Biomechanics in the wild by digital human and artificial intelligence	Mitsunori Tada
AS2-6	Internet of things and remote monitoring, field monitoring	Kamiar Aminian
AS2-7	Data, privacy and the future	Jacqueline Alderson

1720-1850	**Poster 01 Sport biomechanics 1**	2nd Floor, Poster Display #1
P01-01	Differences in joint kinematics between snatch and clean lifts in weightlifting	Ganbat Tumen-Ulzii
P01-02	Comparison of ballistic training and complex training on explosive performance in upper limbs	Hsiang-Hsian Wang
P01-03	Using landing error scoring system with automated joint angle tracking as a screening tool to predicating lower extremity sports injuries for athletes: A prospective study	Hsiao-Yun Chang
P01-04	Profile of hip rotational range of motion for the healthy collegiate baseball players	Chun-Wen Chiu
P01-05	Biomechanical patterns associated with knee injury in female futsal players diagnostic with the change of direction and acceleration test (CODAT): A cross-sectional analytical study	Ferrandez-Laliena Loreto
P01-06	Reducing variability may not increase the success rate of motor task: Toward a proper interpretation of function	Arata Kimura
P01-07	Effect of a physiotherapy program on the reversal of risk factors for patellar tendinopathy in amateur female soccer players. Clinical trial	Lucia Vicente Pina
P01-08	The scapulohumeral rhythm of javelin throwers	Tang-Yun Lo
P01-09	Relationships between the lower extremity biomechanics and forward propulsion in the preparatory motion for an effective judo throw	Takanori Ishii
P01-10	The effect of decreasing COR of baseball on batting stats and batting performance: In a case of professional baseball league	Shu-Wei Chen
P01-11	Evaluation of the muscle work in gym exercises with a “water ball” compared with a medicine ball	Alexis Herbaut
P01-12	Narrow stance width during the bar twist exercise decreases the trunk twist torque	Kazutaka Takahashi
P01-13	Acute: Chronic workload ratio and accumulated neuromuscular fatigue in college male rugby sevens athletes: A pilot study	Qianhui Sun
P01-14	Estimation of time consistency in taekwondo group poomsae with inertial measurement unit	He Minyan
P01-15	Influence of turf fibres on mechanical traction of artificial turf surfaces	Michael Esposito
P01-16	Club head parameter of effecting amateur golfer’s smash factor in real golf course situations	Tsung Yu Huang
P01-17	Biomechanical factors affecting long jump distance in Japanese male university athletes	Yamato Takayama
P01-18	Relationship between the position of hip joint and range of motion of lower limb joint during cycling	Hayato Seki
P01-19	Investigation of archery experience on shoulder girdle motion and acromiohumeral distance at full draw	Takeru Abekura
P01-20	Differences of maximum inclination and center of mass accelerations between professional and amateur ballet dancers during pirouette in classical ballet	Yurina Tsubaki
P01-23	Evaluation of trunk muscle activities during the arabesque	Kanae Ouchi
P01-24	The investigation of the mobility in the first tarsometatarsal joint in forced turnout of ballet dancers	Honoka Ishihara
P01-25	Regulate velocity on combined training improving the college basketball players jumping performance	Chenfu Huang
P01-26	Anteroposterior hand position at set posture affects the subsequent block start performance	Takuma Hayashi
P01-27	Validity of approach-run speed in pole vaulting using laser displacement meter or body-only model	Atsuto Noro
P01-28	Does the lower limb muscularity relate to long-sprint performance in 400-m sprinters?	Keishi Kuroki
P01-29	Age-related differences in electromyographic latencies of the lower limb muscles in standing sprint initiation throughout childhood and adolescence	Mizuki Kitamura
P01-30	Correlation between cue tip speed and kinematics of 9-ball break shot	Pui Wah Kong
P01-32	Potential injury mechanisms in ulnar collateral ligament injuries; magnitude and variability of elbow load in repetitive baseball pitching	Bart van Trigt
P01-33	Sex-specific effects of fatigue on muscle activation during a single-leg lateral jump landing task	Davine Yang
P01-34	Effect of taping on muscle activity during squatting exercise	Mao Zeniya
P01-35	Effects of the incline board on discus throwing motion	Shota Kikuchi
P01-36	Relation between throwing arm angle and trajectory of the pitched ball in baseball	Hirotaka Nakashima
P01-37	Biomechanical analysis of the golf swing in one-length and conventional irons	Yu Kashiwagi
1720-1850	**Poster 02 Biomedical engineering**	**2nd Floor, Poster Display #1**
P02-02	Quantitative estimation of the forearm performance fatigability in a screwing model	Yen-Wei Chiu
P02-04	Effect of insertion speed on the insertion torque value and initial stability quotient of dental implant	Jui-Ting Hsu
P02-05	Development of an advanced prototype simulator for dental education	Mi-El Kim
P02-06	Computational model verifying effects of ultrasound settings on temperature changes in nitinol implants	Shaye Tiell
P02-08	Gait event detection using the single IMU on the unilateral electromechanical KAFO	Sumin Yang
P02-09	Kinematical differences between water surface and underwater conditions in flutter kick swimming	Hiroshi Ichikawa
P02-10	Relationship between sEMG amplitude and muscle fiber conduction velocity each short-term waveform with muscle fatigue	Aya Shirai

P02-11	Development of a statistical shape model of the knee for predicting bone/cartilage morphology and articular contact trajectories during activities	Kuan Hsien Wu
P02-12	A biomechanical study of novel braided PET artificial ligament for ACL reconstruction	Shenglin Li
P02-13	Pre-impact fall detection during electric scooter riding	Seung Hee Lee
1720-1850	**Poster 03 Injuries and rehabilitation**	**2nd Floor, Poster Display #1**
P03-01	Head impacts during judo practice in college judokas: A preliminary study	Sentaro Koshida
P03-02	Injury-related gait variables during running and loaded walking in U.S. army trainees differ by sex, but not physical activity level	Caleb Johnson
P03-03	Establishing scientifically meaningful effect sizes for knee abduction moment curve reductions in side-stepping using 1D power analysis	Mark Robinson
P03-04	Longitudinal recovery of laterality in the upper extremity activity after distal radius fractures	Terufumi Iitsuka
P03-05	Relationship between plantar foot pressure and high-risk and early knee osteoarthritis	Teng Phillis
P03-06	Simulated tunnel vision and lower limb kinematics during gap cross-over	Tadashi Uno
P03-07	Comparison of the effects of vibration therapy with stretching exercise in school teachers with myofascial pain syndrome of the trapezius	Chia-Lin Chen
P03-08	Influence of pelvic and lower limb joint kinematics on hamstring muscle-tendon strain during the late swing phase of maximal speed sprinting	Terumitsu Miyazaki
1720-1850	**Poster 04 Orthopaedics: Bone & cartilage**	**2nd Floor, Poster Display #1**
P04-01	Kinematic comparison of lower extremity before and after total hip replacement for hip dysplasia: A case report	Tserenchimed Purevsuren
P04-02	Stair ambulation reveals greater medial meniscus extrusion in healthy young volunteers	Takato Hashizume
P04-03	Numerical simulation of bone metabolism over time with aging	Teppei Mano
P04-04	Morphological characteristics of the femoral cartilage in trained and untrained individuals	Junhyeong Lim
P04-05	The fatigue life of cortical bone does not increase with test interruptions	W. Brent Edwards
P04-06	Depth dependent tensile properties of articular cartilage	Francesca De Vecchi
P04-07	Effects of high tibial osteotomy on three-dimensional knee kinematics in patients with knee osteoarthritis during isolated knee flexion measured using bi-plane fluoroscopy	Kao-Shang Shih
1720-1850	**Poster 05 Prosthetics and orthotics**	**2nd Floor, Poster Display #1**
P05-01	Adapting the prosthesis evaluation questionnaire to assess sex differences in the prosthetic needs and priorities of lower limb amputees	Tess Carswell
P05-02	Kinematics of downhill skiing with lower limb prosthesis on two skis	Filip Hrusa
P05-03	Non-linear finite element approach for a priori modal analysis of prosthetic foot	Balaramakrishnan T M
P05-04	Unilateral above-knee amputees gait analysis with a statistical parametric mapping	Jin-Joo Yang
P05-05	Effect of silanized ZrO2 addition on the physical properties of 3D printing resin	Jinkyung Park
P05-06	Functional effectiveness of custom ACL bracing: A finite element analysis	Alexandria Mallinos
P05-07	Dynamic finite element analysis for the metamaterial prosthetic liner optimization	Vasja Plesec
P05-08	An affordable soft robotics prosthetic hand with rigid structures	Vani Virdyawan
P05-09	Accuracy of inertial measurement units (IMUS) to measure ankle range of motion: Application in transtibi-al prosthesis user	Manunchaya Samala
P05-10	Biomechanical analysis based on the skull model to derive the optimal screw configuration of the 3D printing patient-specific reconstruction plate used for maxillofacial bone defects	Dong-Young Je
P05-11	Development of a finite element model for simulations of cold flow and neck-liner impingement in hip prosthesis	Lu Shen
P05-12	Reliability analysis of two stability measurement methods depending on dental implant length and bone density	Jungwon Lee
P05-13	Influence of prosthetic ankle-angle and walking speed on pylon moments in the two axis adaptable ankle	Kieran Nichols
P05-14	Patient-specific optimisation of cushioning stiffness in diabetic footwear	Nachiappan Chockalingam
P05-15	A simple method to overcome weakness in FDM 3D printed parts for stronger prosthetic sockets	Mukul Talaty
P05-16	Energetics of a novel passive dynamic custom AFO in gait: Analysis in a sample of foot-drop patients	Luca Zamagni
P05-17	Footwear comfort and the effect of customised foot orthotic insoles and BMI	Lloyd Reed
1720-1850	**Poster 06 Artificial intelligence and machine learning**	**2nd Floor, Poster Display #1**
P06-01	Remote technologies for testing physical function	Neil Cronin
P06-02	Development of a neural network for prediction of ovine hip joint centers	Aaron Henry
P06-03	The influence of protective equipment on performance in ice hockey	Rebecca Lennartz

P06-04	Modeling healthy and impaired gait dynamics using recurrent neural networks	Taniel Winner
P06-05	High efficiency barbell recognition model by considering convolutional neural network	Jin-Yi Lin
P06-06	Prediction of GRF and joint moments from different combinations of kinematic data.	Juan Cordero-Sanchez
P06-07	Evaluation of deep neural networks-based frame interpolation of X-ray fluoroscopic images of dynamic knee motions	Yu-Chien Chen
P06-08	Joint angle calculation and prediction via openpose estimation and machine learning model for riding pose adjustment in cycling	Yun-Ju Lee
P06-09	Estimating hand reaction forces from arm segment accelerations during handcycle propulsion using machine learning	Griffin Sipes
P06-10	Validity and reliability of deep learning methods to analyse knee osteoarthritis using magnetic resonance imaging: A systematic review	Surabhi Thatte
P06-11	Classification of EMG signals during contra-lateral arm movement	Azmin Rambely
1720-1850	**Poster 07 Ergonomics**	**2nd Floor, Poster Display #1**
P07-02	Estimating L5/S1 flexion-extension moment with an artificial neural network method in manual lifting tasks: A preliminary validation study	Chien-Chi Chang
P07-03	The effect of slanted computer mouse in a quick click task: A pilot study	Kuang-Wei Lin
P07-04	Muscle fatigue comparison between slanted and non-slanted gaming mice	Winny Chang
P07-05	Musculoskeletal analysis of upper limb motion during repetitive tasks	Akisue Kuramoto
1720-1850	**Poster 08 Imaging**	**2nd Floor, Poster Display #1**
P08-01	Effect of superficial tissue and intermuscular connections on the shear modulus distribution within the rectus femoris muscle	Taiki Kodesho
P08-02	Short-term impact of basketball workout on knee medial meniscus	Hsin-Min Wang
P08-03	The effect of different file types and DXA protocols on an image processing fracture risk prediction tool	Ali Ammar
P08-04	MRI-based spine models for patient specific surgical planning	David Williams
P08-05	The association of normalized cross-correlation with biplanar videoradiography tracking error	Kaito Lee
P08-06	Towards dynamic CT imaging in revalidation tracking of jaw movements: An experimental phantom study	Benyameen Keelson
P08-07	Effects of physical activity level and motor function on hippocampal volume in the older adults	Kota Anjiki
1720-1850	**Poster 09 Balance and posture**	**5th Floor, Poster Display #2**
P09-01	Task-oriented whole body reaching improves postural performance in hemiparesis patients after stroke	Jen-Suh Chern
P09-02	The effects of internal perturbations on balance for the fallers and non-fallers with Parkinson's disease: A preliminary study	Yu-Chuan Tsai
P09-03	Plantar pressure distribution response to various gait speeds and its relationship with gait balance in overweight adults	Hyun Kyung Kim
P09-04	Reducing fall risk using 12-weeks of online dance classes for women aged 65 and above	Emma Chen
P09-05	Development of the two-dimensional mechanical model of human stability	Martyna Sopa
P09-08	Leg muscle activities during single leg stance	Jooyeon Ko
P09-09	Alteration of inter-joint interaction during standing due to spinal cord injury	Kimiya Fujio
P09-10	Research on the balance ability of freestyle skiing aerial skills athletes based on specific frequency band EEG	Youcai Guo
P09-11	A static model predicts roof-to-ladder transition friction requirements	Sarah Griffin
P09-12	Evidence for modifying extension ladder design to reduce slipping risk	Violet Williams
P09-13	Decompose centre of pressure component affecting centre of mass acceleration in quiet standing	Taku Miyazawa
P09-14	The effectiveness of artificial intelligence sport training mirror combine with chinese martial arts for lower extremities balance	Cheng-Wei Chen
P09-15	Gait stability restrictions did not elicit compensation from remaining strategies	Aaron Best
P09-16	Effects of bilateral subthalamic deep brain stimulation on balance control during sit-to-stand in patients with advanced Parkinson's disease	Ya Hung Wang
P09-17	Effect of small perturbation balance training using wearable device on muscle activity related to reactive postural control	Taku Washida
P09-18	The effect of suspensory strategy on postural control under lateral perturbations: A study on COM height and balance performance	Linjing Jiang
P09-19	Age-induced modifications in postural sway and force steadiness during plantar and dorsiflexion	Ioannis Amiridis
P09-20	Effects of eye dominance on whole-body balance control during level walking in the elderly	Ju Yang Tiong
P09-21	Effects of scoliosis on upper body balance control in middle-age adults during obstacle crossing	Wen-Horng Lo

P09-22	Neuromuscular responses during standing with sensory restrictions are not related to field test performance in children with cerebral palsy	Anastasia Papavasileiou
P09-23	A bi-planar inverted pendulum model for evaluating the dynamic stability in patients with duchenne muscular dystrophy during level walking	Shu-Jiun Lin
1720-1850	**Poster 10 Clinical biomechanics**	**5th Floor, Poster Display #2**
P10-01	Muscle-tendon biomechanics and daily steps in patients recovering from achilles tendon rupture	Taija Finni
P10-03	Effect of isometric quadriceps exercise on stiffness and hemoglobin concentration of the infrapatellar fat pad in knee osteoarthritis	Syoya Nakanishi
P10-04	Effect of creep after twenty minutes of full lumbar flexion on subsequent lifting	Mitsuhiro Ota
P10-05	Computer simulation on obturator prosthesis for velopharyngeal defect	Ho Beom Kwon
P10-06	Biomechanical effects of an aramany class VI obturator prosthesis: A 3D finite element analysis	Aein Mon
P10-07	Biomechanical analysis of the effects of post & core in short clinical crown	Jaebok Lee
P10-08	Stress analysis in the mandible of complete denture prosthesis wearers - A biomechanics perspective	Mary Delia Bondoc
P10-09	Diagnosis of anterior cruciate ligament deficiency using a composite index calculated from the knee flexion and muscle force	Haoran Li
P10-10	Degree of association between knee health with pelvis mobility and plantar pressure	Arnab Sarmah
P10-11	Knee joint moments calculated using markerless motion capture can distinguish osteoarthritis severity during walking gait	Jereme Outerleys
P10-12	In vivo kinematics of total ankle prosthesis with different talar implant shapes	Rea Ikeda
P10-13	Asymmetry on forearm rotation movement in patients with Parkinson's disease and swedd	Ji-Won Kim
P10-14	IMU-instrumented timed-up and go test identified task-specific mobility declines in older adults	Yu-Pin Liang
P10-15	A statistical analysis of the shape and density distribution of the talus	Jordan Stolle
P10-16	Kinematic and kinetic analysis of upper limb elevation exercises in baduanjin	Geonhui Kang
P10-18	Biomechanical effect of floor sit-to-stand movement on the optimal surgical site in ACLR surgery: A computational analysis	Jaewoong Han
P10-19	Optimal hinge positions on tibial wedge in biplane open-wedge high tibial osteotomy as varus deformity angle	Tae Soo Bae

Tuesday, August 1st

0800-0930	**Symposium 03 Artificial Intelligence in Biomechanics: Current and future applications** — Chairs: **Neil Cronin, Jacqueline Alderson**	**Room 1**
SY03-1	Team sports analytics using machine learning	Keisuke Fujii
SY03-2	Estimation of kinetic parameters from video data using supervised machine learning techniques	Marion Mundt
SY03-3	Applications of AI in clinical settings	Eni Halilaj
0800-0900	**Oral 15 David Winter Young Investigator Awards Nominee (Oral)** — Chair: **Elizabeth Clarke**	**Room 2**
O15-1	Influences of alteration in running foot strike angles on internal loading of the tibia	Sanghyuk Han
O15-2	Muscle shape changes and gearing are mediated by internal muscle properties in the human gastrocnemii	Nicole Yvette Kelp
O15-3	Foot and ankle kinetics are coupled during propulsion for walking and running	Quinn Yetman
O15-4	Inertial measurement unit calibration methods for the wrist joint: Which one should I use?	Alessandro Bonfiglio
O15-5	Windlass mechanism engagement influences calcaneocuboid joint kinematics within a robotic-driven tibial movement envelope: A preliminary study	Anthony Le
0800-0924	**Oral 16 Musculoskeletal modeling 3** — Chairs: **Daniel Hahn, Taku Wakahara**	**Room 3**
O16-1	Validation of EMG-driven model-based estimations of joint, muscle, and tendon stiffness	Christopher Pablo Cop
O16-2	Alterations of muscle activation to reduce knee loading for people with limb loss: A musculoskeletal simulation study	Jiayu Hu
O16-3	Creating subject-specific musculoskeletal models via morphometric transformation	Julia van Beesel
O16-4	Video fluoroscopy and advanced musculoskeletal modelling unveil new insights into the mechanics of total knee arthroplasty during the golf swing	Seyyed Hamed Hosseini Nasab
O16-5	Wearable motion capture-driven musculoskeletal framework for multiscale orthopedic biomechanics	Liming Shu
O16-6	Automated generation of personalized foot-ground contact models	Spencer Williams
O16-7	Towards rehabilitation of upper limb disorders via neuro-musculoskeletal modelling	Harnoor Saini
0800-0900	**Oral 17 Methodologies and data analysis 1** — Chair: **Ismail Shariman**	**Room 4**
O17-1	Validation of smartphone-based analysis of human kinematics during 45° changes of direction	Cameron Stephen
O17-2	Estimating how sensorimotor impairments influence walking speed in persons with spinal cord injury with machine learning techniques	Tat Nhat Minh Truong
O17-3	Validity of artificial intelligence-based motion analysis system ~ AI analysis vs. Human analysis	Takumi Ino
O17-4	Deep learning successfully classifies acoustic emission data from knee joints	Ivan Vatolik
O17-5	Evaluation of the estimated length of the plantar aponeurosis using a multi-segment foot model	Yuka Matsumoto
0800-0848	**Oral 18 Impact biomechanics 1** — Chair: **Hironari Shinkai**	**Room 5**
O18-1	Helmet performance and body effects in head impacts in E-scooter falls	Wei Wei
O18-2	Influence of midsole compression on acceleration magnitude in running	Robin Trama
O18-3	Effect of slip anticipation on muscle activation pattern during walking down a slippery slope	Dain Shim
O18-4	Simulation of the impact process of water cannon on cranio cerebral injuries	Yinze Lei
	Comparative Neuromuscular Biomechanics (CNB) Group Symposium: Muscles, Models, Machines — Chairs: **Jonas Rubenson, Greg Sawicki**	**Room 6**
0800-0930	**Slot 1**	
	Topic 1; *In vivo* paradigms	
CNB1-1	**Keynote**: Get real: New experiments, models and parameters for understanding in vivo muscle function.	Kiisa Nishikawa
CNB1-2	3D whole muscle shape changes - exploring a novel approach	Jeroen Aeles
CNB1-3	Direct in vivo assessments of plantar flexor function to guide patient care	Josh Baxter
	Topic 2; modelling paradigms	
CNB1-4	**Keynote**: Task-level feedback control of gait is an emergent property of effort minimization in the presence of noise	Friedl De Groote
1100-1230	**Slot 2**	
CNB2-1	Biophysical muscle models for simulating muscle and muscle spindle response to stretch	Surabhi N. Simha

CNB2-2	Muscle force estimation using convolutional neural networs and hill-type models	Anne Koelewijn
	Topic 3; Engineering/Machine paradigms	
CNB2-3	**Keynote**: Frogs as models for robotics, limb control and muscular ageing	Christopher Richards
CNB2-4	Measuring the motion of human muscle: Devices, disruptions, and deformations	Taylor Dick
CNB2-5	Viewing the elephant trunk as an engineer turned biologist	Andrew Schulz
1330-1500	**Slot 3 Poster viewing and moderated poster flash presentations**	
CNB3-1	Investigating intrinsic muscle mechanics of force production	Caitlin Bemis
CNB3-2	Energetics, mechanics, and muscle: Locomotor adaptations to chronic limb loading during development	Kavya Katugam-Dechene
CNB3-3	Does the *in-vivo* or *in-vitro* environment impact the tendon force-strain relationship?	Fransiska M. Bossuyt
CNB3-4	Blood python *(python brongersmai)* strike kinematics and forces are robust to variations in substrate geometry	Derek J. Jurestovsky
CNB3-5	Creating musculoskeletal models of humans and animals with opensim creator	Ajay Seth
CNB3-6	Residual force enhancement: Active versus passive contribution	Wejdaan Faridi
CNB3-7	Kinetics of a collective load carrying in ants	Jordan Drapin
CNB3-8	Characterizing residula and passive force enhancement in cardiac myofibrils	Seong-won Han
CNB3-9	The intrinsic and neurally-mediated contributions to the balance-correcting torque response differ between the ankle and hip	Kristen L. Jakubowski
0800-0912	**Oral 19 Injuries and rehabilitation 2** **Room 7** Chairs: **Masatoshi Nakamura, Jun Umehara**	
O19-1	Subject-specific FE analysis to investigate how different rehabilitation exercises influence tendon strains in achilles tendinopathy patients	Alessia Funaro
O19-2	Effects of brace wearing and rehabilitation on foot muscle thickness and cross-sectional area after ankle inversion trauma	Rosemary Dubbeldam
O19-3	Identifying movement strategies to offset the performance-injury risk conflict in side-step cutting via optimal control simulations	Aaron Fox
O19-4	Electrical stimulation induced isometric muscle contraction can improve mechanical properties and reduce tendon adhesion followed adipose-derived stromal vascular fraction gel treatment in the rat achilles tendinopathy	Ho-Yi Tuan-Mu
O19-5	Wearable ultrasound sensor for lateral epicondyle tendinopathy surveillance	Yeseop Park
O19-6	Does female handball players with low hip external rotation strength display higher knee abduction moments during side-cutting than players with high strength?	Niels Nedergaard
0800-0924	**Oral 20 Running: Biomechanics 1** **Room 8** Chairs: **Mike Hahn, Kazuhiro Ishimura**	
O20-1	Reduced tibial loading during a 10km run in competitive and recreational runners	Hannah Rice
O20-2	Effects of soft tissue artifacts on the calculated kinematics of the knee during gait	Wenjin Wang
O20-3	Adaptive biofeedback gait retraining on slopes: A proof-of-concept study	Zoe Y.S. Chan
O20-4	Trained novice runners increase step frequency and decrease force application	Janet Zhang-Lea
O20-5	Inter-individual differences in step length and step frequency change across running speeds	Masanori Sakaguchi
O20-6	Variation in tibia-fibular geometry is associated with strain-related changes during running	Meghan Keast
O20-7	Increasing step frequency reduces cumulated patellofemoral joint stress more at low running speed	Michiel Hagen
0940-1030	**Keynote Lecture 2** **Room 1** Chair: **Maarten Bobbert**	
KL2	Complementary Roles of Biomechanics and Machine Learning in Human Motion Monitoring	Sukyung (Sue) Park
1100-1230	**Symposium 04 Contemporary Issues In Ball Kicking Biomechanics Research Across The Football Codes** **Room 1** Chairs: **Alexandra Atack, Hiroyuki Nunome**	
SY04-1	Energy flow in soccer kicking	Neal Smith
SY04-2	Looking beyond the kicking leg: Whole-body strategies for ball kicking performance	Simon Augustus
SY04-3	Sex differences in ball kicking biomechanics (strength, technique and training effects)	Alexandra Atack
SY04-4	Myths and facts on football kicking: Filling the gaps between the player's perspective, coach's observation and scientific evidence	Hiroyuki Nunome
1100-1212	**Oral 21 Musculoskeletal modeling 4** **Room 2** Chairs: **Yasuo Kawakami, Emika Kato**	
O21-1	An advanced modelling framework for assessing knee articular mechanics and soft tissue loading after total knee arthroplasty	Ning Guo

O21-2	Dynamic simulation of running using a full-body model with trunk muscles	Harry George Driscoll
O21-3	Unravelling adaptation strategies in sit-to-walk using predictive neuromuscular simulations: Pain	Eline van der Kruk
O21-4	Towards a musculoskeletal shoulder model depicting glenohumeral translations considering bony, ligamentous and muscular stability constraints	Johanna Menze
O21-5	A dynamic foot model for predictive simulations of gait	Lars D'Hondt
O21-6	Insights into the different state-of-the-art optimisation approaches for solving the shoulder muscle redundancy problem	Maxence Lavaill
1100-1212	**Oral 22 Wireless sensors and wearable devices 1** Chairs: **Yuji Ohgi, Shoji Konda**	**Room 3**
O22-1	Three-dimensional training load of female university volleyball players during practice games	Chuan Fang Hou
O22-2	Sensor number-dependent accuracy of ground reaction forces and center of pressure in simplified pressure sensor insoles	Philip X. Fuchs
O22-3	IMU metrics assessed during 2km of indoor track vs. Sidewalk running	Hannah Dimmick
O22-4	A hybrid machine learning model predicts ankle and knee moments in multiple tasks from a single IMU	Ting Long
O22-5	The relationship between "hitting the wall" phenomenon and gait changes during a full marathon	Nao Hirakawa
O22-6	Probability of cardiac-locomotor coupling during daily activities	Aurora Rosato
1100-1236	**Oral 23 Spine and trunk 1** Chairs: **Pui Wah (veni) Kong, Tadahiko Kato**	**Room 4**
O23-1	New perspective from old data: A contemporary, quantitative analysis of the first reported cervical facet dislocation produced in the laboratory	Ryan Quarrington
O23-2	Differences in trunk rotation between people with and without low back pain during various movements	Batbayar Khuyagbaatar
O23-3	Effect of the draw-in maneuver on lumbar spine and hip motion during sit-to-stand for prevention of low back pain and urinary incontinence	Jin Ishibashi
O23-4	Effects of age and gender on back muscle activations during various spinal movements	Chih-Hsiu Cheng
O23-5	Biomechanical influence of the cage lordosis in an anterior lumbar interbody fusion at L4-L5 - A simulation study	Robin Remus
O23-6	Deep paraspinal muscle volume asymmetry in adolescent idiopathic scoliosis	Phoebe Duncombe
O23-7	Reliability of ultrasonography to assess spinal compression during heavy load carriage	Walters Sherrilyn
O23-8	Targeted multifidus muscle activation reduces fibrosis of multifidus muscle following intervertebral disc injury	Paul Hodges
1100-1224	**Oral 24 Clinical biomechanics 2** Chairs: **Mary Rodgers, Shigeyuki Kato**	**Room 7**
O24-1	Changes in muscular coordination patterns of the elderly population	Elisa Romero Avila
O24-2	Natural knee biomechanics can be restored by customized high-tibial osteotomy: PRE/POST-op functional and morphological evaluations	Claudio Belvedere
O24-3	Effects of unexpected slip and trip-induced perturbations on dynamic stability and support moment	Shabnam Shokouhi
O24-4	An experimental setup for assessment of traction force and associated fetal brain deformation in vacuum-assisted delivery	Estelle Pitti
O24-5	The BASMI limits patient specific examination compared to motion capture of a four-segment spine	Logan Wade
O24-6	The importance of reporting performance-based outcomes following intramedullary nailing of tibial shaft fractures	Simon Thwaites
O24-7	Femoroacetabular impingement patients show altered kinematics during lateral hop and drop jump	Katrin Däetwyler
1100-1236	**Oral 25 Locomotion: General 2** Chairs: **Masahiro Shinya, Kazutaka Takahashi**	**Room 8**
O25-1	Poincaré Analysis detects pathological loading rate variability in post-ACLR individuals	Noah Davidson
O25-2	Test-retest reliability of markerless three-dimensional gait kinematics and kinetics, in healthy older adults	Andreia Filipa Carvalho
O25-3	Differences in frontal joint kinetics between markerless and marker-based motion capture systems during treadmill running	Hui Tang
O25-4	Simple walking model to explain hip torque compensation for reduced propulsive force	Hajime Ohtsu
O25-5	Relationship between bicycle control and gaze behavior during a narrow-path ride	Takashi Kojima
O25-6	Effect of air resistance on braking and propulsive impulses during treadmill running	Jared Steele
O25-7	Influence of neglecting free moment and transverse ground reaction forces in the detection of the instability of gait	Helene Pillet
O25-8	Comparison of two hypomimia indicators in Parkinson's disease	Elena Pegolo

1330-1500	**Symposium 05 Healthy knees after knee injury – challenging the biomechanist's perspectives** Chairs: **Jos Vanrenterghem, Niels Nedergaard**		**Room 1**
SY5-1	To avoid re-injury after reconstruction of the Anterior Cruciate Ligament (ACL), one should screen patients on movement patterns that excessive load the knee ligaments	Jesper Bencke	
SY5-2	Risk of (re-)rupturing the ACL during a side cutting manoeuvre can be assessed by screening standardized hops and jumps	Kevin Ford	
SY5-3	The development of post-traumatic osteoarthritis is primarily caused by pathological load distributions on the tibiofemoral cartilage	David Saxby	
SY5-4	Pathological knee loading observed during gait/running will propagate itself in most if not all other activities a patient/athlete engages in	David Lloyd	
1330-1442	**Oral 26 JSB Awards Nominee (Oral)** Chair: **Yuki Inaba**		**Room 2**
O26-1	Unique mass distribution in the lower limbs of distance runners and its effect on moment of inertia	Takeshi Edagawa	
O26-2	Mechanical interaction between achilles tendon and plantar fascia during isometric ankle plantar flexion	Hiroto Shiotani	
O26-3	Markerless sagittal plane kinematic analysis of sprint running: Comparison between a deep learning analysis and manual digitization	Hiroaki Noro	
O26-4	Extreme elongation of triceps surae muscle-tendon unit was attributable to the elongation of the muscle rather than that of the tendon in rat	Satoru Hashizume	
O26-5	Switch point of impact height of adjusting segments to reach ball heights during a two-handed backhand stroke at various impact heights	Sichao Zhang	
O26-6	Reliability of ultrasound-based muscle cross-sectional area in lower-limb: A comparative analysis between ultrasound and MRI	Yoko Kunimasa	
1330-1454	**Oral 27 Sport biomechanics 2** Chairs: **Daisuke Takeshita, Hiroshi Suito**		**Room 3**
O27-1	The relationship between reaction time and landing mechanics associated with anterior cruciate ligament injury during single-leg landing	Yan-Long Chen	
O27-2	The impulse of the lateral ground reaction force makes runners' lateral velocity change and their variability during the approach phase into the curved path in sprint running	Tatsuro Ishidzuka	
O27-3	Performance strategy in the high jump varies between individuals: Mechanical work exertion vs. Energy conversion	Toshihide Fujimori	
O27-4	Why are force-velocity profiles determined in dynamometer experiments different from those determined in jumping experiments?	Maarten Bobbert	
O27-5	Are lower extremity joint kinetics influenced by shoe collar height in collegiate female volleyball players?	Tanner Thorsen	
O27-6	Pectroralis major and deltoid muscularity in shot putters: Reversal of whether cross-sectional area or volume is related to performance	Shogo Hashimoto	
O27-7	Front knee control in cricket fast bowling	Rene Ferdinands	
1330-1418	**Oral 28 Orthopaedics: Tendon & ligament** Chair: **Mei-ying Kuo**		**Room 4**
O28-1	Biomechanical and histological properties of different human tendons	Samantha Hefferan	
O28-2	Factors associated with good recovery from achilles tendon rupture at 1-year post rupture	Ra'ad Khair	
O28-3	In-vivo patellar tendon strain measured using ultrasound differs by sex and region of the tendon	Naoaki Ito	
O28-4	Near-infrared spectroscopic assessment of patellar tendon mechanics	Adam Kositsky	
1330-1430	**Oral 29 Running: Footwear 1** Chair: **Uwe Kersting**		**Room 5**
O29-1	Effect of minimalist school shoes on intrinsic foot muscle size	Roy Cheung	
O29-2	Investigation of optimal perceived comfort in sports shoes with plantar pressure distribution	Wei Ting Tu	
O29-3	Rate of knee flexion at the instant of landing during running can influence initial knee joint stiffness estimates due to running shoe cushioning	Zhenyuan Zhang	
O29-4	Effects of the Nike Vaporfly 4% features on muscle activity	Ashna Subramanium	
O29-5	The effects of habitual foot strike pattern and footwear on running pattern and economy	Hyunji Kim	
1330-1430	**Oral 30 Prosthetics and orthotics 1** Chair: **Paolo Caravaggi**		**Room 7**
O30-1	Using gaze-tracking to assess cognitive load in lower limb prosthetic users	Sabina Manz	
O30-2	Upper extremity kinematics are affected by socket suspended prostheses during reaching motions	Julia Dunn	
O30-3	Straight-line walking on cross-slope in unilateral transfemoral prosthesis users	Genki Hisano	

O30-4	Unilateral transfemoral amputees might be at risk of lateral compartment degeneration of the knee joint	Diana Toderita
O30-5	A non inferiority approach to investigate the influence of stem fixation and stem type on revision rates in elective THA procedures depending on patient age	Michael Morlock
1330-1442	**Oral 31 Rehabilitation technology: Biorobotics and exoskeletons 1** Chair: **Hiroshi Takemura**	**Room 8**
O31-1	Center of mass kinematics robustly predict reactive joint torques at the ankle, knee, and hip during perturbed standing	Kristen Jakubowski
O31-2	Personal standing mobility Qolo enables people with lower limb impairments to voluntarily stand up	Yukiyo Shimizu
O31-3	Effect of an assistive robotic system's compliance on subject's muscular activation and comfort	Maximilian Siebert
O31-4	Finding assistance strategies based on musculoskeletal simulation and machine learning	Xianyu Zhang
O31-5	Neuromusculoskeletal model-informed bayesian neural networks-based control of a knee exoskeleton	Longbin Zhang
O31-6	Evaluation of a passive upper-limb exoskeleton during a simulated dynamic work task over a large shoulder workspace	Leon Lauret
1510-1610	**Muybridge Award Lecture** Chair: **Toni Arndt**	**Room 1**
MAL	Born to Move: Embracing our Evolutionary Legacy	Irene S. Davis
1640-1810	**Symposium 06 Beyond the Surface: Uncovering the Role of Materials in Biomechanics, Sports, and Rehabilitation** Chairs: **Solehuddin Shuib, Abd Halim Abdullah**	**Room 1**
SY06-1	Development of knee implant using additive manufacturing technology: Lattice design, material and manufacturing	Solehuddin Shuib
SY06-2	Simulating material properties of in-vivo shoe-surface interaction using a robotic platform - opportunities and limitations	Uwe Gustav Kersting
SY06-3	3D printing material in developing assistive adaptive devices for rehabilitation medicine	Abd Halim Abdullah
SY06-4	New materials that modify horizontal forces for injury prevention	Thor Buch Grønlykke
SY06-5	Additive metal: Process, microstructure and properties	Izhar Aziz
1640-1804	**Oral 32 Sport biomechanics 3** Chairs: **Simon Augustus, Koichiro Inoue**	**Room 2**
O32-1	Leg joint kinetic determinants of sprint acceleration running	Ryu Nagahara
O32-2	Biomechanical analysis of an elite paralympic amputee sprinter in steady state running on treadmill and track	Samira Giuliana Breban
O32-3	The influence of lateral wedged insoles on the performance of a shuffle movement	Reyna Crawford
O32-4	Effect of cleat and rider positioning on leg joint function	Colin Firminger
O32-5	Impulse generation and initial velocities in basketball two-foot running jumps	Jun Ming Liu
O32-6	Centre of pressure and roll over shape from wearable sensors during overground running of an elite paralympic amputee sprinter	Sara Barbacane
O32-7	Acceleration transmission during cricket fast bowling	Matthew Lamb
1640-1804	**Oral 33 Locomotion: Clinical gait 2** Chairs: **Brian Davis, Shoma Kudo**	**Room 3**
O33-1	Are sagittal plane leg alignment and the active peak force generated during running associated with medial tibial stress syndrome development?	Joshua Mattock
O33-2	A consumer-grade wearable technology is valid for the assessment of walking gait "in the wild"	Josh Carter
O33-3	Reduced number of motor modules recruited during stair descent in patients with knee osteoarthritis	Lasse Hansen
O33-4	Achievement of bipedal locomotion in a two-dimensional neuromusculoskeletal model of unilateral transfemoral amputation	Daisuke Ichimura
O33-5	The effect of exercises derived from clinical gait analysis on low back pain - A randomized control trial	Christina Kaltenbach
O33-6	Altering foot orientation changes knee loading in people with and without knee osteoarthritis during three daily activities	Yi Wan
O33-7	Impact of age on muscle activation patterns with a prolonged walk	Katherine Boyer
1640-1740	**Oral 34 Simulation techniques and applications 1** Chair: **Shinsuke Yoshioka**	**Room 4**
O34-1	Predicted ground reaction force is plausible to use in inverse dynamics based musculoskeletal simulation during gait	Ryo Ueno
O34-2	Prediction of ground reaction force and moment by inertial measurement units using a 3D forward dynamics model	Naoto Haraguchi

O34-3	Participant-informed models of the tibia-fibula complex: Influence of geometry and density prediction errors on bone strain	Olivia Bruce
O34-4	Sensorimotor noise might explain effort in amputee gait: A simulation study	Wouter Muijres
O34-5	A cadaveric shoulder motion study using open-loop control for simulating in-vivo muscle loading	David Timothy Axford
1640-1804	**Oral 35 Others 2** Chairs: **Hiroki Ozaki, Shinya Sano**	**Room 5**
O35-1	Treadmill versus overground gait characteristics in autistic individuals	Kevin Valenzuela
O35-2	In situ validation of power quantification for dynamic wheelchair sports	Mathieu Deves
O35-3	The immediate effect of a hop-stabilization program on ground reaction force during cutting movements in individuals with chronic ankle instability	Teerapat Laddawong
O35-4	Neuromuscular adaptations to aerial landing performance following a shark bite injury: A case-control study	James Forsyth
O35-5	fMRI reveals fidgeting motor skills in ADHD improves prefrontal cortex activation during executive functioning	Xirui Zhao
O35-6	Breaking ground without breaking the bank - validation of a novel low-cost 3-axis force plate	Yumna Albertus
O35-7	Texture analysis of ultrasound images to evaluate multifidus muscle composition: A comparison between healthy subjects and patients with low back pain	Jong Hun Kim
1640-1804	**Oral 36 Artificial intelligence and machine learning 2** Chairs: **Sina David, Keizo Takahashi**	**Room 6**
O36-1	Improving cycling force sensor accuracy using multilayer perceptrons	Jonas Ebbecke
O36-2	Estimation of ground reaction forces and center of pressure during stair walking using convolutional neural network based model	Ye Ma
O36-3	Comparing the advantages and disadvantages of physics-based and neural network-based modeling for predicting cycling power	Patrick Mayerhofer
O36-4	AI based automated error detection for medical skills training using markerless biomechanics	Travis Eliason
O36-5	Myosuite: Combining neuromusculoskeletal modelling with reinforcement learning to mimic motor control	Guillaume Durandau
O36-6	Estimation of whole-body posture during walking in unilateral transfemoral amputees using sparse inertial measurement units and deep learning	Yuji Kumano
O36-7	Fast bowling performance analysis using inertial sensors and machine learning	Shruti Bhandurge
1640-1740	**Oral 37 Running: Footwear 2** Chair: **Mark John Lake**	**Room 7**
O37-1	A novel method to measuring the slip of foot inside the shoes: Evaluation of socks friction using pressure sensors	Dongwook Seo
O37-2	Influence of the type of running shoes in the lower limb muscular activity	Goncalo Marta
O37-3	Influence of shoe cushioniong on proximal running kinematics and kinetics	Kathy Reyes
O37-4	A pilot study: Effects of an 8-week training intervention in carbon-plated running shoes	Justin Matties
O37-5	Midsole stack height, running economy and step parameters	Montgomery Bertschy
1640-1804	**Oral 38 Muscle tissue and architecture 2** Chairs: **Kohei Watanabe, Katsuki Takahashi**	**Room 8**
O38-1	The effect of initial condition at the onset of stimulation on the ratio of muscle stiffness to force during isometric contraction	Siwoo Jeong
O38-2	Preload affects muscle fascicle mechanics during maximal voluntary MTU lengthening actions	Paolo Tecchio
O38-3	Multiscale hamstring muscle adaptations following a nine week eccentric training program	Max Andrews
O38-4	Typically developing children and children with cerebral palsy have similar leg muscle moment arms	Bart Bolsterlee
O38-5	Muscle- and sex-specific leg muscle volumes in children with cerebral palsy	Jonathan Yu
O38-6	A new model for the molecular mechanism of muscle contraction	Walter Herzog
O38-7	Is the aponeurosis protected from great length changes when active muscle forces change dramatically?	Fransiska Bossuyt

1820-1950	**Poster 11 Sport biomechanics 2**	2nd Floor, Poster Display #1
P11-01	Ground reaction forces during the full driver shot of Japanese male professional golfers	Tomoya Hirano
P11-02	Is there a linear relationship between swimming velocity and vertical body position in front crawl for each stroke phase?	Sohei Washino
P11-03	Evaluation of muscle activations of upper arm in collegiate athlete during 200-m front crawl: A pilot study	Jia-Hao Chang
P11-04	The effects of two-step golf swing drills on swing rhythm and clubhead speed in competitive juniors	Kanji Mori
P11-05	Conserved biomechanical strategies for standing and walking balance in the upright and inverted posture	Charlotte Le Mouel
P11-06	Shoulder, scapulothoracic, and glenohumeral joint movements during badminton overhead swing motion in standing versus wheelchair sitting positions	Yuki Tamura
P11-07	Mass-spring characteristics explain the temporal step parameters but are not specific to individuals across phases in accelerated sprinting	Arata Tatsumi
P11-08	Accuracy of the centre of mass estimation based on pictures among iqfoil windsurfing athletes	Martyna Bialecka
P11-09	Assessing the likelihood of ACL injury in volleyball players at UITM by utilizing the landing error scoring system	Raihana Sharir
P11-10	Measurement of horizontal ground reaction force moment in the golf swing	Sung Eun Kim
P11-11	Longitudinal associations among land-jump biomechanics and imaging of the patellar tendon in male basketball players during the preseason	Andrew Kraszewskia
P11-12	Biomechanical know-how of learning bicycle kick and jumping side volley in soccer	Gongbing Shan
P11-13	A nine-week ACL injury prevention program for female handball players: Effect on knee joint loading, cutting technique and performance	Patrick Mai
P11-14	Reference values of jump tests stratified by sex using an insole-embedded IMU	Meihui Li
P11-15	Associations of rotational range and strength of shoulder with regard to elbow valgus stress during pitching in youth baseball players	Yu-Chun Lin
P11-16	Impact of cold exposure and warm-up on muscle temperature and countermovement jump variables	Itaru Chiba
P11-17	Towards a contact model of the rugby union scrum	Zak Joseph Mascarenas Sheehy
P11-18	Effect of different speed in eccentric phase in squat protocols on hip flexors and extensors activation	Anna Pisz
P11-19	Sagittal plane lower extremity biomechanical response to soccer cleat stud length during a cutting task	Emily Karolidis
P11-20	Biomechanical analysis of the take-off phase in Japanese male pole vaulters	Tomoki Yamamoto
P11-21	A new approach to evaluate the ACL risk of re-injury after reconstruction	Sahar Ostadrahimi
P11-22	Effect of resin on ball velocity of the step-shooting in female handball players	Aoi Fujimoto
P11-23	Head striking patterns of Japanese kendo between elite traditional kendoka and elite tournament players	Ting-Cheng Chou
P11-24	Effect of different knee angles on hamstring muscle activity during nordic hamstring exercise with a sloped platform	Taspol Keerasomboon
P11-25	Angulation of handle force application from the cable direction in achieving a turn in the hammer throw	Eri Nonaka
P11-26	A biomechanical analysis on the straight jump of gymnastics trampoline	Yuji Ohgi
P11-27	The effects of footwear on the plantar pressure under the metatarsal heads during rope skipping	Kaicheng Wu
P11-28	Reduced medial-lateral displacement of the body's center of mass during walking in starting soccer players in high school football league	Anne Dixie Lim
P11-29	Throwing performance and kinematic analysis of overhead throwing in male elite and varsity cup cricketers	Jordan Leondiris
P11-31	Case study: Can tensiomyography predict sports performance?	Kyoungkyu Jeon
P11-32	Comparison of differences in muscle activity according to the types of conventional deadlifts	Seungho An
P11-33	Kinetic determinants of acceleration performance in sideward sprint start from standing position	Takahiko Sato
P11-34	Angular momentum analysis of four styles of baseball pitching	Tomohisa Miyanishi
P11-35	An interaction between landing height and ground condition in ground reaction force during two-leg landing	Jeongeun Moon
P11-36	Differences in lower extremity muscle activation patterns during anticipated or unanticipated single-leg drop jump tasks	Jae Wook Lee
P11-37	Neuromuscular fatigue of vastus lateralis during fatiguing squat exercises in trained and untrained people: Time-frequency analysis	Jihong Park
P11-38	Track GRFs from an elite transfemoral paralympic sprinter using a wearable clamp dynamometer	Mattia Scapinello
P11-40	Comparison between rotational shot put technique and discus throw	Tadahiko Kato
P11-41	The effect of single-leg rotational landing on knee kinematics	Parunchaya Jamkrajang

1820-1950	**Poster 12 Musculoskeletal modeling**	2nd Floor, Poster Display #1
P12-02	Bone-remodelling in the foot: Application to exercise during the covid-19 lockdown	Julie Kim
P12-03	Validation of markerless motion capture for the assessment of joint reaction forces under varying body-borne loads	Isabel Coll

P20-02	Acute effects of dynamic versus static stretching in muscle architecture in adolescents	ZhiYu Tao
P20-03	Torque loss during simultaneous activation of agonistic muscles	Michael Baggaley
P20-04	Is force-generating capacity of the plantarflexor muscles affected by the surrounded skin mechanical property and orientation of gravity?	Yasuhide Yoshitake
P20-05	Musculotendinous architecture and strength of supraspinatus after tear and arthroscopy repair in patients with full-thickness tendon tear	Yen-Ling Chou
P20-06	Mechanical properties of the achilles tendon in middle-aged men and its relation to jump performance	Hae Dong Lee
P20-07	In vivo 3-dimensional ultrasonography of human biceps femoris reveals a twisted proximal aponeurosis	Carmela Julia Mantecon Tagarro
P20-08	Relationship between baseline flexibility and changes after chronic stretching intervention program	Masatoshi Nakamura
P20-09	Force-generating capacity of plantarflexion force is lowered by gravity during standing positions	Kiichi Saji
1820-1950	**Poster 21 Others 1**	**5th Floor, Poster Display #2**
P21-01	A biomechanical 3D analysis of a lab recorded lateral ankle sprain during a handball specific fake-and-cut maneuver	Timo Bagehorn
P21-02	A novel approach for characterizing the individual plantar intrinsic foot muscles: Cluster analysis based on physiological cross-sectional area and muscle fiber length	Yuki Kusagawa
P21-03	Predicting cervical spine dynamics using gaussian processes	Andrea Braschi
P21-04	The influence of bariatric surgery on postural stability - a pilot study	Veronika Szabóvá

Wednesday, August 2nd

0800-0930	**Symposium 07 Musculoskeletal modeling and simulation for injury prevention: State-of-the-art and future needs** Chair: **: Nicos Haralabidis**	**Room 1**
SY07-1	Simulation of lower extremity sports injuries: can we translate theory into practice?	Ton van den Bogert
SY07-2	Including variability into simulations 101: How to handle uncertainty in movement simulations	Anne Koelewijn
SY07-3	Towards the adoption of musculoskeletal modelling in the contact sport industry: Is it dream or reality?	Dario Cazzola
SY07-4	Designing a model of the shoulder joint for sports applications and injury analyses	Jennifer Maier
SY07-5	Musculoskeletal simulation to discover risk factors of hamstring strain injury during sprinting	Reed Gurchiek
SY07-6	OpenCap: 3D musculoskeletal simulation from smartphone video – Applications for injury prevention	Antoine Falisse
0800-0924	**Oral 39 Sport biomechanics 4** Chairs: **Neal Smith, Hironari Shinkai**	**Room 2**
O39-1	Relathionship between knee valgus angle and lateral trunk bending angle during volleyball spike jump	Miki Kawai
O39-2	Framework to solve the optimum armstroke in crawl swimming considering subject-specific shoulder joint torque characteristics	Motomu Nakashima
O39-3	Barbell squats for crossfit athletes: Effect of footwear type and load magnitude on lower limb joint torques	Eduardo Campos Martins
O39-4	Simulation of running prosthetic feet ground reaction forces using a multi-axial robotic walking simulator	Giacomo Fabris
O39-5	Knee biomechanical differences during unilateral landing between symmetrical and asymmetrical groups classified by hop tests	Karine Stoelben
O39-6	Risk factor identification of adductor strain in professional soccer	Rebecca Davis
O39-7	Individualized immediate feedback on sidestep cutting technique reduces knee abduction moments in female handball players	Kevin Bill
0800-0900	**Oral 40 Motor control 1** Chairs: **Motoki Kouzaki, Daichi Yamashita**	**Room 3**
O40-1	Corticokinematic coherence: A proprioceptive biomarker for motor performance	Scott Mongold
O40-2	Evaluating the musculoskeletal impact of local muscle vibration	Andrew Lowry
O40-3	Compensatory covariation of ball launch variables in tennis strokes	Yusuke Sudo
O40-4	Investigation of sensor-embedded key to quantify dynamic pinch force during key turning in young vs older healthy adults	Li Jing Soh
O40-5	Calibrated muscle-synergies method for missing muscle excitations prediction during walking	Marco Romanato
0800-0900	**Oral 41 Others 3** Chairs: **Ismail Shariman, Ryo Iwasaki**	**Room 4**
O41-1	Impact of a high-fat high-sucrose diet on joint and muscle integrity in juvenile sprague dawley rats	Mauricio Delgado
O41-2	Substantial reductions in adult physical activity follow an exercise-restricted growth period in guinea fowl	Derek Jurestovsky
O41-3	Continuum mechanical approach to rigid body mechanics in biomechanics	Salvatore Federico
O41-4	The effects of 10 weeks movement training for a junior student with motor impairment on functional mobility	Sheng-Yang Tso
O41-5	Does a 100-day mentoring program change girls' attitudes & self-identification in science, engineering & biomechanics?	Karen Mickle
0800-0912	**Oral 42 Rehabilitation technology: Biorobotics and exoskeletons 2** Chair: **Chien-chi Chang**	**Room 5**
O42-1	The mechanical energetics of walking on incline surfaces with passive ankle exoskeleton assistance	James Williamson
O42-2	Predicting individualized joint kinetics over continuous variations of walking and running	Emma Reznick
O42-3	Gait adaptation on repeat exposure to a robotic hip exoskeleton	Mark Price
O42-4	An improved design of an upper limb exoskeleton for overhead tasks	Georgios Aronis
O42-5	Walking with exoskeletons: Establishing biomechanical metrics for quantifying assisted-gait familiarization	Giorgos Marinou
O42-6	Metabolic power response to added mass on the lower extremities during running	Raziel Riemer

Hand and Wrist Biomechanics International (HWBI) Symposium		Room 6
0800-0930	**Slot 1** Chairs: **Toshiyasu Nakamura, Veronique Feipel**	
	Welcome	Trey Crisco, Angela Kedgley
HWS1-1	Recovery of thumb joint movement for patients with severe carpal tunnel syndrome	Hiroshi Kurumadani
HWS1-2	Median nerve deformation increases during repeated efforts of a pulp-pinch grip task	Denise Balogh
HWS1-3	Stability of the midcarpal joint post scaphoidectomy in different wrist types	Ronit Wollstein
HWS1-4	Effect of age and sex on the subluxation of the thumb carpometacarpal (CMC) joint	Li-Chieh Kuo
HWS1-5	Using an RGB-depth camera for marker-less estimation of contact between hand and handrim during an in-lab wheelchair tennis propulsion	Enrico Ferlinghetti
HWS1-6	Investigating the long-term impacts of hand tractor operation on the upper limb of farm operators	Josefa Angelie Revilla
1100-1230	**Slot 2** Chairs: **Ronit Wollstein, Angela Kedgley**	
HWS2-1	Keynote: Unsolved clinical mysteries in the hand and wrist	Nina Suh
HWS2-2	The difference in the efficiency of reactive grip force adaptation during static and dynamic tasks between children and adults	Hsiu-Yun Hsu
HWS2-3	Do muscle activity patterns vary according to the severity of carpometacarpal osteoarthritis disease?	Tamara Ordonez Diaz
HWS2-4	Fatigue of hand muscles following pinch grip quantified by surface electromyogram	Kiatbodin Wanglertpanich
HWS2-5	Method for assessing the fine motor skills synergies based on computer vision	Andrey Pomerantsev
HWS2-6	Coordinated muscle activity during chopstick manipulation	Kazuya Kurauchi
1430-1600	**Slot 3** Chairs: **Nina Suh, Darshan Shah**	
HWS3-1	Keynote: Non-surgical carpal arch space augmentation for median nerve decompression	Zong-Ming Li
HWS3-2	Challenges in developing a healthy finite element wrist model: Ligaments	James Yang
HWS3-3	Multi-object and multi-feature models of thumb anatomy for population-based morphological assessment	Cait Farrell
HWS3-4	Evaluation and comparison of in-vitro joint kinematics using motion-based coordinate frames vs. anatomical landmarks	Mohammad Haddara
HWS3-5	Familiarity effect on handwriting performance in school-aged children	Hao-Ling Chen
HWS3-6	Wi-fi based continuous detection of hand movements for motor assessment in Parkinson's disease	Chi-Lun Lin
1630-1720	**Slot 4** Chair: **Zong-Ming Li**	
HWS4	Keynote: Biomechanics of the distal radioulnar joint (DRUJ)	Toshiyasu Nakamura
	Awards	Angela Kedgley, Zong-Ming Li
	Closing	Zong-Ming Li
0800-0912	**Oral 43 Muscle tissue and architecture 3** Chair: **Bart Bolsterlee**	**Room 7**
O43-1	Timing of shortening influences force depression	Joumaa Venus
O43-2	The effects of gait retraining on the behaviours and mechanical properties of medial gastrocnemius-tendon unit during running	Liqin Deng
O43-3	Muscle volumes and moment arms of human rotator cuff muscles in vivo	Yilan Zhang
O43-4	Correlations between achilles tendon moment arm and plantarflexor muscle architecture	Logan Faux-Dugan
O43-5	Regional hamstring hypertrophic adaptation following a nine-week eccentric nordic hamstring training program	Anoosha Pai S
O43-6	Ultrasound based muscle quality and the confounding effect of subcutaneous fat layer in individuals with obesity	Heiliane de Brito Fontana
0800-0900	**Oral 44 Lower extremities 1** Chair: **Aaron Fox**	**Room 8**
O44-1	Orthotropic bone remodelling around uncemented acetabular component	Sanjay Gupta
O44-2	3D personalized foot models using surface-based statistical shape modelling	Liangliang Xiang
O44-3	Changes in hallux movement in people with chronic ankle instability during walking at different speeds	Tunpisith Jeamsupakorn
O44-4	Passive properties of the achilles tendon in athletes	Maria Sukanen
O44-5	Determining torque-angle relationships of human toe flexors	Samuel Wisdish

0940-1030	**Keynote Lecture 3** Chair: **Gregory Sawicki**	**Room 1**
KL3	Brain-Computer Interface Design: Thinking out of the box	Natalie Mrachacz-Kersting
1100-1230	**Symposium 08 Performance Enhancement Footwear in Running** Chairs: **Kim Hébert-Losier, Irene Davis**	**Room 1**
SY08-1	The effects of advanced footwear technology on running performance and lower extremity loading: Current knowledge and future directions	Steffen Willwacher
SY08-2	Footwear energy storage and return: How footwear mechanically cooperates and/or competes with the runner	Emily Matijevich
SY08-3	Effect of increased longitudinal bending stiffness on running economy and biomechanics when running uphill and on unstable terrain: Implications for trail running footwear	Marlène Giandolini
SY08-4	Can we predict who is responding to advanced footwear technology from biomechanics?	Wouter Hoogkamer
1100-1224	**Oral 45 Locomotion: Clinical gait 3** Chairs: **Aoife Healy, Norio Tsujimoto**	**Room 2**
O45-1	Individual rocker shoe parameters that are most effective in reducing plantar peak pressure	Thomas Johnson
O45-2	A segment frame optimisation method to standardise kinematic signals	Ariana Ortigas Vasquez
O45-3	Is peak anterior foot position related to anterior foot position at initial contact during gait training with visual feedback?	Erik Hummer
O45-4	Gait kinematics for severe knee OA and post-Tka from markerless motion capture	Elise Laende
O45-5	Gait characteristics of older adults with sagittal malalignment progression after spinal fixation	Shun Ito
O45-6	Analysis of gait coordination changes after training using HAL in patients with gait impairment due to central nervous system disorders	Hideki Kadone
O45-7	Effects of posterior spinal fusion surgery on gait biomechanics in patients with adolescent idiopathic scoliosis	Manish Gupta
1100-1148	**Oral 46 Methodologies and data analysis 2** Chair: **Kazuhiro Ishimura**	**Room 3**
O46-1	Three-dimensional vector analysis of ground reaction force moment arms: Conceptual considerations and experimental verification	Shinichi Kawamoto
O46-2	Automated generation of patient-specific intervertebral disc FEM models based on CT images	Kati Nispel
O46-3	Backpack carrying: A comparison between marker-based and markerless systems	Jose Heredia-Jimenez
O46-4	Adaptive p-splines for challenging filtering problems in biomechanics	Andrew Pohl
1100-1200	**Oral 47 Prosthetics and orthotics 3** Chair: **Hiroaki Hobara**	**Room 5**
O47-1	Shape optimization of dental implant thread geometry	Andi Isra Mahyuddin
O47-2	Thermal assessment of an ankle-foot orthosis for varied climatic conditions	Ganesh Bapat
O47-3	Gait analysis and energetics of a novel passive dynamic custom foot and ankle orthosis in a population of foot-drop patients	Paolo Caravaggi
O47-4	Simulating prosthesis conditions in cycling: A comparative study	Heloisa Seratiuk Flores
O47-5	3D printed customized insoles: A FEM and gait analysis combined approach	Zimi Sawacha
1100-1224	**Oral 48 Biomedical engineering** Chairs: **Taylor Dick, Haruki Toda**	**Room 7**
O48-1	Biomechanical investigation of a novel plate for posterior tibial plateau fracture with posterior cruciate ligament avulsion fracture	Peter Andreas Timotius
O48-2	Predicting the mechanical properties of atherosclerotic coronary arteries	Ricardo Caballero
O48-3	Mechanical characterization of passive myocardial response at different animal ages in porcine hearts	Nicolas Laita
O48-4	Evaluation of biomechanical effieciency of dual mobility total hip arthroplasty: Multibody dynamic analysis	Jeong Ah Pak
O48-5	Improving prosthetic feet with polymer materials: A study of mechanical properties	Agus Setyo Nugroho
O48-6	Pilot study of cartilage creep and recovery determined with noninvasive magnetic resonance imaging and classical mechanical testing	Bo Eitel Seiferheld
O48-7	Finger palpation on an artery as gaussian space filter	Debadutta Subudhi
1100-1200	**Oral 49 Impact biomechanics 2** Chair: **Hiroki Ozaki**	**Room 8**
O49-1	Deformable headform design choices: An evaluation of brain simulant stiffness influence on intracranial displacements and strain	Sheng Xu
O49-2	The influence of the tertiary bronchi on strain-induced pulmonary injury	MacKenzie Brannen

O49-3	Identification of joint motions affected knee valgus after multi-directional single-legged drop landing by principal component analysis	Takayuki Koike
O49-4	Vinyl sports floor cushioning thickness affects shoe-surface traction in futsal but not mechanically evaluated ankle inversion moment	Filip Gertz Lysdal
O49-5	In vivo investigation of microstructural brain changes following football heading	Hugh McCloskey
1330-1420	**Keynote Lecture 4** Chair: **Wolfgang Potthast**	**Room 1**
KL4	The Mechanics of Running Fast and Jumping High: from small Differences in Ground Force to Big Differences in Performance	Peter Weyand
1430-1600	**Symposium 09 Human Motion Analysis With Wearable Inertial Sensors: Standardizations and Advances** Chairs: **Reed Gurchiek, Kamiar Aminian**	**Room 1**
SY09-1	Deep kinematics: Uncovering human biomechanics with IMUs and deep learning – preliminary result	Yong Kuk Kim
SY09-2	Inertial measurement unit calibration methods for the wrist joint: Which one should I use?	Alessandro Bonfiglio
SY09-3	Three-dimensional scapular tracking using inertial measurement units: A regression-modelling approach	Zhou Fang
SY09-4	Do different methods for mimu-based posturography lead to the same results?	Annamaria Guiotto
SY09-5	Opensim-based estimation of lower body kinematics using magneto-inertial recordings – recovery from ankle fractures and achilles tendon ruptures as a pilot case	Timo Rantalainen
SY09-6	Body segment orientation tracking with IMU: An adaptive robust ekf for dynamic long-duration activities	Hossein Rouhani
SY09-7	Bout duration during out-of-lab walking affects gait kinematics	Mayumi Wagatsuma
SY09-8	ISB recommendations on the assessment and reporting of joint kinematics in human motion analysis applications using IMUs	Reed Gurchiek Kamiar Aminian
1430-1542	**Oral 50 Sport biomechanics 5** Chair: **Ryu Nagahara**	**Room 2**
O50-1	Influence of sport surface properties on utilized traction and lower extremity biomechanics of american football players	John Wannop
O50-2	Exploring the acute neuromuscular effect of accentuated eccentric loading during unconstrained vertical jump with different loading locations on the body	Eric Yung-Sheng Su
O50-3	Dynamic sagittal plane joint loading biomechanics in individuals with ACL reconstruction with and without a history of ankle sprains compared to healthy controls	Yuki Sugimoto
O50-4	Use of a novel mobile application to assess calf muscle function in sport	Hebert-Losier Kim
O50-5	Influence of immediate dry needling therapy for hamstring muscle fatigue on standing balance control	Shih-Wun Hong
O50-6	Contribution to the racket head velocity in the tennis forehand drive between intermediate and high-performance players	Pedro Bruno
1430-1542	**Oral 51 Balance and posture 2** Chairs: **Masahiro Fujimoto, Arata Kimura**	**Room 3**
O51-1	Vsimulators to explore human static and dynamic balance control	Genevieve Williams
O51-2	A model predictive control scheme for human balance recovery in response to a continuous time-varying platform motion	Naser Taleshi
O51-3	Influence of spring-loaded ankle exoskeletons on gastrocnemius fascicle behaviour during balance tasks	Jemima Po
O51-4	A single session treadmill perturbation-based balance training for fall prevention: Efficacy and mechanisms	Deepak Ravi
O51-5	Emulating human postural control adjustment with perturbation using quadratic objective function	Seongwoong Hong
O51-6	Motor performance after treatment of pilocytic astrocytoma in childhood	Fredrik Oehberg
1430-1530	**Oral 52 Running: Biomechanics 2** Chair: **Wouter Hoogkamer**	**Room 4**
O52-1	Accuracy of a 2d camera for obtaining 3D data in running	Iain Hunter
O52-2	Improving estimation accuracy of energy expenditure during running from a single IMU by estimating mechanical power via estimating ground reaction force	Bumjoon Kim
O52-3	Groucho running reveals disparate results between ground reaction force and tibial bone strain: A finite element analysis	Arash Khassetarash
O52-4	Effect of running speed and inclination on biomechanical risk factors for medial tibial stress syndrome	Leon Robertz
O52-5	Influence of walking and running speeds on tibia impact stress	Qichang Mei

1430-1518	**Oral 53 Simulation techniques and applications 2** Chair: **Todd Pataky**	**Room 5**
O53-1	How does the inclusion of glenohumeral joint stability affect the estimates of individual muscle forces during shoulder movements?	Italo Belli
O53-2	The effect of touchdown configuration on top sprinting speed: A simulation study	Nicos Haralabidis
O53-3	Design and simulation of flow field for sinusoidal scaffold using computational fluid dynamics	Theresia Baumgartner
O53-4	Development of a workflow to morph volumetric meshes consistently across a population of pediatric femurs	Yidan Xu
1430-1554	**Oral 54 Artificial intelligence and machine learning 3** Chairs: **Marion Mundt, Daisuke Ichimura**	**Room 7**
O54-1	Physics-based features improve the generalizability of a neural network predicting ground reaction forces	Janelle Kaneda
O54-2	Gait abnormality detection by inertial measurement unit and machine learning	Ferryanto Ferryanto
O54-3	Using IMU to predict the effect of prosthetic alligment on knee moments	Gilmar Fernandes dos Santos
O54-4	The approach chosen for data dimensionality reduction affects the results of running technique clustering	Adrian Rivadulla
O54-5	Conditional generative deep learning in biomechanics: Generating synthetic motion capture datasets by controlling subject anthropometrics	Metin Bicer
O54-6	Gait-based person re-identification across force platform datasets from different countries	Kayne Duncanson
O54-7	Deep learning-based vertical ground reaction force estimation during walking with inertial measurement units of the left wrist and both heels	Yuta Takanobu
1430-1530	**Oral 55 Prosthetics and orthotics 2** Chair: **Steffen Willwacher**	**Room 8**
O55-1	Investigating the effects of transfemoral amputee anatomy on stress and strain distribution in osseointegrated implants using a 3D FE model	Tiereny McGuire
O55-2	Relationship between time since amputation and gait asymmetry in unilateral transfemoral amputees	Takeshi Hara
O55-3	Metabolic cost and musculoskeletal metabolic quantification of walking with an above knee prosthesis simulator	Xavier Bonnet
O55-4	Influence of hip flexion contracture on gait parameters of transfemoral amputees: A preliminary study	Kevin Arribart
O55-5	Bilateral asymmetry of ground reaction forces during running in unilateral transfemoral amputees	Mai Watanabe
1630-1800	**Symposium 10 Ankle injury biomechanics – a 2023 update on injury mechanism, risk factors, and long-term consequences** Chairs: **Filip Gertz Lysdal, Masafumi Terada**	**Room 1**
SY10-1	Debunking the myth - the noncontact lateral ankle sprain is not just the result of a bad landing: A systematic video analysis of 445 injuries	Filip Gertz Lysdal
SY10-2	Fatigue increases risk of lateral ankle sprain injuries i badminton - a biomechanical analysis	Alexis Herbaut
SY10-3	Why friction matters: Zooming in on the shoe-surface interaction of the ankle sprain injury	Filip Gertz Lysdal
SY10-4	Breathing out ankle instability: Addressing impairments in diaphragm function associated with chronic ankle instability	Masafumi Terada
1630-1742	**Oral 56 Sport biomechanics 6** Chair: **Mark Robinson**	**Room 2**
O56-1	The effect of a 6-week intrinsic foot muscle training intervention on static and dynamic balance in team sports players	Matthew Stoner
O56-2	Lumbar and pelvis movement comparison between cross-court and long-line topspin forehand stroke: Based on musculoskeletal model	Yuqi He
O56-3	Influence of release positions on optimal release conditions in basketball	Yuki Inaba
O56-4	The influence of pocket characteristics on lacrosse shot performance	Dean Hay
O56-5	Simulated knee mechanics during a maximal forward braking and backward acceleration in elite athletes	Rodrigo Bonacho Mateus
O56-6	Neuromuscular effect of warm-up on regulation of motor unit properties during isometric torque production tasks	Jiseop Lee
1630-1754	**Oral 57 Locomotion: General 3** Chairs: **Veerle Segers, Keiichiro Hata**	**Room 3**
O57-1	Effects of speed on ground reaction forces during skipping gait	Genki Tokuda
O57-2	Neuromuscular responses to unexpected slips during human walking	India Lindemann
O57-3	The differences in the characteristics of the body part angular momentum in the frontal plane during walking between young and older adults	Kodai Kawase

O57-4	Pendular energy exchange at very slow walking speeds reveal positive work shift from double support to single stance	Timothy Byles-Ho
O57-5	The effect of knee extensor fatigue on metabolic cost in running	Key Nahan
O57-6	The achilles subtendons exhibit distinct loading patterns during walking	Lauren Welte
O57-7	Patellofemoral kinetics walking in maximal, minimal and traditional shoes	JJ Hannigan
1630-1806	**Oral 58 Wireless sensors and wearable devices 2** Chairs: **Kota Takahashi, Takeo Matsubayashi**	**Room 4**
O58-1	How well do machine learning models trained on treadmill walking perform on overground data?	Sailee Sansgiri
O58-2	Timed-up-and-go test segmentation algorithm based on a wearable sensor technology: A technical validation in people with multiple sclerosis	Fabien Masse
O58-3	Detecting the progression of gait impairments in Parkinson's disease using Wi-Fi	Tzu-Yang Weng
O58-4	Capacitive sensing for natural environment rehabilitation monitoring	Owen Pearl
O58-5	Estimating energy expenditure using wearable sensors during indoor and outdoor locomotion	Mohammad Mohammad
O58-6	Validation of the lower limb joint kinematics in the sagittal and frontal planes calculated by a self-developed dual kinect azure sensors system	Hsuan-Lun Lu
O58-7	Changes in foot pressure during downhill walking after using a biofeedback which reduces acceleration	Alexandra Giraldo-Pedroza
O58-8	Automated gait event detection using wearables/ IMU for data acquisition and deep learning for placement classification	Yong Kuk Kim
1630-1742	**Oral 59 Clinical biomechanics 3** Chairs: **Yumna Albertus, Takuya Ibara**	**Room 7**
O59-1	Evaluation of hip joint kinetics in rehabilitation exercises for children with cerebral palsy	Jasper Kwasny
O59-2	Longitudinal changes in kinematics of the lumbopelvic hip complex and their association with the onset of cam deformity: A two-year follow-up of high-risk adolescent elite football players	Dalia Al Otti
O59-3	Validity and reliability of bodiometer mobile app for postural analysis	Nesa Keshavarz Moghadam
O59-4	A machine learning approach to differentiate stable from unstable total knees for data mining	Erica M. Ramirez
O59-5	Engagement of the cruciates and medial meniscus is related to anterior-posterior knee laxity but not cruciate ligament volume	Erin Berube
O59-6	Investigating the influence of different foot positions during the golf swing on the skin-marker-based kinematics after total knee arthroplasty	Nils Horn
1630-1806	**Oral 60 Musculoskeletal modeling 5** Chairs: **Barbara Postolka, Yoko Kunimasa**	**Room 8**
O60-1	Inclusion of distal fibular translations in multi-segmented foot modeling for lateral ankle ligament strains	Renee Alexander
O60-2	Identifying the slack postures of human skeletal muscle across three-dimensional joint	Jun Umehara
O60-3	Easy-to-use matlab software for personalizing opensim neuromusculoskeletal models	Claire V. Hammond
O60-4	Combined statistical shape model can predict lower limb bone shape variation in a paediatric population	Julie Choisne
O60-5	Muscle force estimation based on angle-EMG-force relationship and electromechanical delay	Takuya Mitani
O60-6	Relative energy cost of the gait phases across walking speeds	Israel Luis
O60-7	Towards automatic generation of subject-specific knee joint kinematic models from medical imaging	Beichen Shi
O60-8	Advanced signal processing techniques integrated into a textile-embedded EMG garment for ankle torque estimation in post-stroke individuals	Donatella Simonetti

1810-1940	**Poster 22 Sport biomechanics 3**	2nd Floor, Poster Display #1
P22-01	Relationship of jump performance and ground reaction force variables between young adults and different maturity adolescent soccer players	Takahiro Namiki
P22-02	Quantifying the contralateral repeated bout effect of the triceps surae	Nicole S. Jones
P22-03	Influence from wetsuit on the assessment of biomechanical parameters through imu measurements	Alexander Weiss
P22-04	Effect of motor synergies on posture and performance stability: A comparison of self- and external-triggered shooting in simulated archery	Junkyung Song
P22-05	Muscle activity timing and amplitude in the early acceleration phase of curve sprinting	Benjamin Millot
P22-06	Developing a simulation model considering frictional force during turning in dance	Akiko Imura
P22-07	Comparison of the difference between countermovement and squat jump in trained and untrained adults	Ching-Feng Cheng
P22-08	Get on up; Relating objective hip-hop dance biomechanics to subjective scoring	Joshua Vicente
P22-09	Changes in 5-10m elapse time in kick start of a swimming race at different back plate positionings	Masayuki Umemoto
P22-10	The influence of projectile mass on throw distance	John H Challis
P22-11	Changes in kinematic patterns in response to ball velocity in tennis forehand drive	Yoon-Seok Choi
P22-12	Characteristics of the steps in each section in a tailwind sprint	Koichi Nakayama
P22-13	Effects of strength training targeting medial quadriceps/hamstrings on knee joint biomechanics during single-leg landing	Jiyoung Jeong
P22-14	Effects of wearing a mask on heart rate variability during kendo practice	Minato Kawaguchi
P22-15	Quantification of external work using mechanical crank power with a bicycle ergometer underestimates the net external work exerted by a human	Yuta Yamaguchi
P22-16	Assessment of strain components for kinesiology taping techniques with digital image correlation	Chia-Han Hu
P22-17	Contact force during maximal snatches	Michael Webb
P22-18	How do grip-enhancing agents affect friction between a fingertip and a baseball?	Takeshi Yamaguchi
P22-19	A pilot study on the plantar pressures in females during sprinting on natural grass, 3G and cork surfaces	Jo Reeves
P22-20	Relationship between bilateral asymmetry in lower limb joint biomechanics and jumping height during single-leg countermovement jump	Shota Yamamoto
P22-21	A biomechanical study of uchimata in judo - comparison of different skill levels-	Kazuto Hamaguchi
P22-22	Effects of nordic hamstring exercise on hamstring stiffness, strength, and flexibility	Konstantinos Kaliarntas
P22-23	Effect of the upper limb joints on the control of ball speed in throwing distance control of throw-in	Rintaro Miyake
P22-24	Relationship between ball velocity and kinematics of pelvis and upper torso in female collegiate baseball players	Takuya Sekiguchi
P22-25	Characteristics of leg movements that induce red cards in race walking	Naoki Takahashi
P22-27	A comparison of rotation sequences for shoulder 3D kinematics in the volleyball attack	Kiara Barrett
P22-28	Associations between unilateral drop landing mechanics and diaphragmatic contractility in individuals with recurrent lateral ankle sprains	Shunya Nonoyama
P22-29	Grading of jumping height by quick movement	Yoshiho Muraoka
P22-31	Acceleration comparison between peak height velocities in male youth soccer players	Kavon Bonakdar
P22-32	Electromyographic activity during different phases in the bench press exercise	Dusan Blazek
P22-33	Waltz swing characteristics of the competitive ballroom dance world champion couple	Yasuyuki Yoshida
P22-34	Validity of spring-like behaviour performance during hopping using a smart watch	Atsuki Kageyama
P22-35	Cross-sectional area of hand intrinsic muscles and upper limb length associated with throwing record of female discus throwers	Yukiho Arano
P22-36	Relationship between propulsive force and hip joint motion during eggbeater kick in artistic swimming	Hiroki Hyodo
1810-1940	**Poster 23 Sports and exercise for persons with impairment**	**2nd Floor, Poster Display #1**
P23-01	Development of an adjustable sledge for paralympic cross-country skiing with a particular focus on neurological and physiological improvement of the sitting position	Leonie Hirsch
P23-02	Effects of trunk extension on body and wheelchair centers of gravity during wheelchair propulsion movements	Koichi Kawabata
P23-03	Effect of short-term combined intervention program on erector spinae contractile properties in patients with non-specific chronic low back pain	Hyungwoo Lee
P23-04	Biomechanics of wheelchair propulsion in athletes of wheelchair racing	Mikito Hikosaka
P23-05	Influence of seat pan angle and lower leg stabilizer on lower limb muscles activation during simulated sit-ski	Masashi Naoe

1810-1940	**Poster 24 Orthopaedics: Tendon & ligament**	2nd Floor, Poster Display #1
P24-01	Size dependent transport dynamics in the rat achilles tendon	Jarod Forer
P24-02	Sensitivity analysis of four graft parameters on knee kinematics following pediatric anterior cruciate ligament reconstruction: A linked neuromusculoskeletal-finite element modelling approach	Ayda Karimi Dastgerdi
P24-03	Effects of different carpal tunnel release surgeries on migration patterns of flexor tendons	Hsiao-Feng Chieh
P24-04	Compressive force inhibits excessive volar displacement of the fds tendon in patients after carpal tunnel release surgery	Chien-Ju Lin
1810-1940	**Poster 25 Rehabilitation and neurorehabilitation**	**2nd Floor, Poster Display #1**
P25-01	Assistance of the paretic knee in the sit-to-stand motion of acute stroke survivors prevents their trunk overuse	Hiroki Hanawa
P25-02	Clinical efficacy of 3 different types of digital mirror therapy on motor and daily functions in stroke survivors: A preliminary study	Yu-Wei Hsieh
P25-03	The effect of draw-in maneuver on knee joint function and thoracic kyphosis angle in patients with osteoarthritis of the knee	Yasuha Murakami
P25-04	Validity and reliability of mobile applications in physical therapy: A systematic review	Ibiza Gonzaga
P25-05	Change in ankle dorsiflexion motion during cycling generated by ankle assist ergometer	Keisuke Hirata
P25-06	Virtual reality balance training improves balance in patients with lumbar spinal stenosis: A pilot study	Po Jung Chen
P25-07	Effect of increasing weight-bearing during the seat-off task with sit-to-stand training augmented feedback and epidural electrical stimulation in people with incomplete spinal cord injury: A preliminary study	Tzu-Ming Chang
P25-08	Acute effects of dynamic stretching on muscle contractile properties of ankle plantar- and dorsi- flexors	Shuya Fukuoka
P25-09	Characteristics of trunk muscle activity in children with cerebral palsy during horseback riding -multiresolution analysis of semg-	Kenichi Kaneko
P25-10	Statistical shape modelling and reconstruction of subject-specific foot soles for two-point discrimination neuromuscular sensory tests	Yun-Chen Hsu
P25-11	A scoping review on effects of exercise training on hand dexterity in patients with parkinson	Ying-Ming Liu
1810-1940	**Poster 26 Rehabilitation technology: Biorobotics and exoskeletons**	**2nd Floor, Poster Display #1**
P26-01	Towards crutch-less exoskeleton-assisted geriatric sit-to-stand motions -- an experimental and optimization-based study	Jan Lau
P26-02	A usability evaluation of the powered-wheelchair for severely disabled in Korea	Eung-Pyo Hong
P26-03	Development of autonomous driving sensor system for wheelchair application	Yongcheol Kim
P26-04	Performance and usability evaluation of an intelligent wheelchair	Ki-Tae Nam
P26-05	A new coupling mechanics model for lower limb exoskeletons to account for initial surface forces	Christian Mele
1810-1940	**Poster 27 Simulation techniques and applications**	**2nd Floor, Poster Display #1**
P27-01	Biomechanical evaluation of difference between customized angled abutments and commercial angled abutment for dental implant in maxillary incisor region	Heng Li Huang

Summary

The understanding of foot and ankle biomechanics is flourishing as new technology provides more detailed information about in vivo foot morphology and motion. The recent availability of cone beam CT in orthopaedics now enables 3D weight bearing measurements for the foot and ankle. Additionally, biplane fluoroscopy now provides the ability to measure dynamic bone motion. While there is increased research and clinical activity using these technologies, there are no commonly accepted 3D definition of foot bones axes and orientations or defined methodologies to calculate angulations and relationships between the bones. Despite this, a host of commercial software are being produced without any specific reference guidelines. This limits comparison of studies across different research centers. There is a growing interest in the orthopaedic and biomechanics communities to develop standardized terminologies, 3D orientation and measurements that can be reliably applied and generalized, ensuring consistency across international clinicians whatever the platform used.

A task force was established with representatives from three international societies (International Society of Biomechanics, Orthopaedic Research Society, and International Weightbearing CT Society). It consisted of orthopaedic surgeons, radiologists, and engineers with significant clinical and research expertise in foot and ankle. The task force aimed to establish accepted guidelines for these standards based on relevant measures of importance, a review of the literature, and when appropriate, develop new methodologies. It also aimed to evaluate current methodologies across multiple foot pathologies.

To achieve universal and disseminated acceptance for foot and ankle terminologies, 3D bone spatial orientation and tarsal inter-bone relationships, the standards defined by a group of experts on the foot and ankle and biomechanics environment must be understandable, interpretable, and most importantly reproducible. Reference definitions can be highly variable based on the shape of each individual tarsal bone, which can vary based on foot morphotype, age, deformity or pathology. Principal Componant Analysis is advantageous because it does not require user definitions however, may not represent the biomechanical joint axes. Identification of anatomic landmarks and/or fitting geometric primitives allow for better representation of bone morphology variations however it is vital that methods established be automation-compatible because one of the main objectives of clinicians is to improve accessibility through time-efficiency, in analyzing 3D datasets.

This symposium will present a summary of this group’s ongoing and future work to evaluate existing and new proposed references.

STANDARDIZING TERMINOLOGY, 3D SPATIAL ORIENTATION, AND RELATIVE POSITIONING OF THE FOOT AND ANKLE BONES: AN EXPERT CONSENSUS TASK FORCE

INTRODUCTION

The understanding of foot and ankle biomechanics is becoming richer as new technology provides more detailed information about in vivo foot morphology and motion. The recent availability of cone beam CT in orthopaedics now enables 3D weight bearing measurements for the foot and ankle. Additionally, biplane fluoroscopy now provides the ability to measure dynamic bone motion. While there is increased research and clinical activity using these technologies, there are no commonly accepted 3D definition of tarsal bones axes and orientations or defined methodologies for calculation angulations and relationship between the bones [1]. Despite this, a host of commercial software are being produced without any specific guidelines. There is a growing interest in the orthopaedic and biomechanics communities to develop standardized terminologies, 3D orientation and measurements that can be reliably applied and generalized, ensuring consistency across international clinicians whatever the platform used. The goals of this group are to provide recommendations on terminologies, 3D orientation, and inter-bone measurements backed by evidence-based information that is clinically relevant. We also aim to provide a toolkit what will provide the agreed upon methodologies to to the foot and ankle community.

METHODS

A task force was established with representatives from three international societies. It consisted of orthopaedic surgeons and engineers with significant clinical and research expertise in foot and ankle. The task force aimed to establish important criteria for these standards, to determine relevant measures of importance, to review the literature, and when appropriate, develop new methodologies [2-4].

RESULTS AND DISCUSSION

Relevant criteria established included: desired reliable automatic refence frame generation, low processing times, relevant joint motion, and ability to accommodate various pathologies. A literature review showed methodologies in use include identification of specific anatomical landmarks, fitting of geometric primitives to surface anatomy, and principal component analysis (PCA). Many published methods in the literature lacked automated methodology.

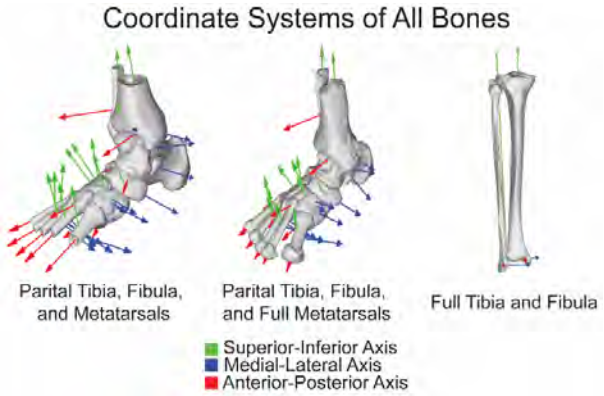

Figure 1 The anatomical coordinate system applied to all fourteen bones individually, with green signifying the superior-inferior axis, blue signifying the medial-lateral axis, and red signifying the anterior-posterior axis for full and partial bones

CONCLUSIONS

To achieve universal and disseminated acceptance for foot and ankle terminologies, 3D bone spatial orientation and tarsal inter-bone relationships, the standards defined by a group of experts on the foot and ankle and biomechanics environment must be understandable, interpretable, and most importantly reproducible. Reference definitions can be highly variable based on the shape of each individual tarsal bone, which can vary based on foot morphotype, age, deformity or pathology. PCA is advantageous because it does not require user definitions however, may not represent the biomechanical joint axes. Identification of anatomic landmarks and/or fitting geometric primitives allow for better representation of bone morphology variations however it is vital that methods established be automation-compatible because one of the main objectives of clinicians is to improve accessability in analyzing 3D datasets. Ongoing and future work within the task force will aim to evaluate existing and new proposed references in the light of available clinical data including various foot pathologies to establish a scientifically grounded consensus.

INTRODUCTION

Anatomical coordinate systems (ACS) are necessary for analyzing bone position and orientation during static and dynamic movements. Unfortunately, there is no agreed-upon automatic definition for individual foot and ankle bones [1]. Many primary foot and ankle coordinate systems currently used require manual inputs of bony landmarks, are not practical in clinical settings, depend on other bones, and do not analyze pathologies [2]. This study aimed to develop an automatic ACS definition for the fourteen foot and ankle bones individually and analyze the ACS across different segmentation processes and throughout multiple populations demonstrating different deformities.

METHODS

A toolbox was developed to calculate these ACSs automatically in MATLAB (R2022b, MathWorks, Natick, MA, USA). This study used twenty-four models: eight asymptomatic, eight with PCFD, and eight with a cavovarus deformity. These twenty-four models were segmented automatically with DISIOR (Bonelogic Ortho Foot and Ankle 2.1, Helsinki, Finland) and manually cleaned up using Mimics (v22.0, Materialise, Leuven, Belgium), referred to as the DISIOR and Mimics models henceforth. The only required input for the toolbox was the bone model. The toolbox aligns the input and assigns it a coordinate system, as seen in Figure 1. To determine the consistency of this toolbox, each population was analyzed separately. A mean axis was determined for all three axes for each population, and the angle difference between an individual's coordinate system axes and the mean axes was calculated. A similar process of determining angle differences between the DISIOR and Mimics models was performed.

RESULTS AND DISCUSSION

The angle differences between the individual coordinate system axis and the mean axis for all fourteen bones combined are reported in Table 1. The maximum angle difference from the mean is from one of the medial-lateral cavovarus cuboid axes with a difference of 8.79°. The minimum angle difference from the mean is from one of the anterior-posterior PCFD fourth metatarsal axes with a difference of 0.01°. Additionally, the angle differences between the DISIOR and Mimics models are reported in Table 1. The maximum angle difference is from the medial-lateral second metatarsal axes with a difference of 6.02°. The minimum angle difference is from the anterior-posterior second metatarsal axes with a difference of 0.22°.

	DISIOR vs. MIMICS	Mean vs. Individual
Healthy	1.69° ± 0.97°	2.19° ± 0.63°
PCFD	2.21° ± 1.37°	2.33° ± 0.96°
Cavovarus	1.69° ± 0.88°	2.41° ± 0.79°

Table 1: Angle difference between the DISIOR and Mimics models and angle differences between individual axes compared to the mean axes.

CONCLUSIONS

This study aimed to develop a toolbox to automatically calculate an ACS for fourteen bones in the foot and ankle. This definition requires no user input, which eliminates errors in repeatability. Additionally, this toolbox is not drastically affected by pathological morphologies or segmentation processes, as seen by the minimal angle variation in Table 1. Primary future work of this methodology includes creating a statistical shape model to determine mean bones for the initial alignment step and expanding the analysis using kinematic data to evaluate crosstalk.

INTRODUCTION

Previous *in vivo* single -plane videoradiography (BVR) work reported that the calcaneus, navicular, and cuboid's (tarsal bones) motion relative to the talus occurs about the same axis of rotation [1]. Efforts have been made to quantify this axis using morphological features [2,3]. However, given the complexity of the articular geometry, muscle insertions, and ligament geometry of the tarsal bones, we questioned whether the axis based on talus articular morphology is sufficient to capture tarsal bone rotation. Here, we took advantage of the large range of motion during single leg hopping to compute the helical axis of motion (HAM) from BVR measurements. We hypothesized that the tarsal bones would rotate relative to the talus about the morphology-based axis. Secondarily, we compared the range of motion among the joints in the tarsal bone complex.

METHODS

Computed tomography scans (0.356mm x 0.356mm x 0.625mm) were obtained from nine asymptomatic feet (5 females, mean ± std height 171 ± 11cm, body mass 71 ± 15kg). We used BVR (125 Hz) to capture the motion of the talus, calcaneus, cuboid, and navicular during single leg hopping (156 bpm). All bones were tracked with Autoscoper (Brown University) using an established approach [4]. We computed the HAM for the calcaneus, navicular, and cuboid relative to the talus from landing to foot flat and from foot flat to push-off. All HAMs were resolved in the morphology-based coordinate system, whose z-axis is defined by the line joining the centroid of two spheres fit to the calcaneus and navicular facets on the talus, designed to capture the subtalar axis (Figure 1) [2,3]. We expected most tarsal bone rotation to occur about this axis. Differences for all metrics between landing and push-off were tested via paired t-tests. Differences in orientation between the morphological axis and z-direction of each bone's HAM were investigated via boxplots (not shown here). To compare each joint's range of motion, paired t-tests were performed. Non-parametric tests and Bonferroni corrections were applied when required.

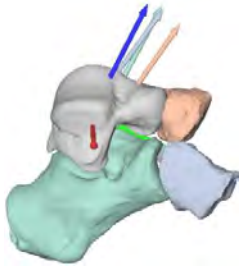

Figure 1 Color-coded HAM matching the bones, and the morphology-based coordinate system; blue indicates the morphological axis (representative participant).

RESULTS AND DISCUSSION

There were no differences between the tested variables regarding landing and push-off ($p \geq 0.04$). Most motion occurred about the morphological axis (Table 1), confirming that navicular, cuboid, and calcaneus motion is primarily driven by the articular morphology of the talus. This may imply that changes in the shape of the talonavicular or subtalar facets disturbs the normal uni-axial function of the tarsal complex. The cuboid rotated 89% and the calcaneus rotated 66% ($p \leq 0.008$) relative to the talus compared to talonavicular motion. This indicates the great mobility of the talonavicular and talocuboid joint in comparison to the more restricted subtalar joint. These findings strengthen previous results [1,5] of the foot being highly mobile during ground contact, exhibiting joint rotations about a single axis without "midtarsal locking".

CONCLUSIONS

Our data shows that most motion of the tarsal bones occurs about a morphological axis based on articular geometry of the talus, suggesting a strong influence of joint facet shapes on tarsal kinematics.

INTRODUCTION

The foot complex in the elderly and its age-related degenerative processes need careful attention to prevent and treat major disorders and disabilities [1]. Current computed tomography (CT) allows three -dimensional (3D) analysis with varying levels of accuracy depending on the machine and settings used, but generally in the absence of physiological load on lower limb, including the foot. Patients are in fact supine within the CT bore, which greatly limits realistic reconstruction of joint relationships and deformities of normally loaded structures. Weight-bearing CT (WBCT) devices based on cone-beam technology have recently been developed for clinical evaluations of human limbs. These allow patient scans in standing posture and thus also foot scans finally in loading conditions [2]. These also allow very accurate 3D morphological reconstructions with minimal alterations [3] via reduced exposure doses. WBCT in foot assessments, especially in the elderly, can thus provide access to important measurements, like plantar tissue thickness, bone inclinations and identification of vascular calcifications, all of which are subject to age-related alterations. The aim of this study is to perform these measurements in three different populations and detect any correlations with age.

METHODS

Twenty-one flatfeet, seventeen diabetic feet, and four normal feet underwent WBCT (OnSight 3D Extremity System, Carestream, Rochester, NY-USA) scans on single-leg up-right posture. DICOM slicing of 0.26 mm and high-resolution image size of 884x884x960 voxels were set. 3D models of the distal tibia and all foot bones were reconstructed through semi-automatic segmentation with a state-of-the-art software (Mimics Innovation Suite - MIS, Materialise, Leuven, Belgium) based on initial HU masks. The same segmentation software was also used to reconstruct possible vascular calcifications in 3D and to quantify their volumes with an ad hoc software function. Principal Component Analysis was used to define anatomical reference systems on all 3D bone models using recent proposals [4], from which absolute and relative orientations and bone-to-ground heights (Hg) were calculated.

RESULTS AND DISCUSSION

In the flatfoot population, medial longitudinal arch collapse, talus supination, and 1st metatarsophalangeal joint and calcaneal valgism were revealed by calculated bone orientations; the 2nd metatarsal head was found correlated with age (R^2=0.23; p=0.04). In the diabetic population (Figure 1), the plantar tissue was found to thin with age, with significant ($p<0.05$) correlations for the 4th (R^2=0.26) and 5th metatarsal (R^2=0.28) heads. The diabetic subject most affected by vascular calcifications (volume 3920 mm^3) was the oldest and the one with the longest disease course.

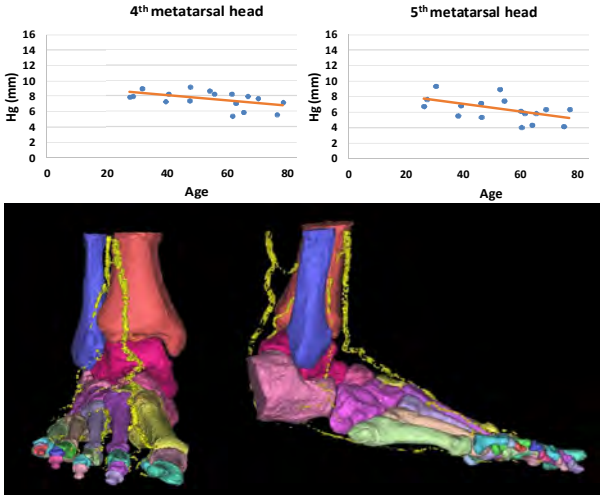

Figure 1 From the diabetic foot population: correlations between 4th and 5th metatarsal and age (top). Frontal and lateral views of 3D bones, with vascular calcifications in yellow (bottom).

CONCLUSIONS

These preliminary findings demonstrate the potential of WBCT for 3D foot measurements. Very accurate instrumental analysis can now be performed to monitor the progression of skeletal changes and vascular disorders over time, thus predicting, and possibly preventing, major problems, like instability, ulceration, cartilage degeneration, bone deformities and pain.

Summary

The goal of the ISB Technical Group in Motor Control is to provide a forum to highlight and foster the increased interest in scientific work that bridges the fields of Motor Control and Biomechanics. The Motor Control Technical Group was established as a Seed Group affiliated with the International Society of Biomechanics (ISB) at the XXIV Congress of ISB in Natal (Brazil), in 2013. It was recognized as a Working Group of ISB at the XXV Congress of ISB in Glasgow in 2015; and as a Technical Group of ISB at the 2019 ISB/ASB Congress in Calgary, Canada.

This 90 minute symposium includes a 30 min keynote talk and 6 oral presentations selected from submitted abstracts to ISB/JSB 2023. This will cover advancements in the understanding of human movement through an integrated approach that includes both the study of the organization of the nervous system and the biomechanical properties of the musculoskeletal system. This symposium will highlight novel scientific work that bridges elements of motor control and biomechanics to facilitate and encourage an integrated approach to the study of human movement. This symposium will include talks on the development of musculoskeletal models of muscle function, the interaction between muscle activity and cerebral dynamics in the brain, coordination and modelling of impairment, and the modulation of mechanical and reflexive responses to perturbations.

Executive Board Members: Professor Jim Richards, University of Central Lancashire, UK; Professor Walter Herzog, University of Calgary, Canada; Associate Professor Matt S. Stock, University of Central Florida, USA.
Advisors: Dr Paola Contessa, Padua University Hospital, Italy; Professor Patria Hume, Auckland University of Technology, New Zealand; Professor Jean-Benoit Morin, Université Jean Monnet in Saint-Etienne, France; Dr Archit Navandar, Aspire Academy, Qatar.

Scheduling
11:00 – 11:05 Introduction to Motor Control Technical Group: Professor Walter Herzog
11:05 – 11:25 Keynote
11:25 – 11:30 Discussion
6 oral presentations 8 mins each including question time.

Interaction analysis between sEMG signals and cerebral dynamics in brain regions during isometric contraction of elbow joint

INTRODUCTION

The motor function of the human body requires constant interaction between the brain and muscles. Functional near-infrared spectroscopy (fNIRS) can quantitatively analyse changes in HbO_2 and HbR concentrations in brain [1]. Surface electromyography (sEMG) is a complex bioelectrical signal that is directly related to body motor control [2].In this study, correlation analysis was conducted around cerebral cortex blood oxygen signals and the fuzzy approximate entropy (fApEn) of sEMG signals. We investigated the interaction between brain region activation and peripheral muscle contractions during elbow isometric motor tasks in healthy adults under different conditions.

METHODS

Twenty-one healthy subjects (12 males, 9 females) were recruited in this study. Subjects completed elbow isometric contractions with visual feedback adjustment. Subjects were required to complete both 20% maximum voluntary contraction (MVC) and 80% MVC conditions in each trial. Each trial consisted of a three-minute relaxation phase, a 15-second task phase and a 30-second rest phase. In this study, a total of 30 channels were used to cover the left and right prefrontal cortex (LPFC, RPFC), left and right motor cortex (LMC, RMC), and left and right occipital lobe (LOL, ROL). Then, circular silver-silver chloride (Ag-AgCl) electrodes were attached to the abdominals of the subjects' biceps (BIC) and triceps (TRI) muscles. The sEMG signal was recorded by a dual channel custom EMG amplifier and sampled by a data converter at a resolution of 1000Hz.

We analysed activation intensity of each brain region and sEMG signal eigenvalues under different motor tasks. Pearson correlation analysis was used to test the correlation between the activation intensity of each brain region and the fApEn of EMG signals under different task conditions.

RESULTS AND DISCUSSION

The results of fNIRS study showed that the activation of all brain regions was significantly enhanced under the condition of higher force during motor tasks, especially the contralateral motor cortex. Meanwhile, the fApEn of BIC and TRI were compared under different conditions, and the fApEn under the condition of more force were higher than those under the condition of less force ($P < 0.001$). As the strength level increases, more muscles are required to maintain the strength output, resulting in a significant increase in the complexity of sEMG signals and muscle coordination. The results showed a significant positive correlation between fApEn and HbO_2 in the contralateral motor cortex ($r = 0.594$, $p < 0.01$) (Fig.1). It showed that fApEn of BIC were significantly positively correlated with changes in HbO_2 in the contralateral motor cortex, suggesting correlation between the central nervous system and peripheral muscle contraction when performing motor tasks.

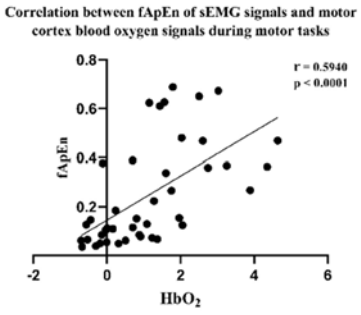

Figure 1 Correlation between fApEn of sEMG signals and motor cortex blood oxygen signals during motor tasks in healthy adults under different conditions.

CONCLUSIONS

In this study, we examined the correlation between sEMG signals and the intensity of activation in brain regions during motor tasks. We found that in motor tasks, the higher the force intensity, the more muscle motor units are involved in the motor task, and the higher the complexity of sEMG signals. At the same time, as the complexity of the motor task increased, the degree of activation of the corresponding brain regions increased. This finding provides evidence for further clinical rehabilitation of patients with impaired motor function.

INTRODUCTION

Early diagnosis of declining cognitive abilities in old age is important, since modifying risk factors may delay the onset of dementia [1]. Abnormal cognitive decline is currently diagnosed using either cognitive tests or objective but complex and expensive screening methods, such as brain imaging or blood-based biomarkers. Therefore, identifying reliable, sensitive, and objective low-cost markers is of great interest. We therefore investigated a simple foot-eye coordination test and its benefit for predicting mild cognitive impairment (MCI), a possible pre-stage of dementia.

METHODS

222 participants ≥ 80 years performed a cognitive test (MoCA, Montreal Cognitive Assessment) based on which they were stratified into two groups using the recommended MoCA-cutoff of MCI < 26: Cognitive healthy individuals (**CHI**: n=162, 82.3 (2.2) years, male/female: 75/87, MoCA score: 27.2 (1.6)) and **MCI** (n=59, 82.3 (2.2) years, male/female: 38/21, MoCA: 22.4 (1.4)). In addition, they performed a foot-eye coordination task, in which they rotated a foot pedal to follow a 0.15 Hz sinusoidal target curve presented on a screen. The difference between the target and the actual movement curve was quantified using Sample Entropy (SampEn) with parameters m=2 and r=0.3 [2]. Low SampEn values indicate that the signal is regular and predictable, while high values indicate greater complexity or randomness.
To quantify the added value of SampEn, two binary logistic regression models ('A', 'B') were fit: **'A'** models the probability of MCI using predictor variables age and sex. **'B'** is equal to model 'A' plus SampEn. Age and SampEn were modelled using restricted cubic splines. The added value of SampEn was quantified using the Fraction of New Information (FNI) [4]: FNI=1 - (LR_A/LR_B), where LR is a likelihood ratio chi-square test. The internal validity of the model was evaluated using overfitting-corrected estimates of the mean squared difference between the predicted probability and the actual outcome (MSE) and Nagelkerke's pseudo-R^2.

RESULTS AND DISCUSSION

The results indicate that SampEn adds diagnostic value (Figure 1). FNI from SampEn was 0.57, which represents a substantial gain in information regarding MCI status.

Table 1: Results for both statistical models.

	LR X^2	pseudo-R^2	MSE
Model 'A'	9.85	0.02	0.2
Model 'B'	22.9	0.07	0.19

The performance of the model, however, was poor, as evidenced by the high MSE and low pseudo-R^2 values (Table 1). This was caused largely by the simplicity of the baseline model, which predicts the complex outcome variable using only two basic variables. Therefore, more powerful predictor variables should be collected in future studies, e.g., genetic, lifestyle, or clinical variables. In addition, uncertainty is introduced by the MoCA scores. [5] estimate the random variation of MoCA scores across repeated tests to ±4 points, resulting in a substantial risk of assigning individuals to the wrong group. We generally recommend moving away from dichotomization toward modeling cognitive scores as ordered categorical responses to use the full information in the data.

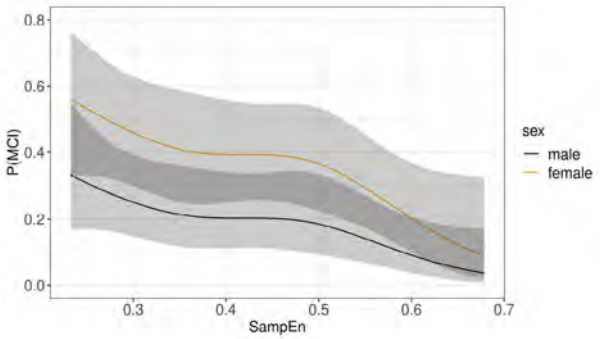

Figure 1 Predicted probability of MCI as a function of SampEn and sex for an 82 year old individual.

CONCLUSIONS

SampEn provides additional value for the prediction of cognitive status, but the performance of the prediction model must be improved to be able to assess the actual benefit of the new parameter.

REFLEX MODULATION DURING GAIT WITH MECHANICAL PERTURBATIONS

INTRODUCTION

Reflexes play an important role in the control and stability of human walking. H-reflex studies, which involve a controlled electrical stimulation of the muscle spindle afferents, have shown that reflexes are modulated through the gait cycle [1]. Direct mechanical perturbation with an exoskeleton showed quadriceps stretch reflex modulation between stance and swing phase [2], but is technically challenging and not clinically applicable. Treadmill-induced mechanical perturbations allow for reflexes to be observed in a more natural situation [3]. Potential clinical applications are the diagnosis of abnormal reflexes and the development of bio-inspired control systems for exoskeletons and prostheses. The aim of this study is to examine the normal reflex responses in eight lower extremity muscles, and how these are modulated through the stance phase of gait.

METHODS

Ten participants each walked for 30 minutes (six 5-minute trials) on an instrumented treadmill at a speed of 1.2 m/s. Each gait cycle had a 17% probability of being perturbed. The perturbations consisted of an increase of belt speed (by 0.75 m/s for 50 ms), delivered with equal probability at 10%, 20%, 30%, 40%, 50%, 60%, 70%, or 80% of the stance phase. Data were recorded using motion capture with 25 markers and electromyography (EMG) from the tibialis anterior (TA), soleus (SOL), lateral gastrocnemius (LG), rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), and gluteus maximus (GM). EMG signals were bandpass filtered, rectified, and separately ensemble-averaged for the unperturbed gait cycles and the perturbed gait cycles from each type of perturbation. Reflex responses were determined by subtracting the EMG envelope of the unperturbed gait from the EMG envelope for each perturbation type. A single-factor ANOVA with repeated measures was performed to test for the effect of perturbation time on the peak magnitude of the reflex response.

RESULTS AND DISCUSSION

For each of the 8 types of perturbation, 20-30 gait cycles were recorded, which was sufficient to obtain clear ensemble averages. The remaining gait cycles (more than 1000) were not perturbed. For most muscles, the ensemble-averaged EMG envelopes of the perturbed gait cycles showed a noticeable difference compared to the unperturbed gait cycles. SOL, LG, VL, and VM (Figure 1) responded immediately following a joint angle change induced by the perturbation, suggesting a stretch reflex mechanism. Other muscles had a more delayed response, suggesting an indirect response to an altered gait cycle.

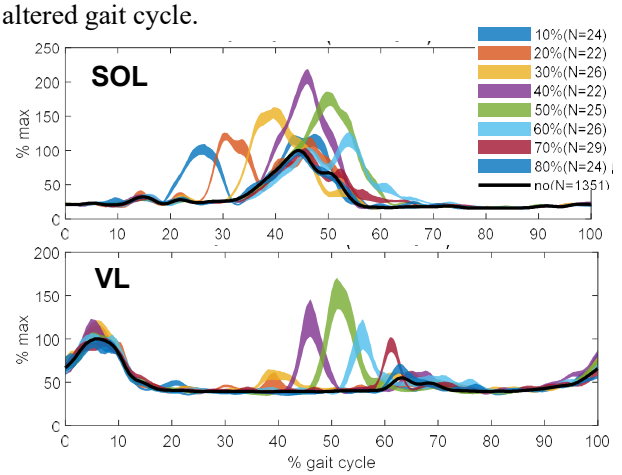

Figure 1 Normalized EMG of the Soleus (top) and Vastus Lateralis (bottom) in one participant during normal walking (black) and during perturbations starting at 10% to 80% of the stance phase.

Statistically significant effects of perturbation time were found in TA, LG, SOL, RF, VM, and BF. The results appear to show that the calf muscles have large responses during most perturbation types, indicating that ankle stabilization is important throughout the stance phase. The quadriceps and hamstring muscles, important in knee and hip stabilization, have stronger reflex responses later in the stance phase.

CONCLUSIONS

We conclude that mechanically induced reflexes are modulated during the stance phase. We suggest that control systems for prostheses and exoskeletons should be designed with similar modulation, i.e., time-varying feedback gains. Further work will be directed at determining control laws that explain the observed EMG responses.

EMBEDDING THE CONTROL OF BALANCE INTO THE MUSCLE COORDINATION FOR WALKING IS ASSOCIATED WITH BETTER WALKING FUNCTION.

Jessica L. Allen
Department of Mechanical and Aerospace Engineering, University of Florida, Gainesville, FL, USA.
Email: jessal@ufl.edu

INTRODUCTION

Maintaining balance is critical for successful walking and converging evidence suggests that the neuromuscular control of walking and balance may share common structure. For example, several studies using motor module (a.k.a. muscle synergy) analysis have demonstrated that young adults recruit balance-specific motor modules during walking [1,2]. Whether recruiting balance-specific modules during walking is important for walking function is unknown but may have important implications for gait rehabilitation. This study tested the hypothesis that recruiting fewer balance-specific motor modules during walking would be associated with worse walking function.

METHODS

Electromyography was recorded from trunk and leg muscles while walking at preferred speed and during a standing reactive balance task in 9 chronic stroke survivors (57±12.7 years old, 46.3±23.1 months post-stroke), 8 neurotypical older adults (62±6.6 years old), and 20 young adults (21.9±2.8 years old). Muscle coordination was quantified using motor modules identified with nonnegative matrix factorization [2]. Motor module number in each behaviour was chosen such that at least 90% of the variability in muscle activity was accounted for. The number of balance-specific motor modules recruited during walking was identified using Pearson's correlations [1,2]. The relationship between module number and three metrics of walking performance were analysed: preferred walking speed (all groups, where higher values are better), range of frontal-plane whole-body angular momentum during walking (WBAM; stroke and older adults only, where lower values are better [3]) and distance walked on a narrow balance beam (young adults only, where higher values are better).

RESULTS AND DISCUSSION

In support of the study hypothesis, recruiting balance-specific motor modules during walking was associated with walking function (Fig. 1). In the stroke and older adult cohorts, the number of balance-specific modules recruited during walking was significantly associated with walking speed (Fig. 1A; r = 0.59, p<0.01) and frontal plane WBAM (r = -0.58, p=0.02). Or in other words, those individuals who walked at slower speeds and with larger range of frontal-plane WBAM recruited fewer balance-specific modules during walking. Moreover, neither walking speed or WBAM were related to the number of modules identified in walking alone (r = -0.01, r = -0.04), providing support that embedding the control of balance into the muscle coordination for walking is important.

In the young adult cohort, the number of balance-specific modules recruited during walking was significantly associated with distance walked on the balance beam (Fig. 1B; r = 0.45, p=0.02). Or in other words, those young adults who could walk farther on the beam recruited more balance-specific modules during walking. Moreover, such a relationship only emerged when balance was specifically challenged in the beam-walking task (r=0.09, p=0.35 for walking speed), providing support that this may reflect a neuromuscular strategy for the control of walking balance.

CONCLUSIONS

This study identified a positive relationship between walking function and recruiting balance-specific motor modules during walking. That such a relationship was found in both neurologically impaired and intact individuals suggests that this may reflect a general neuromuscular strategy contributing to the maintenance of balance while walking. As such, it may be an effective target for gait rehabilitation.

INTRODUCTION

Physics-based computer simulations that can predict the effect of treatments (e.g., bony and soft tissue correction, ankle-foot-orthoses) on gait in children with cerebral palsy (CP) have the potential to improve the clinical decision-making. For that, an important challenge is to accurately model patient-specific non-selective muscle control. Muscle synergies, which are groups of muscles activated in a fixed ratio (described by synergy weights) by a single input signal, can be used to describe the ability to selectively control muscles. Children with CP present fewer synergies [1], which are more variable [2], than typically developing individuals. Recently, it has been shown that reducing the number of synergies in musculoskeletal simulations had a minor effect on gait kinematics [3]. Therefore, we expect that capturing the effects of impaired muscle control on individual gait patterns will require imposing not only a customised number of synergies but also personalised synergy weights.

METHODS

We predicted gait [3] based on a musculoskeletal model scaled to the anthropometry of a healthy adult. We imposed a speed of 1.33m/s. We imposed the number of synergies to simulate healthy and impaired control. A healthy control strategy was simulated using five synergies per leg, whereas an impaired control strategy was represented with asymmetric and/or fewer synergies. We also explored the influence of imposing patient-specific synergy weights (co-activation patterns) obtained from data of two children with diplegic CP with low selectivity at the left ankle on a clinical scale. Patient-specific synergy weights were consistent across different activities within patients but varied between patients. The first child (CP1) had increased knee flexion at initial contact, while the second child (CP2) walked slowly with reduced motion in the knee and ankle during stance (Fig. 1b).

RESULTS AND DISCUSSION

We found that synergy-based control could produce a healthy walking pattern (Fig. 1a). Moreover, the predicted kinematics and muscle activation patterns remained almost unchanged when a reduced number of synergies (e.g. four or three) were imposed, even if the number of synergies was asymmetric (e.g. five right, three left). Finally, imposing patient-specific weights resulted in different knee kinematics for the two sets of weights. When imposing synergy weights as well as gait speed from CP2, the simulated knee pattern resembled experimental data (Fig. 1b). This suggests that impaired selective control contributed to this gait deficit. We did not expect our simulations to capture all the deficits in the gait pattern because we did not model musculoskeletal impairments whereas these were present in both children. Simulated muscle activations patterns were different when imposing CP1 and CP2 weights and resembled measured EMG.

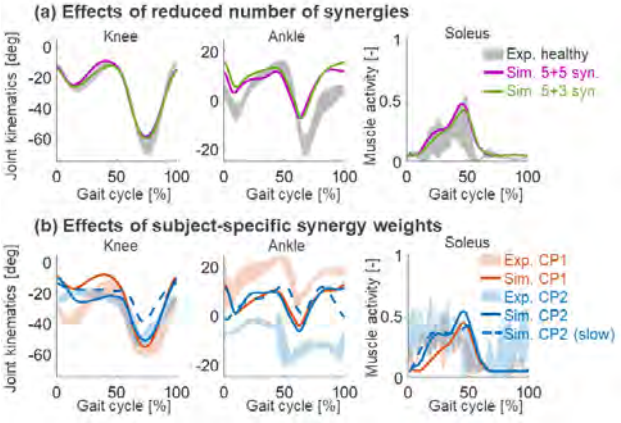

Fig. 1: Experimental (Exp.) and simulated (Sim.) kinematics and muscle activity (most impaired side of children with CP).

CONCLUSIONS

Muscle co-activation patterns derived from synergies might capture non-selective muscle control in children with CP and offer a way to include for motor control deficits in our current simulation workflow [3]. Accounting for motor control deficits might be crucial to achieve accurate gait predictions.

PRE-PROGRAMMED HAMSTRING ACTIVATION DURING SIDECUTTING IS ASSOCIATED WITH REFLEXIVE RESPONSE DURING A SINGLE-LEGGED PERTUBATION TEST

INTRODUCTION

Increased knee joint stiffness is required to reduce injury risk in demanding sports situations like sidecutting or landing. Improving knee joint stiffness may be obtained through both preparatory and reflexive responses that are mediated by proprioceptive feed-forward and feedback mechanisms, respectively [1]. Previous studies have shown that an optimal pre-programmed activation of the medial hamstring (i.e. semitendinosus (ST)) during sidecutting is important to reduce risk of knee injuries [2]. To further explore the relation between proprioceptive reflexive and pre-programmed activation in injury risk situations, the aim of this pilot study was to investigate, if the ST muscle activity response obtained during a new knee joint pertubation test could explain the level of ST activity during sports movements with various demands of knee joint stability.

METHODS

Fourteen elite-level female handball players were recruited (age:18-30). All performed a knee perturbation test (KPT) standing with the dominant foot on a sliding surface keeping the shank near vertical and a knee flexion of 30 degrees and the other foot supported on a 40 cm box (see figure 1). Subjects would hold this position and look straight ahead, and the test leader would quickly pull the sliding surface 5-9 cm anteriorly for 5 trials and thereafter 5 trials of a lateral pull perturbation. The test was performed in a biomechanical lab. The velocity and distance of the anterior movement was measured using 3D recordings of a reflective marker on the ankle, and muscle activity of the ST was recorded simultaneously using EMG (Cometa, IT). Also, the subjects performed a dynamic horizontal single-legged landing on the dominant leg (SLL) with some demand of knee joint stiffness and a handball specific sidecutting movement (SC) requiring high knee joint stiffness. EMG data was high-pass filtered with a cut-off of 20 Hz and a RMS filtered with window of 30 ms and 29 ms overlap. Subsequently, EMG data was normalised to the maximal EMG activity obtained during maximal isometric contractions. The peak ST activity recorded during the first 150 ms after the perturbation was calculated for the KPT (figure 1), and the mean activity during the last 50 ms prior to landing during SC and SLL was collected [1]. Linear regression analysis was used to test to what extent ST activity during KPT (independent parameter) could explain sports specific ST pre-landing activity (dependent parameter). The test protocol was approved by the local ethics committee.

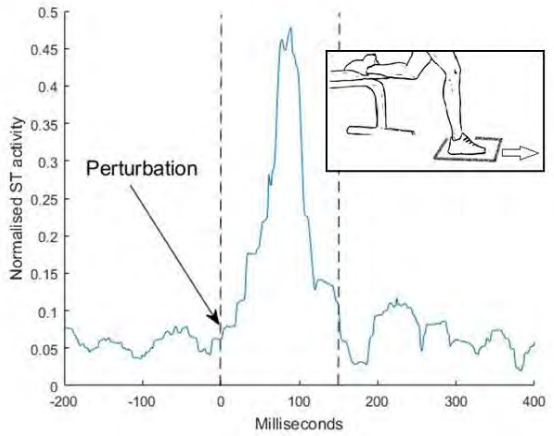

Figure 1 Representative trial of filtered, normalised ST activity for the anterior KPT. Vertical dashed lines indicate the 150 ms period after perturbation where peak ST activity was recorded.

RESULTS AND DISCUSSION

The KPT was feasible and simple. Mean peak perturbation velocity (SD) was 1.6 (0.2) and 1.2 (0.1) m/s, and the distance of the foot movement was 76 (9) mm and 66 (10) mm, for anterior and lateral pull, respectively.

Peak ST activity during the anterior (R^2=0.76, F=31.1, p<0.001) and lateral KPT (R^2=0.62, F=14.9, p=0.004) showed a high association with ST pre-activity during SC. Whereas the anterior (R^2=0.33, F=5.9, p=0.031) and lateral KPT (R^2=0.08, F=0.9, p=0.36) was poorly associated with ST pre-activity during SLL.

CONCLUSIONS

The results showed that medial hamstring reflexive response during a standing test is highly associated with pre-programmed activity during an ACL injury-risk movement (SC), but not to a low-risk movement (SLL).

Summary

In recent years, artificial intelligence (AI) has penetrated every domain of our lives, and forms an important component of any modern technology. For example, mobile phones are no longer just telephones, but are advanced computers capable of real-time analysis of movement data, image interpretation and much more. These developments are timely for biomechanists, who have long sought ways to analyse human movement in conditions outside of a laboratory, and over longer timespans than a few minutes or hours. This symposium will feature presentations from leading scientists in the field of biomechanics-related AI. They will introduce novel applications of AI techniques to solve biomechanical problems in various sub-domains. These applications will include markerless motion analysis methods, estimation of ground reaction forces from video data, and sport-related applications. We aim to give audience members an up-to-date picture of the AI landscape, and inspire new ideas and possible applications in the broader field of biomechanics. We will also address some of the challenges of using algorithms that, despite being trained on large volumes of data, do not always make perfect decisions.

Summary

This symposium will consist of a series of presentations from invited speakers with expertise in the biomechanics of ball kicking across football codes. We aim to address a number of contemporary issues across the field, highlighting both the current knowledge and pertinent questions that should be considered in future research.

SY04-1

- Neal Smith - Energy flow in soccer kicking
  The action of kicking in the football codes has been well described over the years. With angles and angular velocity values in good agreement amongst studies, it is important to understand the energetics of the motion and how these very fast foot velocities are obtained. We will look across the football codes and attempt to unpack energy flow in the kicking leg towards ball contact, and the transfer to the ball. Skill development will also be observed as key degrees of freedom are involved at higher skill levels.

SY04-2

- Simon Augustus – Looking beyond the kicking leg: whole-body strategies for ball kicking performance
  Descriptions of kick leg function during ball kicking are extensive, but less is known about how the support leg, pelvis and upper body contribute to kicking performance. Understanding whole-body strategies used to perform fast and accurate kicks can help players and coaches develop and train effective kicking actions. This presentation will provide an overview of research conducted over the last decade that has attempted clarify such strategies. Attention will be paid to a) common 'observable features' of ball kicking that have been identified as the foundation of successful performance b) different inter-individual strategies and classification of different 'types' of kicker.

SY04-3

- Alexandra Atack – Sex differences in ball kicking biomechanics (strength, technique and training effects)
  For a number of years research has sought to understand differences in ball kicking performance and technique between male and female players. Early research found female soccer players demonstrated different kicking leg mechanics and ultimately reduced ball velocities compared with males. Some researchers aligned this to differences in their physical performance capacities, others suggested it may be an effect of their training experiences. This presentation will take a holistic overview of these factors (strength, technique and training experience) through a comparison of elite female and male rugby place kickers.

SY04-4

- Hiroyuki Nunome – Myths and facts on football kicking: Filling the gaps between the player's perspective, coach's observation and scientific evidence
  There are many myths about how to perform football kicking better. A series of our studies demonstrated a more representative nature of the leg swing kinematics and ball impact dynamics, which concurrently proposed substantial gaps between what players try to do and phenomena actually happening during kicking. These natures should be carefully interpreted from practical and scientific perspectives. In some cases, coaching cues, which are not consistent with scientific evidence likely provide some benefit for players. In the current talk, we would like to emphasize the discussion about whether scientific evidence is relevant to improve the performance of football kicking.

Summary

In this symposium the aim is to critically revisit common biomechanical perspectives on how to maintain healthy knees after knee injury. Experts in the field of knee joint biomechanics will therefore challenge the audience by offering convincing arguments explicitly favouring or opposing statements such as:

- To avoid re-injury after reconstruction of the Anterior Cruciate Ligament (ACL), one should screen patients on movement patterns that excessive load the knee ligaments.
- Risk of (re-)rupturing the ACL during a side cutting manoeuvre can be assessed by screening standardized hops and jumps.
- The development of post-traumatic osteoarthritis is primarily caused by pathological load distributions on the tibiofemoral cartilage.
- Pathological knee loading observed during gait/running will propagate itself in most if not all other activities a patient/athlete engages in.

The experts will avoid technical language and build their arguments towards a non-expert audience, as such inviting everyone in the audience to actively participate in the debate, even if one is not working in the field of knee joint biomechanics.

Speakers:

- SY05-1: Jesper Bencke
- SY05-2: Kevin Ford
- SY05-3: David Saxby
- SY05-4: David Lloyd

Summary

The symposium - ***"Beyond the Surface: Uncovering the Role of Materials in Biomechanics, Sports, and Rehabilitation"*** brought together experts from various fields to discuss the latest advancements and applications in understanding human movement, optimizing sports performance, injury prevention and enhancing rehabilitation strategies. The symposium covered a wide range of topics and highlighted key research findings, technological advancements, and practical implications in these interconnected disciplines. Here is the list of material presented:

SY06-1: Solehuddin Shuib (Universiti Teknologi MARA, Malaysia)
Development of knee implant using additive manufacturing technology: lattice design, material and manufacturing

SY06-2: Uwe Gustav Kersting (German Sport University Cologne)
Simulating material properties of in-vivo shoe-surface interaction using a robotic platform - opportunities and limitations

SY06-3: Abd Halim Abdullah (Universiti Teknologi MARA, Malaysia)
3D printing material in developing assistive adaptive devices for rehabilitation medicine

SY06-4: Thor Buch Grønlykke (Spraino ApS)
New materials that modify horizontal forces for injury prevention

SY06-5: Izhar Aziz (3D Gens)
Additive metal: Process, microstructure and properties

Overall, the symposium provided an in-depth exploration of the interdisciplinary nature of biomechanics, sport biomechanics, and rehabilitation. It showcased the importance of biomechanical analysis in optimizing sports performance, designing effective rehabilitation protocols, and advancing our understanding of human movement. The event fostered collaboration and knowledge sharing among experts, paving the way for further advancements in these fields.

Summary

The theme of this symposium will be the application of modeling and simulation approaches to study sports injuries, and it will feature six invited talks followed by a discussion. The primary goals of the symposium are to: a) cover existing state-of-the-art modeling and simulation methods in the context of sports injury research and b) highlight necessary avenues for improvements in existing methods to enable real world impact.

SY07-1 ***Ton van den Bogert*** *(Parker-Hannifin Endowed Chair in Human Motion and Control in the Department of Mechanical Engineering, Cleveland State University, USA):*

Simulation has enormous potential for research on sports injuries. Tissue loads can be predicted and experiments conducted without risk to human subjects. Numerous scenarios can be rapidly evaluated to determine injury risk and the effects of risk factors or protective interventions. Now that software tools and methods are widely available, the focus needs to shift towards asking good research questions and designing good studies to answer those questions. Using previous work on ankle sprains and ACL injuries, we will discuss current obstacles on the path towards validated and trusted models that can be successfully translated into injury prevention practice. Translational research must consider the trade-off between sports performance and injury risk.

SY07-2 ***Anne Koelewijn*** *(Biomechanical Motion Analysis and Creation, Department Artificial Intelligence in Biomedical Engineering, FAU Erlangen-Nürmberg, Germany):*

In biomechanical investigations relying on predictive simulations it is common to solve a single optimal movement trajectory. However, in reality, when an individual performs a movement several times there is variability, which most predictive simulation frameworks do not capture. To capture this variability it is possible to perform the predictive simulations in a stochastic environment. In this talk I will briefly outline how predictive simulations in a stochastic environment can be performed and how this approach could benefit research in sporting settings.

SY07-3 ***Dario Cazzola*** *(Department for Health, University of Bath, UK):*

Musculoskeletal modeling has shown great potential when applied to sport and injury prevention scenarios. For this reason, such modeling approaches have started to have some traction in the sport technology industry, which needs fast and reliable models to monitor athletes' load during training and matches, and inform training or injury prevention strategies. In this talk, I will explore and discuss how musculoskeletal modeling can be used in contact sports for the estimation of contact and joint forces from video footages, and its integration with pose estimation algorithms and Gaussian processes.

SY07-4 ***Jennifer Maier*** *(Department of Mechanical Engineering, Stanford University, USA):*

The shoulder joint is the most complex joint in the human body. It is therefore challenging to find a model representation of this joint that can represent the high flexibility of the shoulder joint while allowing only for physically feasible types of motion. A particular challenge is the analysis of overhead athletes, as they perform highly dynamic movements that go far beyond the range of motion required in daily life. The high loads associated with the high range of motion makes them more susceptible for injuries like rotator cuff tears or labrum tears. Previous work has presented models on both ends of the spectrum: Models that are

constrained and physically feasible while not allowing for highly flexible and dynamic motion, and models that are highly flexible and individualizable but in need of accurate data for feasible solutions that is challenging to collect. We will talk about the challenges and considerations for designing a model of the shoulder joint that lies somewhere between the two extremes and is physically limited yet flexible and customizable to enable high ranges of motion for sports applications and injury analysis. Special focus will lie on the role of the scapula in shoulder motion.

SY07-5 ***Reed Gurchiek*** *(Department of Bioengineering, Stanford University, USA):*

Hamstring strain injuries are one of the most prevalent time-loss injuries in athletes, and re-injury is common. Research on injury mechanisms and kinetic and kinematic risk factors is often limited by drawbacks of prospective designs. In this talk, I will present preliminary results demonstrating the utility of simulation and optimization to overcome these limitations. Specifically, musculoskeletal simulations of maximal velocity sprinting revealed features of hip-knee coordination that could be used for injury risk assessment. These findings provide new insight regarding injury mechanisms and approaches for incorporating simulation and optimization for evaluating injury risk.

SY07-6 ***Antoine Falisse*** *(Department of Bioengineering, Stanford University, USA):*

There has been a lot of interest in developing methods to perform analyses of human motion based on non-invasive techniques in recent times. The development of such techniques permits large scale studies to be conducted more easily and with more participants, and they could also enable participants to be more monitored more regularly to track injury progression/rehabilitation. In this talk, I will first present OpenCap, an open source software system to measure human movement kinematics and kinetics from smartphone videos. I will then describe how this tool can be useful for diverse applications, including injury prevention and rehabilitation. I will then conclude by outlining the next steps for having this system deployed in sport settings.

Summary

The emergence of advanced footwear technology has altered the running landscape in the last decade and has divided the running community. Performance enhancement footwear in running – also known as “super shoes” – typically contain a stiff plate, lightweight, high-energy returning foam, and have a curved geometry that together enhance performance and reduce metabolic cost. The scientific community has been seeking to better understand the underlying mechanisms and conditions that lead to meaningful performance enhancements in runners, while considering the potential risks linked with rapid adoption of technologically advanced shoes.

This symposium will provide an overview of studies that have investigated the effects of advanced footwear technology on running economy, performance, and biomechanics. It will dive into misconceptions about the role of footwear energy storage and return (mechanical work) on running performance. The symposium will explore opportunities for evaluating how footwear energy storage and return cooperate and/or compete with the runner. A framework for evaluating foot and footwear mechanical power profiles during running will be presented to support biomechanics researchers and footwear developers. Furthermore, considerations with regards to the widespread adoption of advanced footwear technology in running will be discussed. Notably, the use of advanced footwear technology is now filtering to trail running, despite the limited amount of research examining the effects of such footwear on the economy and biomechanics of runners in trail-like conditions. The symposium will also speculate on how the use of advanced footwear technologies potentially affects lower extremity loading with implications for injury risk, whether it is possible to predict from biomechanics who is benefiting from wearing these shoes, and “where to from here”.

This symposium involves four invited presentations moderated by two running experts. The presentations will be followed by a panel discussion and questions from the audience.

- Kim Hébert-Losier and Irene Davis (moderators): Introduction
- SY08-1 Steffen Willwacher: The effects of advanced footwear technology on running performance and lower extremity loading: Current knowledge and future directions
- SY08-2 Emily Matijevich: Footwear energy storage and return: How footwear mechanically cooperates and/or competes with the runner
- SY08-3 Marlène Giandolini: Effect of increased longitudinal bending stiffness on running economy and biomechanics when running uphill and on unstable terrain: Implications for trail running footwear
- SY08-4 Wouter Hoogkamer: Can we predict who is responding to advanced footwear technology from biomechanics?

Summary

Motion analysis based on the use of inertial measurement units (IMUs) has expanded rapidly in recent years. In both academia and industry, IMUs have enabled development of software applications for joint kinematics estimation targeting the medical, health and wellness sectors. Proprietary algorithms and software or the lack of technological transparency of some applications can preclude assessing accuracy, validity, and reliability of the estimated parameters and comparing products and results of research studies. The rapid and growing development of IMUs and related methods has not yet resulted in consistent standards or recommendations of use. Proper use of IMUs relies on knowledge of sensor calibration procedures, sensor-to-segment alignment, data fusion algorithms, biomechanical models, reporting kinematic variables, and validation procedures. Hence, there is an urgent need to define standards and reporting guidelines for IMU-based kinematic analysis.

The two symposium chairs along with an international team of five other experts in inertial motion capture are developing these recommendations and standards. A written proposal has been reviewed and approved by the ISB committee. We believe this symposium is the ideal medium through which to present our ideas to and gather feedback from the ISB community.

Our intent is to advance the field and maximize transparency, reproducibility, generalizability, and validity of joint kinematics estimated using IMUs. Accordingly, this symposium will feature seven additional talks with IMU applications that span upper and lower limb kinematic analysis, remote gait assessment, and deep learning approaches. These will highlight novel techniques in our field and will facilitate a rich discussion amongst symposium attendees regarding our proposed recommendations.

Deep Kinematics: Uncovering Human Biomechanics with IMUs and Deep Learning – Preliminary Result

INTRODUCTION

Gait analysis is a crucial tool for clinicians evaluating gait impairments stemming from neurological and musculoskeletal disorders. Healthcare professionals can gain invaluable insights into a patient's well-being by analysing parameters such as stride length, variability, and swing time. Though regarded as the gold standard, traditional marker-based 3D optical motion tracking systems are hindered by time-consuming setups and restrictions to clinical facilities. Interestingly, the Hawthorne effect highlights the need for gait analysis in natural settings, as patients' performance often differs between home and clinical environments. Inertial Measurement Units (IMUs) offer a compelling alternative as wearable devices, supplying essential data regardless of location. These compact devices facilitate more practical and accessible gait analysis, promoting enhanced clinical assessments and patient care in various settings. Deep learning (DL) and IMU technology are widely used in computer graphics and vision[1]. However, clinical gait analysis requires higher accuracy than typically reported in these fields.

This study explores the potential of DL to address the limitations of traditional gait analysis methods and evaluate the accuracy and applicability of 3D human pose reconstruction using IMUs.

METHODS

3-D kinematic and IMU data were collected from 69 healthy participants (41 young: 20±2.26 years, 17 elderly: 68±5.91 years) during a 29-minute treadmill walk, a total of 1624 minutes at a sampling frequency of 200Hz. We assigned 70% of the data to the training set, 15% to the validation set, and 15% to the test. The kinematic trajectory of joint centres from motion capture data was used as ground truth. Pelvis was used as the root to serve as the origin, and height was normalised to the length of the femur. Two models were developed: the first (feed-forward) comprises three linear layers with a hidden size of 1024 and ReLU activation. The second model was built upon unidirectional Recurrent Neural Networks (RNN) with two LSTMs[2], each having a hidden size of 1024. Both models feature a final layer with an output dimension of 24 outputs: eight joint centres, each consisting of three axes.

RESULTS AND DISCUSSION

Table 1: Predicted joint centres' kinematic trajectory evaluated in Euclidean distance; The numbers presented with averages and standard deviation (SD) in centimetres, JC = Joint Centres.

	Feed Forward (FF)		RNN	
	Left	Right	Left	Right
Hip	1.47 ± 0.6	1.4 ± 0.58	1.15 ± 0.33	1.09 ± 0.29
Knee	4.52 ± 2.97	4.02 ± 2.72	3.41 ± 1.45	3.44 ± 1.45
Ankle	6.42 ± 4.32	5.36 ± 3.43	4.22 ± 2.2	3.84 ± 1.82
Toe	6.93 ± 4.27	6.21 ± 3.69	4.17 ± 2.33	4.08 ± 2.95

Both models predict joint centres with an average of 5cm error. A general pattern of increase in error distally, away from the root (pelvis), was observed. Additionally, both models do not show a significant difference between left and right predicted joint centres, although, for the ankle, the difference is more prominent. RNN displays a much lower error in Ankle and Toe than FF. Our results were based on a primitive DL model and approach, thus losing participant-specific information. Therefore, it is future work to apply body-model fitting with more advanced models to improve the accuracy in both kinematic and containing participant-specific information. Furthermore, it is of practical relevance to derive the required gait parameters mentioned in the introduction.

CONCLUSION

Both models have shown a similar pattern and promising 3D human reconstruction feasibility, where RNN outperforms the FF model. Further investigation with more advanced models and approaches is required to meet the accuracy level for clinical gait analysis.

INTRODUCTION

Inertial Measurement Units (IMU) require complex calibration algorithms to convert orientation data expressed in their local reference frame into a clinically meaningful reference system. The algorithms require the wearer to perform a series of movements or poses. Several calibration methods have been developed to find the perfect trade-off between ease of use, accuracy and speed. Still, little work has been done to compare different calibration methods with each other and against a gold standard reference system [1,2]. Therefore, this paper contributes to covering this gap by assessing the accuracy and precision of a number of calibration techniques (static and dynamic) and comparing them against a gold-standard camera system.

METHODS

Seven healthy subjects with no signs of upper limb injury were recruited for this study. Five IMU sensors (Xsens DOT, Movella, The Netherlands) and five active 3-marker clusters (Optotrak Certus®, NDI, Canada), used as a gold standard reference system, were attached to the participants on the thorax, scapula, upper arm, forearm and wrist. The bony landmarks for the optical reference system presented in [3] were digitized after subjects were instrumented. Four IMU models were developed by employing different calibration techniques: 1) N-pose calibration (NP): the subject stands in neutral pose for three seconds; 2) Functional calibration (FC): the subject performs single plane movements for each joint to estimate individual rotation axes; 3) Manual alignment (MA): each sensor reference frame is manually aligned with the underlying bone frame; 4) One-Axis alignment (OA): one axis of the sensor is aligned with the long axis of the segment. The data acquisition protocol consisted of 1) Sensor calibration: a static N-pose and a series of controlled single-plane dynamic movements for shoulder, elbow and wrist; 2) Tasks: subjects were required to execute single-plane tasks for each upper limb joint and a series of multi-joint tasks that resemble common activities of daily living. A graph of an unconstrained wrist flexion/extension task at full range of motion is presented for one subject in the following paragraph.

RESULTS AND DISCUSSION

The four IMU models accurately estimated the wrist flexion/extension angle during a wrist flexion/extension task (Figure 1A). The maximum root mean squared error (RMSE) for the flexion/extension angle is 12.84±5.20° for NP, whereas the lowest RMSE is 8.76±4.16° for MA (Table 1). However, when performing the same task, the four models perform differently in estimating the radial/ulnar deviation angle (Figure 1B). In the same scenario, the highest RMSE is 34.76±9.53° for NP, whereas the lowest RMSE is 20.75±10.61° for FC.

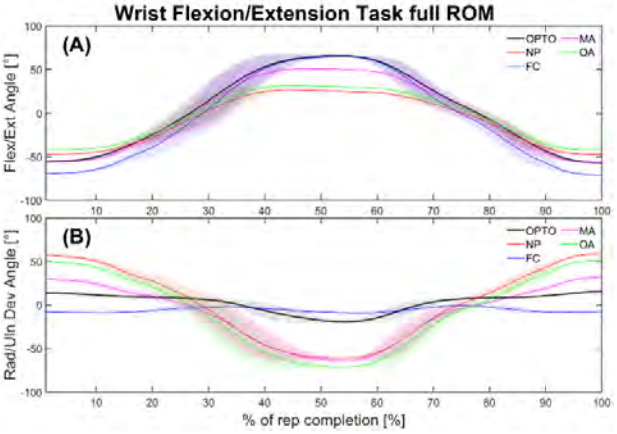

Figure 1: Plot of a wrist flexion/extension task starting from wrist fully flexed (0%) to fully extended (50%) and ending with full flexion (100%). Graph (A) displays the flexion/extension axis and graph (B) displays the radial/ulnar deviation axis.

CONCLUSIONS

All the four models presented perform rather similar in estimating the wrist flexion/extension angle, but their performance differs on the secondary rotation axis. Therefore, we advise a functional calibration approach for the best estimation of the overall wrist joint motion. However, for the highest accuracy possible on the flexion/extension axis, then we recommend the manual alignment (MA) method.

THREE-DIMENSIONAL SCAPULAR MOTION TRACKING USING INERTIAL MEASUREMENT UNITS: A REGRESSION-MODELLING APPROACH

Zhou Fang[1], Damith Senanayake[1], Peter Lee[1], David Ackland[1]
[1] Department of Biomedical Engineering, The University of Melbourne, Melbourne, Australia.
Email: zhouf1@student.unimelb.edu.au

INTRODUCTION

Skin-marker-based scapular motion measurement can be challenging due to skin-motion artefact. Previous studies have validated the accuracy of optoelectronic-based methods [1] and shown that scapular motion can be predicted using a thorax-humeral regression model with RMS errors of less than 10º [2]. However, optoelectronic systems can be expensive, require considerable technical expertise and are generally confined to the laboratory environment. In recent years, wireless and lightweight inertial measurement units (IMUs) have become increasingly used to address these limitations and provide motion measurement capacity in the home setting. The aim of this study was to develop a scapulo-humeral regression model based on healthy subjects, calculate the three-diamensional scapular motion during daily activities using IMUs, and validate the results against an optoelectronic system.

METHODS

Thirty healthy subjects (age: 28±4 years) were recruited for testing. A set of 11 retro-reflective markers were placed on anatomical landmarks of the right upper limb of each subject. Three bony landmarks of the scapula, the TS (Trigonum Scapulae), AA (Angulus Acromialis) and AI (Angulus Inferior), were digitized at 21 humeral positions using an adjustable scapula locator and a 10-camera video motion analysis system. In addition, two IMUs were placed on the chest and the upper arm of the subjects. The orientations of the IMUs relative to body segments was computed using the ISB recommended coordinate systems [3] via two-stage static poses [4] and a T-pose. Subjects performed a range of activities of daily living including flexion-extension, abduction-adduction, head touching and reaching, synchronised to a metronome. The video motion data was processed using inverse kinematics with subject-specific musculoskeletal models. Then, an averaged regression model derived from 29 subjects was developed to predict scapular protraction, external rotation and tilt in the thorax reference frame given plane of humeral elevation and humeral elevation angle as input. This 'reference-standard' scapular motion was then compared to IMU-based scapular motion measurement, which was calculated by inputting each subject's humeral plane and elevation angles measured by the IMUs into the regression model.

RESULTS AND DISCUSSION

At the humerothracic joint, the RMSE in prediction of plane of elevation and elevation angle during reaching using IMU was 7.60º and 4.19º, respectively (Figure 1). For the scapular angles, the RMSE in prediction of protraction, external rotation and posterior tilt was 1.79º, 1.34º and 1.65º, respectively (Table 1). The reported IMU-based kinematics accuracy at the scapulothoracic joint (< 2º) is considered equivalent to that of direct scapula registration [2].

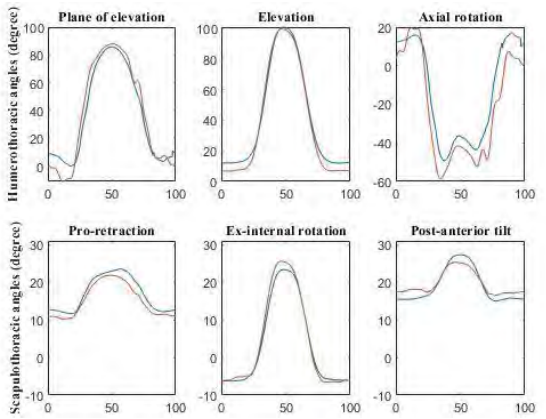

Figure 1 Three-dimensional humerothoracic and scapulothoracic angles during reaching. Horizontal axes: scaled task timeline (%); Blue curves: optoelectronic kinematics; red curves, IMU kinematics.

CONCLUSIONS

This study presents a new method to measure the three-dimensional scapular motion in healthy adults using IMUs and linear regression modelling. Scapula motion can be predicted with accuracy in three rotational degrees-of-freedom with errors less than 2º, which is within the range of optoelectronic motion tracking accuracy. Future studies will focus on evaluation of pathological kinematics, and upper limb muscle force predictions using predicted kinematics.

DO DIFFERENT METHODS FOR MIMU-BASED POSTUROGRAPHY LEAD TO THE SAME RESULTS?

[1] Department of Information Engineering, University of Padua, Padua, Italy.
[2] Department of Medicine, University of Padua, Padua, Italy.

Email: annamaria.guiotto@unipd.it

INTRODUCTION

Posturography is considered the objective measurement of standing posture control. The main parameters for assessing balance generally are obtained from the center of pressure (COP) (i.e. in time or frequency domain), registered through force/balance plates [1-2] (COP approach, A-COP). In recent years, the extraction of such parameters has been performed through [3]:
- Inertial Measurement Units (IMU) by extracting metrics directly from the acceleration measured through a sensor applied close to the COM [4] (acceleration approach, A-ACC);
- Magneto-IMU (MIMU) by reconstructing the position of the center of gravity (COG - projection of COM on the base of support, COG approach, A-COG) [5-6];
- the center of mass (COM) by registering the trajectory of a marker applied on the 5th lumbar vertebra (L5) with video-based methods [2] (A-L5). The aim of this study was to compare the posturographic parameters calculated with the above mentioned approaches: **1.** A-L5 [2], **2.** A-ACC [4], **3.** A-COG [5], **4.** A-COP [1-2].

METHODS

Thirteen healthy subjects (4M-9M, mean age 27.5±4.3 years, mean BMI 22.5±1.8 kg/m^2, 41.4±1.8 shoe size) stood for 60 seconds in upright position with eyes open and closed (arms along the body, feet 30° appart through a cardboard triangle, looking at a target at eye level, 5 meters away). Data were simultaneously acquired through a MIMU sensor (Muse, 221e srl, Italy, 100 Hz) applied on the L5/COM, fixed through an elastic band (A-ACC and A-COG), through a force plate (Bertec corp, FP6040, 200 Hz) as reference gold standard (A-COP) [2-3] and a stereophotogrammetric system (SMART-D, Bts srl, 200 Hz) (for A-L5). After a calibration refinement, MIMU data were processed as in [4] for A-ACC and by applying a Kalman extended filter for A-COG [5-6]; hence the posturographic parameters were extracted [4]. A-COP and A-L5 parameters were calculated as in [2-3]. Root mean square distance (RMSD) was calculated from the measures obtained in A-L5 and A-COG. Pearson's correlation analysis was performed among all the different posturographic measures.

RESULTS

A RMSD of 22.1±2.1 mm and 26.1±10.7 mm (mean±sd among all the subjects' data) was detected in the medial-lateral and anterior-posterior direction respectively, between A-L5 and A-COG. Results of the Pearson's correlations coefficients showed excellent to good correlation on the ellipse area and sway area between A-COP/A-L5/A-COG, very good correlation on the sway path between A-L5/A-COG, moderate correlation on the ellipse area between A-COP/A-L5/A-ACC (Table 1).

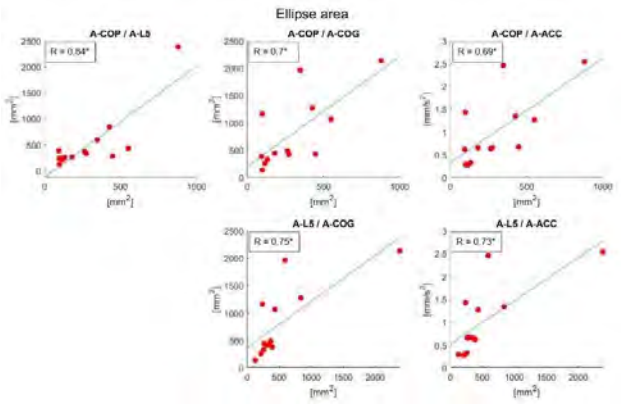

Figure 1. Scatterplot with regression line and Person's correlation coefficient (R). * Statistically significant correlation.

CONCLUSIONS

Results of the correlation between MIMU and the parameters computed through the standard methodology (i.e. A-COP) look promising toward an application in everyday living environments. Further studies are needed to assess their reliability in pathological conditions.

INTRODUCTION

Gait kinematics assessments provide relevant information for evaluating the recovery of lower limb injuries. Optical 3D motion capture is most often used for the purpose but the method is resource-intensive and only applicable in a laboratory setting. Wearable magneto-inertial measurement units (MIMU) could provide a more flexible and cost-effective alternative for gait kinematics evaluation compared to motion capture, however, more work is still required to establish the standard operating procedures that result in valid and reliable kinematics estimates [1]. Therefore, the purpose of the study was to develop a MIMU-based lower body gait kinematics assessment pipeline based on the cutting-edge best practices proposed in the literature (e.g., Opensim/OpenSense) [2]. The pipeline was piloted with apparently healthy adults and in monitoring a series of cases recovering from a lower limb trauma.

METHODS

Six adults with a lower limb trauma (three Achilles tendon ruptures [ATR], three ankle fractures [AF]) and 28 apparently healthy adults (controls) volunteered as participants. The participants were asked to walk 10 times back-and-forth a 20 m long straight path at their preferred/allowed by pain pace. MIMUs (NGIMU, x-io Technologies, UK) recording at 200 Hz were mounted on the feet, legs, thighs, and the waist using elastic Velcro bands. Madgwick's gradient descent algorithm [3] was used to estimate sensor orientations and OpenSim software to provide 3D joint kinematics [2]. Steps were segmented based on distance between virtual OpenSim heel markers. Fukuchi's open optical motion capture-based dataset (N = 42 healthy adults) [4] was used as a reference dataset for the controls.

RESULTS AND DISCUSSION

Some offset and a scaling biases were observed between the controls and the reference data (Figure 1). The step cycle segmentation appeared reasonable as the expected healthy gait flexion patterns were produced for the lower body joints (Figure 1). The AF and ATR cases differed clearly from the controls at 8 weeks post trauma and the kinematics recovered towards that of controls from 8 weeks to 6 months post trauma, although the recovery was heterogeneous. The detected improvements in the joint angles during the recovery were 4–12-fold larger than the minimal detectable change measurable with the MIMU-based method.

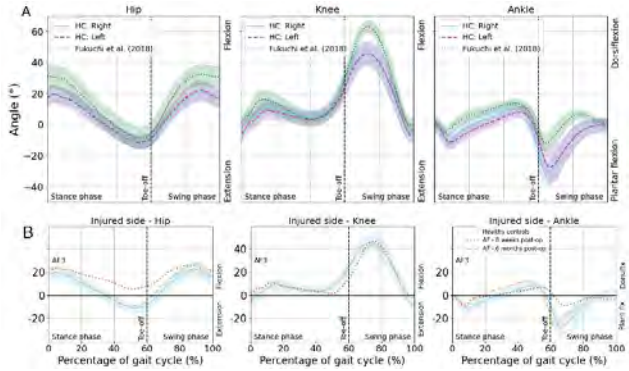

Figure 1 A) Hip (left), knee (mid) and ankle (right) flexion angle of the controls (red) compared to the reference dataset [4] (blue). Systematic offset and scaling biases are evident, however, the expected healthy gait pattern is reproduced. B) An ankle fracture case at 8 weeks (blue controls, red 8 weeks past trauma, yellow 6 months past trauma). Recovery towards the controls' kinematics is evident from 8 weeks to 6 months.

CONCLUSIONS

The simplicity of use and low cost coupled with the present findings warrant further investigation of MIMU-derived gait kinematics for use in applied settings, such as in the clinics, or in the ecologically valid free-living conditions.

BODY SEGMENT ORIENTATION TRACKING WITH IMU: AN ADAPTIVE ROBUST EKF FOR DYNAMIC LONG-DURATION ACTIVITIES

Milad Nazarahari[1] and Hossein Rouhani[1]
[1] Department of Mechanical Engineering, University of Alberta, Edmonton, Alberta, Canada.
Email: hrouhani@ualberta.ca

INTRODUCTION

Wearable inertial measurement units (IMUs) are ideal for human motion analysis, especially for out-of-lab applications. Yet, due to measurement errors of the gyroscope, accelerometer, and magnetometer embedded in an IMU, a sensor fusion algorithm (SFA) is required to estimate the body segment orientation accurately. Despite its importance, the literature lacked a systematic SFA design methodology and benchmarking of SFAs performance. Thus, we developed a full-state robust extended Kalman filter (REKF) and a method for optimal adaptation of its gains (e.g., covariance matrices). Then, we compared the performance of our REKF against three highly-cited SFAs from the literature. Finally, we benchmarked 30+ SFAs against a reference camera motion-capture system. We shared codes and sample data on our lab's website (ncbl.ualberta.ca/codes).

METHODS

We structured a novel full-state EKF by including the orientation quaternion, gyroscope bias, non-gravitational acceleration, and magnetic disturbance in the state vector (hence called a full-state EKF) [1]. 2nd-order strap-down integration of the corrected angular velocity and the 1st-order Markov process of the non-gravitational acceleration and magnetic disturbance were used to construct the state-transition matrix. The measurement-update equation was derived using a single-iteration gradient descent algorithm. Next, we improved the developed EKF to a REKF using H_∞ filter structure (i.e., manipulating the a posteriori error covariance matrix equation) to achieve robust estimations under various motions. To ensure that the REKF performance is not affected by improper gains, we developed a framework (which can be applied to every SFA) for optimal adaptive gain tuning. We used a hard switch with two levels for each gain and optimized the gains and switching thresholds by minimizing the error between the estimated and true orientations [2]. We compared the performance of our adaptive REKF using IMU raw data against three highly-cited SFAs (with optimal gain tuning), including, Madgwick2011, Mahony2008, and SFA from MATLAB Sensor Fusion and Tracking Toolbox; see [1] for further details. Then, after removing the gyroscope bias, we benchmarked 30+ SAF from the literature [3]. Experiments included continuous walking at a normal and fast pace (~10 min) with an IMU attached to the foot.

RESULTS AND DISCUSSION

Table 1 shows the mean (standard deviation) of the root-mean-square error between the estimated and true orientations. Our proposed REFK obtained significantly ($p<0.05$) lower estimation errors for roll, pitch, and yaw angles. Then, using the same data, we showed that removing the gyroscope's static bias before orientation estimation can significantly improve SFAs' accuracy, even for SFAs with a mechanism for online gyroscope bias removal, such as our REKF [4]. We compared the accuracy of estimated orientations by our REFK and 30+ SFAs against a motion-capture system [4]. The median errors between estimated and true orientations for the nine best SFAs (including our REFK) were less than 5 degrees, mainly due to the short duration of tests (~10 min); see [4] for reference to methods and detailed results.

Table 1: Mean (standard deviation) of root-mean-square error of orientation tracking using IMU raw data obtained by various SFAs.

	REKF	Madgwick2011	Mahony2008	MATLAB
Roll	7.3(2.9)	23.2(5.1)	23.8(4.7)	37.9(19.1)
Pitch	6.1(2.0)	22.3(6.1)	21.1(5.7)	16.1(7.8)
Yaw	7.8(3.3)	28.0(7.4)	27.7(7.8)	48.6(23.8)

CONCLUSIONS

This work presents a systematic approach to designing an adaptive REKF and its benchmarking against the literature. We showed that for IMU raw data, our REFK is superior to the literature. We also showed that for ~10 min tests, gyroscope static bias removal effectively reduced the estimation error of SFAs in general. In the future, longer tests (i.e., 30 min to 1 hour) must be performed to reveal the benefits of our full-state REKF with online gyroscope bias estimation and removal.

BOUT DURATION DURING OUT-OF-LAB WALKING AFFECTS GAIT KINEMATICS

INTRODUCTION

Gait kinematics differ between in-lab and out-of-lab settings [1,2]. Out-of-lab collections may provide a more complete insight into daily function as opposed to acute in-lab setting designs. Data collected out-of-lab have varying bout characteristics (i.e. time, speed, or step count) and there are no standardized procedures for segmenting or selecting out-of-lab walking data. We do not know how the duration of walking bouts included in analyses affects gait analysis results. Therefore, the purpose of this study was to compare the effects of walking bout duration on gait kinematics among healthy young adults, and older adults with and without knee osteoarthritis (OA).

METHODS

Ten healthy younger (28.1±3.5yrs) and older (60.8±3.3yrs) adults, and seven older adults with knee OA (64.1±3.6yrs) participated in this study. Four IMUs [Opal v2, APDM] were placed on the pelvis, and right (healthy) or more affected (knee OA) limb's thigh, shank, and foot. Participants walked a set, ~10 min route in a campus building. A zero-velocity update algorithm was used to calculate spatiotemporal variables from foot-mounted IMU data [3]. Medial-lateral axes for the pelvis, thigh, shank, and foot were defined using a functional sensor-to-segment alignment [4]. Level strides without turns were selected and walking velocity, stride length, and knee, hip, and ankle angular excursion (ROM) were calculated per stride and averaged for each subject. Variables were compared between long (>60 secs) and short (≤60 secs) bouts among young and older healthy adults, and older adults with knee OA using a 2x3 ANOVA (α=0.05).

RESULTS AND DISCUSSION

Short bouts were 32.1±19.1 sec and long bouts were 188.8±137.6 sec, on average. Walking speed (p<0.001), stride length (p<0.001), knee (p=0.017) and ankle ROM (p=0.012) were greater for the long compared to short bouts (Fig 1). Group x condition interactions were observed for walking speed (p=0.027) and stride length (p=0.036). Healthy older adults had significantly greater walking speed (p<0.001) and stride length (p<0.001) in long compared to short bouts. Older adults with knee OA showed significantly greater walking speed (p=0.001) and stride length (p=0.004) with longer bout duration. Our finding of greater walking speed and stride length with longer bout duration agrees with the suggestion of a previous study [2], but interestingly only for older adults.

CONCLUSIONS

Kinematics differed when out-of-lab gait data were divided into strides that occurred as part of short (≤60 s) or long (>60 s) bouts. Previous studies suggested that most walking bouts in daily life have more variety of bout duration (e.g. <10 secs, <30 secs, < 5 mins, >10 mins, etc.) [2,5,6]. A previous real-world study suggested the use of longer walking duration (10mins) to explain spatiotemporal gait characteristics [6]. We had minimal variability in bout duration length, therefore the out-of-lab setting in this study may not characterize real-world bout duration effectively. Bout duration selection criterion is important and should be carefully considered based on the research question for out-of-lab gait.

INTRODUCTION

Motion analysis based on the use of inertial measurement units (IMUs) has expanded rapidly in recent years. In both academia and industry, IMUs have enabled development of software applications for joint kinematics estimation targeting the medical, health and wellness sectors. Proprietary algorithms and software or lacking technological transparency of some applications can preclude assessing accuracy, validity, and reliability of the estimated parameters and comparing products and results of research studies. The rapid and growing development of IMUs and related methods has not yet resulted in consistent standards or recommendations of use. Proper use of IMUs relies on knowledge of sensor calibration procedures, data fusion algorithms, biomechanical models, reporting kinematic variables, and validation procedures. Hence, there is an urgent need to define standards and reporting guidelines for IMU-based kinematic analysis. The aim of this project is to develop these standards and recommendations incorporating feedback from the ISB community.

RECOMMENDATIONS

Following the procedure to propose an "ISB Recommendations" paper [1], our written proposal has been reviewed and approved by the ISB committee. Our recommendations address basic principles and serve generally as reporting guidelines. We maintain consistency with established standards in human motion analysis where appropriate and have organized our recommendations under five topics described here.

Measurement device. Estimation performance depends on the hardware specifications of the device and the mechanism of bodily attachment. These specifications comprise parameters of the measurement model and are often calibrated (e.g., sensor bias and sensitivity). Our recommendations encourage reporting hardware specifications (sampling rate, range, noise levels, etc.), calibration procedures, sensor attachment modalities and synchronization for multi-sensor configurations.

Kinematic model. As for any kinematic analysis, the adoption of joint kinematic models facilitates interpretation of the results and provides the basis for implementing the subsequent stages of the analysis. Our recommendations concern describing the kinematic model, its parameterization, and joint and segment coordinate systems.

Sensor to segment calibration. This is to determine the orientation and position of sensor axes relative to joint/anatomical coordinate systems. It enables a biomechanical and clinical interpretation of sensor measurements. Our recommendations will support continued advancement in this field and encourage reporting the calibration procedures, algorithms, and justification based on the kinematic model.

Signal processing. Many algorithms exist for estimating kinematic variables with IMU data (e.g., Kalman filtering/smoothing, global optimization methods) with customization for specific tasks and/or joints. We encourage a clear description of the algorithm that is fully reproducible and (where applicable) the process for adjusting tuning parameters of the algorithm.

Assessment of validity and reliability. This concerns the correct use of the reference system for comparison and the related statistical characterization of estimation errors assessed by a range of different metrics and analyses. We encourage a description and justification of the statistical analysis, a clinically meaningful interpretation of errors, and description of the reference system used for comparison.

DISCUSSION & CONCLUSION

Our intent is to advance the field and maximize transparency, reproducibility, generalizability, and validity of joint kinematics estimated using IMUs. Although several other societies have shown interest in the use of IMUs, biomechanically grounded ISB recommendations would be most effective in establishing good practice for both biomechanics and human health research.

Summary

Join us for an enlightening symposium dedicated to the Biomechanics of Ankle Injuries. This event, open to medical practitioners, researchers, sports professionals, healthcare industry stakeholders, and footwear manufacturers, brings together the latest in biomechanics and its role in better understanding, treating, and preventing ankle injuries.

One of the highlights of this event will be an in-depth exploration of lateral ankle sprains, a common yet misunderstood injury. Our invited speakers will debunk pervasive myths, presenting detailed video analyses that demonstrate how these injuries are not merely the result of bad landings. This topic will provoke a vital discussion about preconceptions and open up new perspectives on the causes of these injuries.

The symposium will delve into the relationship between physical fatigue and increased risk of ankle sprains, using badminton as a case study. It will illuminate the biomechanical shifts occurring under fatigue conditions, providing crucial insights for athletes and trainers.

We'll also bring the spotlight onto the shoe-surface interactions, emphasizing their importance in ankle sprain injuries. Attendees will gain an understanding of how friction can be a game-changer, transforming their view on injury prevention and footwear choice.

The prevention of sports injuries in youth athletes, particularly lateral ankle sprains, is a pressing issue. Additionally, we will explore the critical role of diaphragm function and how it influences chronic ankle instability. This intriguing talk will delve into the physiological connections between our respiratory system and ankle stability, offering insights that could significantly inform rehabilitation strategies and injury prevention.

The symposium will wrap up with an engaging networking and co-creation session, providing a platform for speakers and attendees alike to exchange ideas, foster collaborations, and spark innovative research projects in the fascinating realm of ankle injury biomechanics.

This symposium promises a dynamic learning environment, networking opportunities, and the chance to reunite with members of the International Ankle Consortium. We look forward to welcoming you to the ankle injury symposium.

Kind regards,
Filip Gertz Lysdal, Alexis Herbaut, and Masafumi Terada

Latest updates for recording, analysis, and interpretation of electromyographic (EMG) data: in the lab and the clinic

ISEK

The International Society of Electrophysiology and Kinesiology (ISEK) is a multidisciplinary organization composed of members from all over the world in health-related fields and basic science with a common desire to study human movement and the neuromuscular system.

The purpose of the Society is to promote research and teaching in the disciplines of Electrophysiology and Kinesiology in normal, experimental, and pathological conditions of the sensory and motor systems, with emphasis on the interactive use of the two disciplines.

With this purpose in mind, the ISEK-ISB joint symposium aims to bring together experts from around the world to discuss the use of electromyography.

This symposium will include:

(i) A short introductory presentation about ISEK by their current vice president A/Prof Kylie Tucker
(ii) An introduction to the Consensus for Experimental Design in Electromyography (CEDE) project by Professor Paul Hodges
(iii) A presentation by Dr. Taylor Dick about gaining consensus through this process with regard to using EMG to estimate muscle force
(iv) An overview of Surface EMG in Clinical Assessment and Neurorehabilitation by M.Sc. Elisa Romero Avila.
(v) A series of talks from those submitted to ISB including the use of high-density EMG in biomechanics, by Professor Kohei Watanabe[7] and clinical assessments by Dr. Yuichi Nishikawa[8].
(vi) A moderated panel discussion (chaired by A/Prof Tucker) where the attendees can ask questions about the use of EMG
(vii) And, will finish up with an invitation to attend the ISEK congress, to be held in Japan in 2024 by Professor Kohei Watanabe.

What is EMG?

Electromyography (EMG) is a tool used to record the electrical activity produced by skeletal muscles. It typically involves placing surface electrodes on the skin above a test muscle, or needle electrodes within the muscle, with the aim to detect the electrical signals generated by muscle fibers during their contraction.

EMG may be used in a variety of clinical and research settings to evaluate muscle function and assist with the diagnosis of neuromuscular disorders. EMG is most typically used by researchers to detect the timing and pattern of muscle activation during different tasks.

What is the CEDE project?

The CEDE project is an international initiative aimed at promoting standardization and best practices in the use of electromyography (EMG) for research and clinical purposes. The project involves a collaborative effort by experts in the field of EMG.

Through the CEDE project, consensus on the essential components of experimental design and methodology for EMG research has been reached. This includes defining the key parameters to be measured, selecting appropriate recording equipment and techniques, and establishing standardized protocols for data analysis and interpretation.

To date, the CEDE project, led by Professor Paul Hodges and coordinated by Dr. Manuela Besomi, has included a series of workshops, online surveys, and expert consensus meetings to establish best practices and recommendations for EMG research. Most recently, the team has called for researchers working with EMG and interested in translating the latest research into practice, to take part in a collaborative project with CEDE team members to develop knowledge translation strategies for CEDE.

CEDE project has resulted in six publications[1-6] in the Journal of Electromyography and Kinesiology (JEK) since 2019, including a consensus statement on electrode selection[1], normalisation[2], terminology[4], the use of HDsEMG[5], and identifying single motor unit beahviour[6].

Summary

The Comparative Neuromuscular Biomechanics Working Group of the ISB is excited to present CNB-ISB II in Fukuoka! The CNB-ISB meeting will feature synergistic research in comparative (non-human) and human biomechanics. The meeting will center on three themes: 1) direct in vivo and ex vivo experimental approaches; 2) computational modelling; 3) robotic/engineering approaches to understanding muscle function in movement. In particular, we will focus on areas where coordination between fields offers potential for innovation.

The meeting consists of three thematic keynote presentations and accompanying oral presentations, as well as a moderated 'flash' poster presentation session (see program schedule). Dedicated time is set aside to allow for Q&A and discussion.

The CNB aims to increase the visibility of comparative biomechanics and neuromechanics at the ISB. Our goal is to accelerate cross-pollination between comparative and human biomechanics fields. We believe that an exchange between comparative and human research fields will accelerate discovery, both of biomechanical principles as well as novel health and engineering applications.

[The CNB-ISB II Fukuoka meeting is sponsored by the ISB and the Journal of Experimental Biology; The Company of Biologists]

Get real: New experiments, models and parameters for understanding in vivo muscle function

INTRODUCTION

Several recent studies have combined in vivo measurements of muscle fascicle length, force and activation with different Hill-type muscle models [1,2,3]. While the results vary among studies, the relatively low accuracy of in vivo force predictions suggests that key features of muscle function are not captured by existing models. Here, we use ex vivo data from cockroaches [4] and mice [5], and in vivo data from guinea fowl [6] to explore new experiments and models that suggest alternative approaches for predicting muscle force during in vivo movements.

NEW EXPERIMENTAL APPROACHES

To provide insights into in vivo muscle function, experiments should include perturbations that emulate in vivo conditions. We performed three experiments. First, we used ex vivo data from cockroach leg muscles (Fig. 1) that were stretched at the same length and phase of activation in work loops over a range of frequencies [4]. These experiments challenge Hill models because length, velocity and activation are constant, so Hill model-predicted force must also be constant. Yet, the observed force depends on frequency (Fig. 1, right).

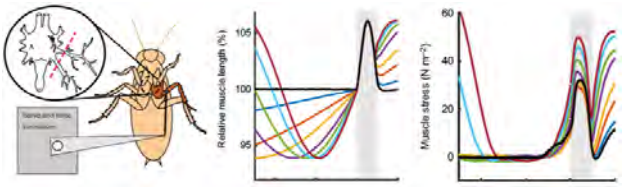

Figure 1 Cockroach stretch perturbation experiments from [4]. **Left**: In situ preparation. **Center**: Length vs. time. **Right**: Force vs. time.

Next, we investigated how the muscle force response depends on stiffness, activation, and length perturbations [5]. Submaximal isometric contraction was established for mouse soleus muscles, followed by active shortened at three velocities. Muscle stiffness increased with activation but decreased as shortening velocity increased. The results suggest that length history determines muscle stiffness, and that history-dependent stiffness influences the contributions of both activation and length perturbations to muscle force.

Thirdly, we used length and activation inputs from guinea fowl running on a treadmill with obstacle perturbations [6] as input parameters in ex vivo work loop experiments using mouse extensor digitorum longus (EDL) as an avatar.

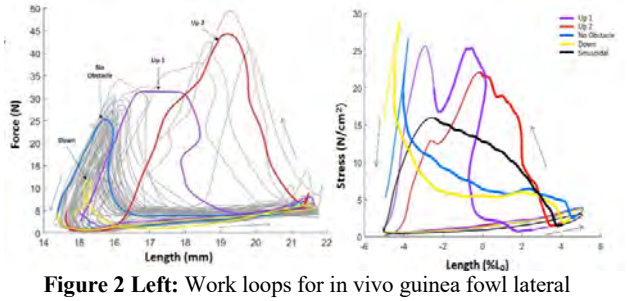

Figure 2 Left: Work loops for in vivo guinea fowl lateral gastrocnemius muscles during treadmill running over obstacles. **Right**: Mouse EDL muscles with the strain and constant activation.

ALTERNATIVE MUSCLE MODELS

We modelled data from in vivo guinea fowl and ex vivo experiments using 1st, 2nd, and 3rd order Hill-type models [3], phenomenological models that included muscle equilibrium length as a parameter [4,5], and a titin-inspired muscle model. We compared R^2 and RMSE among the different models, quantified overfitting using a training/testing protocol, and evaluated the biological relevance of the models by determining the effects of removing selected parameters.

CONCLUSIONS

R^2 increased as the order of Hill-type models increased, but overfitting also increased and biological relevance decreased with the order of the model. Phenomenological and titin-inspired models predicted muscle force with higher R^2 and lower RMSE than all Hill-type models, suggesting that muscle equilibrium length is a useful parameter for predicting history-dependence of muscle force. Calcium-dependent titin-actin binding and interactions between cross-bridges and titin have been suggested as factors that may regulate the equilibrium length of muscle sarcomeres.

3D WHOLE MUSCLE SHAPE CHANGES – EXPLORING A NOVEL APPROACH

Jeroen Aeles[1,2], Peter Aerts [1,3], and Sam Van Wassenbergh[1]

INTRODUCTION

When animals, including humans, move, their muscles contract, and by doing so change shape. While such shape changes are obvious and are inevitable for a muscle when generating force, we know little about its functional role in force production. Little is currently known about 3D whole muscle shape changes, which are evidently complex and non-linear in nature. The ability to ultimately measure shape changes during contraction would drastically improve our understanding of *in vivo* muscle biomechanics. Here we explore a novel approach for experimentally measuring 3D whole muscle shape changes using X-ray imaging. We present preliminary data on a validation experiment.

METHODS

Fresh cadaveric lower limbs of the domestic chicken (*Gallus gallus domesticus*) were used for this experiment. After surgically opening the skin over the posterior side of the lower leg, and removing most of the connective tissue surrounding the muscle, 35 opaque beads (⌀ = 0.35mm) were fixated all around the lateral gastrocnemius with a cyanoacrylate. The distal gastrocnemius tendon was severed distally as well as at the muscle-tendon junctions of the other gastrocnemius muscles. Two beads were implanted into the tendon, and three into the distal tibia (reference). Barium sulphate powder was applied to the entire muscle. High-speed stereo (3D) X-ray videos (750Hz) were recorded while the muscle was stretched cyclically by applying a force on the tendon. Ultrafast computed tomography (<2s) scans were reconstructed from images acquired while rotating the lower leg 360 degrees approximately along its longitudinal axis, with the muscle at resting length. 39 out of the 40 markers (beads) were successfully tracked during two shortening-lengthening cycles using XMALab [1]. The 3D Euclidean distance between each of the 35 muscle markers and the most distal reference marker was calculated for the entire cycle, and compared between the start and end of the cycle. CT slices were segmented in Matlab with Sashimi V1.1 [2].

RESULTS AND DISCUSSION

The distal tendon marker was used as a reference for the stretch-shortening cycles. This marker was displaced along the muscle-tendon line of action over 8.30 and 8.34 mm in cycle 1 and 2 respectively. One of the 34tracked muscle markers only had a displacement of 2.14 and 2.18 mm over cycle 1 and 2 respectively, which was considered too small given the amplitude of the displacement of the reference marker. On closer inspection, it appeared the marker got detached from the muscle and was therefore removed from further analyses. Of the remaining 33 muscle markers, the displacement ranged from 6.15 to 8.86 mm and from 6.11 to 9.05 mm for cycle 1 and 2 respectively.
Very small differences in the distance between the muscle markers and the distal reference marker were found when comparing the distance at the start and end of each cycle (mean: 0.07 ± 0.12 mm and 0.05 ± 0.05 mm for cycle 1 and 2 respectively), indicating no shifts in bead placement along the muscle surface.

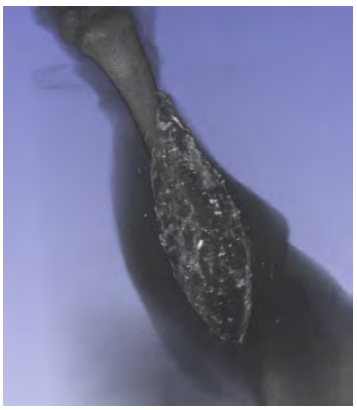

Figure 1 CT reconstruction of the gastrocnemius muscle.

CONCLUSIONS

These preliminary results suggest that the proposed approach can be used to track 3D whole muscle shape changes dynamically, at least during muscle stretching. Currently, we are working on comparing the 3D whole muscle shape between the CT reconstructed scans and reconstructed muscle shapes based on the marker data, as well as creating statistical shape models of these data. Ultimately, we aim to validate this technique for muscle shortening and *in situ* muscle contraction induced by electrical stimulation.

ACKNOWLEDGEMENTS

DIRECT IN VIVO ASSESSMENTS OF PLANTAR FLEXOR FUNCTION TO GUIDE PATIENT CARE

My My Tang and Josh R. Baxter
Department of Orthopeadic Surgery, University of Pennsylvania, Philadelphia, Pennsylvania, USA
Email: josh.baxter@pennmedicine.upenn.edu

INTRODUCTION

Achilles tendon ruptures are devastating injuries that cause long-term functional deficits in two-thirds of patients. Treatment for these injuries in the United States focuses on surgical care within the first 7 days of injury and rehabilitative care during the first 10 weeks of injury. Our thorough investigation of the literature and clinical collaborations suggest that new research models are needed to mechanistically establish optimal treatment strategies. This current study aimed to build confidence in a rat model to test the effects of surgical repair and rehabilitation loading. In this symposium presentation, we will describe our small animal dynamometer, how we use it, and why we think it will strengthen our clinical studies and impact patient care. We tested 2 hypotheses: 1) plantar flexor deficits are caused by an acute Achilles tendon rupture and 2) that repairing the rupture will mitigate some of the functional deficits compared to non-surgical treatment.

METHODS

We designed, fabricated, and validated a small animal dynamometer (see [1] for complete description and validation data). We surgically induced Achilles tendon ruptures in 20 adult male Sprague Dawley rats and repaired the rupture in half of these animals. Then, all animals completed 2-weeks of joint immobilization in plantarflexion followed by 2-weeks of unrestricted cage activity. We quantified isometric plantar flexor torque across the range of ankle motion by maximally stimulating the sciatic nerve. We approximated plantar flexor work as the summed area under the torque-angle curve because patient functional deficits are typically quantified by heel raise height ability. Estimating potential plantar flexor work is a good surrogate measure of this clinical test.

RESULTS AND DISCUSSION

Plantar flexor deficits following non-surgically repaired Achilles tendon ruptures in rats (n=10) closely match our dynamometer measurements we collected in a cohort of patients that were also treated non-surgically [1]. These findings are important because they establish this animal model as a clinically relevant model beyond it's typical use to study isolated Achilles tendon healing biomechanics. Because we have confidence in this animal model, we can now test the isolated effects of different clinical parameters and treatment strategies on functional outcomes. In this first set of experiments, we tested the isolated effects of surgically repaired the ruptured tendon followed by 2-weeks of unloaded immobilization. We found that animals who were surgically repaired suffered plantar flexor functional deficits compared to the control limb, but these functional deficits were lessened compared to animals that were treated non-surgically ($p = 0.037$, **Figure 1**).

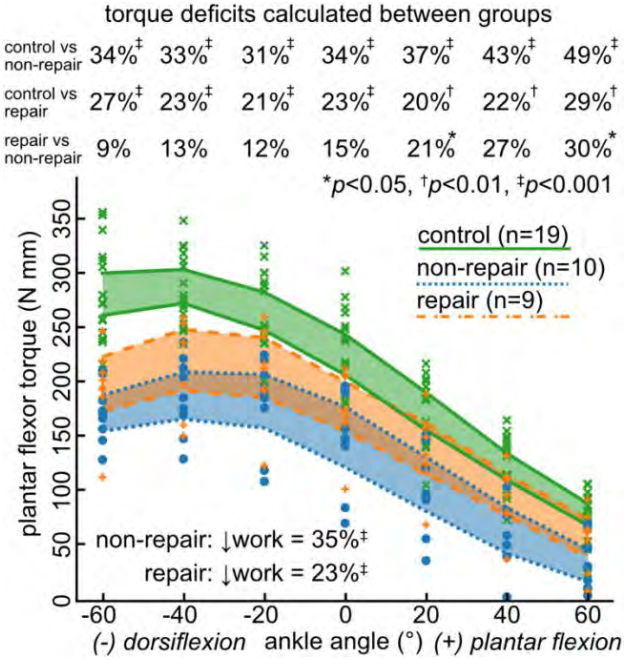

Figure 1. Plantar flexor function across the ankle range of motion decreased following Achilles tendon injury. These functional deficits were lessened in animals that were surgically repaired suggesting that stabilizing the tendon immediately following injury improves muscle-tendon healing.

CONCLUSIONS

Achilles tendon ruptures are typically viewed as an isolated tendon injury. But clinical observations [2] and our small animal experiments suggest that changes to muscle structure explain functional deficits. Our findings support surgical treatment to minimize functional deficits following Achilles tendon ruptures. This model system provides a unique opportunity to understand the basic mechanisms that govern muscle-tendon structure and function across multiple species. Our ongoing work is defining the link between tendon injury, rehabilitation loading, and muscle remodeling.

TASK-LEVEL FEEDBACK CONTROL OF GAIT IS AN EMERGENT PROPERTY OF EFFORT MINIMIZATION IN THE PRESENCE OF NOISE

INTRODUCTION

Deterministic simulations of human and animal locomotion based on effort minimization capture many features of experimentally observed gait mechanics and energetics. However, such simulations do not capture how locomotion is stabilized against sensorimotor noise or external perturbations. The ankle torque response to perturbations of walking balance can be explained by delayed feedback from center of mass (CoM) kinematics [1]. Here, we tested whether this apparent center of mass control strategy emerges from minimal effort simulations of walking in the presence of noise.

METHODS

We performed stochastic optimal control simulations based on a torque-driven skeletal model with five segments (trunk, upper legs, and lower legs) and five degrees of freedom (stance ankle angle, knee angles, and hip angles) [2]. Torques were controlled by feedforward and full state (joint angles and angular velocities) time-varying linear feedback and were corrupted by Gaussian noise. The reference state trajectory for the feedback controller was the state trajectory that would result from applying the feedforward torques in the absence of noise. We solved for control parameters, i.e. feedforward torque trajectories and time-varying feedback gains, that minimized a cost function while imposing mean stride time, mean stride length, and left-right symmetry (of the state distribution) using our recently developed framework for stochastic optimal control [3]. We considered two cost functions. (1) Minimizing expected effort resulted in a minimal effort controller. Effort was modelled as the sum of squared total (feedforward and feedback) torques. (2) Minimizing a weighted sum of feedforward effort and deviations from the reference state trajectory resulted in a trajectory controller. We then generated forward simulations of unperturbed and perturbed walking using the two optimal control laws. Perturbations consisted of support surface accelerations and decelerations of different magnitudes, similar to an experimental protocol we previously applied [1]. We evaluated whether CoM kinematics feedback could explain stance ankle feedback torques in the simulated dataset.

RESULTS AND DISCUSSION

The stochastic optimal control laws stabilized walking across a range of perturbations even though only motor noise was accounted for during the optimization. The feedback ankle torque could be explained by CoM feedback for the minimal effort controller (R^2 = 0.99) but not for the trajectory controller (R^2 = 0.18) (Figure 1).

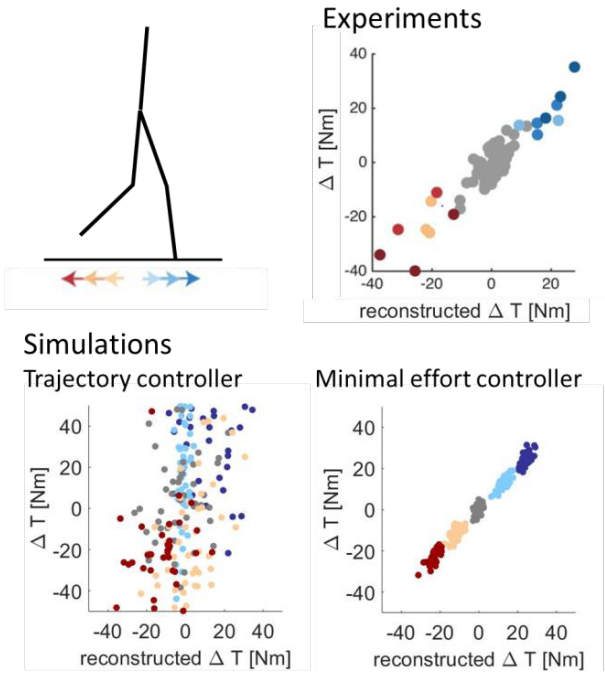

Figure 1 Experimental/simulated feedback torques versus best reconstruction by a linear sum of CoM position and velocity.

CONCLUSIONS

Task-level feedback control for stability is an emergent property of effort minimization in the presence of noise.

Biophysical muscle models for simulating muscle and muscle spindle response to stretch

INTRODUCTION

The fastest two mechanisms that the body uses to recover from a physical perturbation are muscle response to stretch and stretch reflex. Muscle short-range stiffness—rapid, large, and brief increase in force due to cross-bridge dynamics in response to a stretch—is important in both these stabilization mechanisms. However, Hill-type muscle models, based on steady-state forces, do not exhibit short-range stiffness. De Groote et al. phenomenologically added short-range stiffness to a Hill-type model to better predict the initial joint torque and kinematics in a biomechanical model of perturbed balance [1]. Short-range stiffness is also critical in muscle spindle response to stretch, as muscle spindles contain *intrafusal* muscle fibres innervated by sensory neurons, that together drive the stretch reflex. Blum et al. found that these sensory neurons' output can be predicted as a linear sum of force and rate of change of force—yank—from the intrafusal fibres [2]. Despite the significance of muscle short-range stiffness to perturbation responses, we lack widespread use of muscle models capable of predicting short-range stiffness in musculoskeletal modeling.

Biophysical muscle models predict short-range stiffness as emerging from cross-bridge dynamics, making them generalizable across fibre types and behaviors. Short-range stiffness arises when the number of bound cross-bridges is high, e.g., in isometric muscle. It rapidly decreases when sarcomeres are stretched beyond a few nanometres and cross-bridges detach. Here, we compared muscle force response to stretch using biophysical and Hill-type models. We then varied the contractile properties of a biophysical model to evaluate their effect on sensory signals from a muscle spindle.

METHODS AND RESULTS

We used a ramp-and-hold protocol to evaluate muscle response to stretch. Using MATMyoSim, we parameterized a biophysical model to match force from an isolated rat soleus muscle fibre when it was stretched at constant velocity (ramp) and then held stationary (hold) (Fig. 1A). To compare the biophysical and Hill-type models' response to stretch, we generated force-length and force-velocity curves from the biophysical model. We found that, in the biophysical model, force rose sharply at ramp onset, continued a slower rise through ramp, and dropped slowly at hold (Fig. 1A, green). In contrast, force in the Hill-type model rose sharply at ramp onset, plateued through ramp, and dropped quickly at hold (Fig. 1A, purple). Unlike the Hill-type model, the biophysical model also predicted empirically-observed changes in short-range stiffness with muscle activation and prior movement [3].

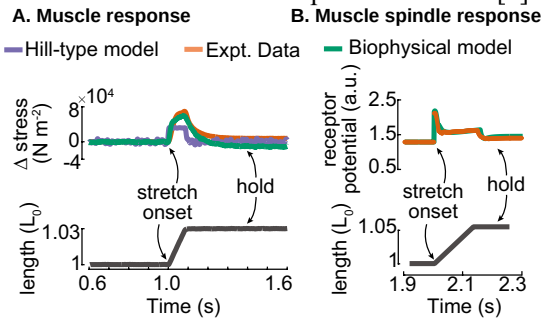

Figure 1: Top rows show experimental data and modelling results of muscle force (left) and muscle spindle sensory output (right) in response to muscle stretch as shown in the bottom rows.

We used a similar ramp-and-hold protocol to evaluate muscle spindle response to stretch. We tuned two biophysical models and used them to predict a phenomenological receptor current, modeled as a weighted sum of the force and yank of a dynamic bag1 fibre, and the force of a static bag2/chain fibre [2]. We tuned the biophysical model parameters to match experimentally measured Ia afferent output from the soleus muscle of an anaesthetized rat in response to a ramp-and-hold stretch (Fig. 1B). Intrafusal fibres express a broad range of myosin types; in our model, varying actin and myosin properties changed the predicted Ia sensory output. The model also predicted empirically-observed dependencies of muscle spindle sensory output on muscle inter-stretch interval, pre-stretch amplitude, sinusoidal stretches, and alpha and gamma drive [2]; such dependencies in behaviorally-relevant conditions would not arise using Hill models.

CONCLUSION

Biophysical muscle models are generalizable across fibre types and behaviors. They may help generate testable predictions about the role of muscles and muscle spindles in sensorimotor control.

INTRODUCTION

Musculoskeletal simulations are gaining popularity for movement predictions and reconstructions (e.g. [1]). These models are usually actuated using Hill-type muscle models. Hill-type models are fitted to static experimental muscle data [2], and could therefore be viewed as early machine learning models. Since different datasets have been used for this fitting process, many variations of the Hill-type model exist [3], while validations and comparisons are limited. Furthermore, static data, and thus Hill-type models, do not represent certain dynamic aspects of muscle mechanics (e.g. [4]). Therefore, we would like to (1) compare the quality of force estimations of different Hill-type model variations, and (2) investigate if we can outperform Hill-type models using a modern machine learning model.

METHODS

We used a dataset of muscle fibre length and velocity (sonomicrometry), activation (electromyography), and tendon force (tendon buckle) of five guinea fowls who ran with different speeds on level surfaces, and surfaces with a sudden height increase or obstacle [5]. Here, we mainly use data of the lateral gastrocnemius of one bird, running at 1.8 m/s and 3.8 m/s on the level surface.

For (1), we implemented 6 different Hill-type models from literature [1, 6-10]. For model [9], we adapted the slack length of the parallel elastic element to 1.2 l_{opt} to obtain realistic forces. We estimated muscle force for each of these models for the trial at 3.8 m/s and compared those forces to the experimental forces.

For (2), we trained a convolutional neural network (CNN) to estimate muscle force from activation, muscle length and velocity using the 1.8 m/s trial. We optimized hyperparameters with a Bayesian approach and an 80/20 data split. We tested the CNN using the trial at 3.8 m/s.

RESULTS AND DISCUSSION

We found comparable mean absolute errors and correlations between three Hill-type models [1,6,7], a higher error and lower correlation for models [8,9], and the worst performance for model [10]. The CNN model matched the experimental data better (Figure 1), leading to the smallest error and highest correlation (Table 1).

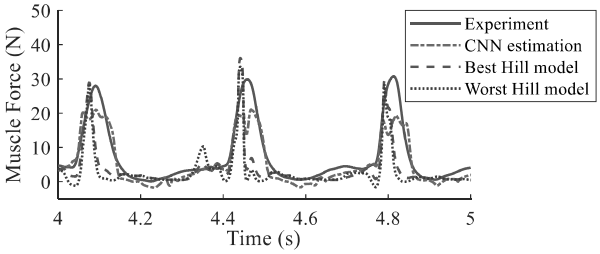

Figure 1 Experimental and estimated muscle force with the Hill-type model with lowest and highest error, as well as the CNN

In this abstract, we have tested the CNN on data of the same muscle and bird. However, for movement simulations, training cannot be performed for each species and their muscles. When we tested on data of another muscle (digital flexor) in another bird, we found that the CNN still outperformed the Hill-type models, but the errors and correlations were more similar.

CONCLUSIONS

We have shown that muscle force estimation lead to small differences between different variations of Hill-type models. The resulting effect on simulation outcomes should be further investigated. We also found that a CNN outperforms Hill-type models. Therefore, more accurate muscle models could potentially be developed using modern machine learning and representative datasets of muscle force generation.

ACKNOWLEDGEMENTS

We acknowledge Jessica Korten's contribution to the Hill-type model comparison.

FROGS AS MODELS FOR ROBOTICS, LIMB CONTROL AND MUSCULAR AGEING

Christopher T. Richards[1]
[1] Comparative Biomedical Sciences, The Royal Veterinary College, London, UK.
Email: ctrichards@rvc.ac.uk

INTRODUCTION

Frogs are known for their stunning diversity in ecology and locomotor behaviour, despite conserved musculoskeletal features across thousands of species. Even frogs of a single species have impressively versatile limbs; they can perform multiple locomotor tasks with little evidence of functional tradeoffs. Frogs are thus an ideal model for studying how vertebrate limbs achieve mechanical multifunctionality. In this talk, I will discuss the integration of experimental, computational and robotic techniques to a) better understand the neuromuscular and biomechanical basis for limb multifunctionality (i.e. swimming versus jumping versus walking) and b) develop hybrid experimental-computational tools to ultimately explore how limb anatomy, musculoskeletal architecture and motor control interact to govern limb motion. The talk will be in four parts. 1) I will present recent work on the mechanics and kinematics of frog jumping versus running. 2) I will overview prior work from my group towards developing "musculo-robotics" [1, 2] approaches involving closed-loop interactions between *in vitro* muscle tissue and a simple swimming robotic model. 3) I will introduce work using a frog jumping simulation interfaced with either a robotic arm or *in vitro* muscle tissue. 4) I will discuss current work investigating how ageing properties of muscle affects the neuro-mechanics of human reaching. From these above approaches we are working to gather evidence for how limb internal morphology (e.g. moment arms, limb inertia) as well as external morphology (e.g. foot shape) interact with locomotor substrate to influence limb dynamics. Furthermore, we are working to better understand how the above anatomically dependent interactions influence the motor control strategy of coordinated tasks such as jumping and reaching. In terms of real-world applications, our we are currently applying our suite of methodology to investigate the ageing process to better understand how age-related neuromuscular degradation leads to loss of limb function.

MEASURING THE MOTION OF HUMAN MUSCLE: DEVICES, DISRUPTIONS, AND DEFORMATIONS

School of Biomedical Sciences, University of Queensland, Brisbane, Australia
Email: t.dick@uq.edu.au

INTRODUCTION

Skeletal muscle is the actuator that powers human and animal locomotion. Muscles function to change length and produce force to enable movement, posture, and balance. Given the intimate links between contractile length, velocity, and force—measurements of muscle length provide insights into the energetics, mechanics, and control of movement. As technology has advanced, measures of muscle length have expanded from two-point measures of length into broader dimensional analysis of muscle motion in both time and space.

The first direct measures of *in vivo* muscle fibre length [1] demonstrated that muscle fibres can shorten while the whole muscle-tendon unit lengthens. A series of studies in animals have since demonstrated that muscle motion and joint motion are uncoupled—owing to fibre rotations and stretching of elastic elements. Just a few years after the first sonomicrometry experiments in animals, B-mode ultrasound emerged as a technique to non-invasively look 'under the skin' and measure muscle-tendon architecture in humans, both at rest and during contractions [2]. The first studies to combine ultrasound with motion analysis demonstrated, perhaps unsurprisingly, that the ankle plantar flexor fascicles behaved near isometrically despite substantial length changes in the muscle-tendon unit during walking in humans [3]. Studies have since illuminated that changes in length of elastic tissues or the rotation of muscle fibres can alter the timing and rate of muscle length changes—with implications for locomotor function. The goal of this presentation is to showcase novel ways our research team is using B-mode ultrasound to look under the skin and measure *in vivo* muscle motion.

METHODS

We have experimentally measured *in vivo* muscle behavior during static and dynamic tasks using B-mode ultrasound. B-mode ultrasound images are analyzed using manual and semi-automated approaches to quantify muscle or tendon length changes, pennation angles, and muscle thickness. In some cases, measurements of muscle dynamics are combined with information about muscle activation, muscle stiffness, or muscle volume from electromyography, shear wave elastography, or magnetic resonance imaging, respectively. Using these tools, we have: (1) explored the influence of spring-loaded ankle exoskeletons on muscle behaviour during steady and perturbed hopping; (2) compared the synchronous fascicle strain patterns in agonist and antagonist ankle muscles during unexpected perturbations to walking; and (3) investigated the influence of internal muscle properties on shape changes and gearing in synergist muscles.

RESULTS AND DISCUSSION

Results from our exoskeleton-perturbation study have shown that assistance at the ankle leads to a reduction in soleus muscle activation, increases in fascicle length change and decreases in muscle forces during perturbed hopping. These changes have competing effects on the mechanics and energetics of lower limb muscles, likely limiting the capacity for series elastic tissues to absorb energy during a perturbation.

During unexpected 'slip' perturbations in walking, we found that the tibialis anterior and medial gastrocnemius fascicle length changes shift from their out of phase behaviour during normal walking to an in phase pattern whereby fascicles in both muscles undergo rapid shortening. These results suggest that effective perturbation recovery may be enabled via a muscle-based latch mechanism which is mediated by co-activation of agonist-antagonist muscles.

Results from our shape chage and gearing study shows that during high force contractions, stiffer muscles bulge less, muscles with higher amounts of intramuscular fat undergo less fibre rotation, and muscles with greater force-generating capacity operate at higher gearing. Interestingly, at submaximal contraction levels, differences in internal muscle properties had a minimal influence on shape changes and gearing.

CONCLUSIONS

Using ultrasound-based measures of muscle in motion, we have shown that measures of muscle fibre length change, architecture, and shape, when coupled with an understanding of muscle physiology, can offer critical insights into the energetics, mechanics, and motor control of movement during a variety of locomotor tasks.

INTRODUCTION

The elephant trunk is an immensely complex appendage with deeply folded skin on the dorsal portion for protection and intermediate wrinkles for gripping slippery objects [1]. The skin covers the inner portion of the trunk, comprised of several thousand muscle fibers that, through actuation, can erect vibrissae or whiskers for added sensing [2]. With no bones or joints, this hydrostat is an infinite degree of freedom system, as any two constraints will have a third in between them [3]. Here, we discuss utilizing different engineering-based techniques, including innovative types of microscopy, work loops, and knitted mimics, to generate a more holistic understanding of the limitations and capabilities of the elephant trunk.

METHODS

The methods described will be that of two different sets of experiments, including both with living African elephants *(Loxodonta africana)* at Zoo Atlanta, as well as diseased African and Asian elephant trunk specimens taken at Humboldt University in Berlin, Imperial College London, and Icahn School of Medicine at Mount Sinai. Additionally, we utilized uni-axial strain testing of elephant trunk skin to determine the mechanical properties of the different load-bearing layers of the skin. Finally, to understand collagen alignment and interaction, pieces of skin were stained and imaged using Second Harmonic Generation Microscopy, Micro-CT, and classical hematoxylin and eosin staining. All experiments and dissections performed were under approved research by Georgia Tech's IACUC and Zoo Atlanta's ethics team.

RESULTS

The elephant trunk has asymmetries in function from the micro to the macro levels. Macro size asymmetries were observed from the muscular to the skin levels. During elongation trials with living elephants, we see the dorsal portion of the trunk elongates 20% more than the ventral portion of the skin. This is due to the asymmetries of skin function at each of these sites. When performing uni-axial tests of the elephant skin, we see a divergence of strain stiffening versus strain softening behavior, with the dorsal skin exhibiting strain softening due to the wrinkled geometry, whereas the ventral skin is strain stiffening. To understand these asymmetries in skin function, we utilized Second Harmonic Generation (SHG) microscopy to view collagen alignment and interaction in the skin. We find that the elephant skin's collagen is entangled across all sections. The uni-axial asymmetries are explained by the pre-tension the collagen in the skin experiences. The dorsal portion of collagen is relaxed with room to stretch and elongate, whereas the ventral collagen is stiff. We conclude that the dorsal folds are built for protection and stretching, whereas the ventral skin is built for wrapping, gripping, and protection. By collaborating with the Matsumoto lab at Georgia Tech, we have worked to understand utilizing knitting's asymmetries to re-create the morphologies and compositional asymmetries in the skin. This has enabled us to generate connections between the collagen orientation of the skin and specific knitting stitches. Additionally, in working with Zoo Atlanta, we have worked to understand the elephant trunk using an in-vivo work loop technique Figure (1).

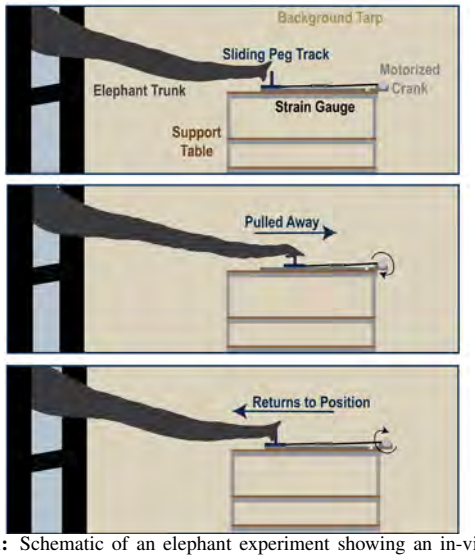

Figure 1: Schematic of an elephant experiment showing an in-vivo work loop technique of hydrostats.

These techniques utilize basic engineering principles, and the model hydrostatic of the elephant trunk has generated new types of bio-inspiration for soft robotics, bio-materials, and conservation technologies.

CONCLUSIONS

Overall the ability of engineers and biologists to share knowledge and techniques allows more scientifically encompassing comparative biomechanics studies to occur. Using uni-axial strain tests, complex materials mimic, advanced microscopy, and work-loop techniques can all be applied to various biological organisms to help advance biomechanics, bio-inspired robotics, and even wildlife conservation. By utilizing these engineering-based techniques and collaborating with biologists, we can discover connections between a macro function and micron-sized discovery, such as non-homogenality of elephant skin explained by collagen entanglement in the skin.

INTRODUCTION

Movement through environments requires responses to varied forces facilitated by rapid processing of multi-modal sensory information and coordinated actuation of limbs and joints [1,2,3]. Responses can be mediated by intrinsic mechanical properties of the musculoskeletal system as well as by neural control to produce force and regulate work output [1]. Muscles have been viewed as motors producing force depending on their activation, strain, and velocity under isometric and isotonic conditions [2]. *In vivo* strain trajectories arise dynamicallly from interactions among neural activation, musculoskeletal kinematics and loads applied by the environment resulting in force production that is not accurately represented in traditional views of muscle [3]. Titin function in active muscle suggests alternatively that muscle develops force through combined effects of activation and viscoelastic resistance to applied loads [2]. Here we present a novel work loop technique that replicates *in vivo* muscle force using a mouse muscle "avatar" during controlled *ex vivo* experiments.

METHODS

In vivo fascicle strain trajectories were chosen from individual rat medial gastrocnemius (MG) (strides =3) [4], and guinea fowl lateral gastrocnemius (LG) (strides = 2) and digital flexor-IV (DF-IV) (strides = 2) [1] muscles during locomotion at various speeds on a level treadmill. Measured *in vivo* strain trajectories and activation patterns from rat and guinea fowl were used as length and stimulation inputs in *ex vivo* work loops on mouse extensor digitorum longus (EDL) (n = 24). Mouse EDL muscles were surgically removed without their tendons prior to experiments. Amplitudes of *ex vivo* strain trajectories were scaled to match *in vivo* passive force rise. Constant (1-ms square wave) submaximal stimulation (45V, 110Hz) was used during *ex vivo* work loops. Stimulation protocols were optimized to account for differences in activation and deactivation kinetics among muscles. For each strain trajectory and stimulation protocol, force was measured and work per cycle was calculated. Relative work per cycle (mJ/g) of *in vivo* and *ex vivo* muscles was compared by dividing work per cycle (mJ) by muscle mass (g).

RESULTS AND DISCUSSION

Our *ex vivo* "avatar" work loop experiments accurately replicated force production and work output in several conditions across rat and guinea fowl muscles at varying speeds based on measured strain trajectories, with an optimized stimulation protocol based on measured EMG *in vivo*. *Ex vivo* experiments using *in vivo* rat strain trajectories and an optimized stimulation protocol at various speeds resulted in high R^2 (R^2 = 0.74 – 0.97) (Figure 1) for force production.

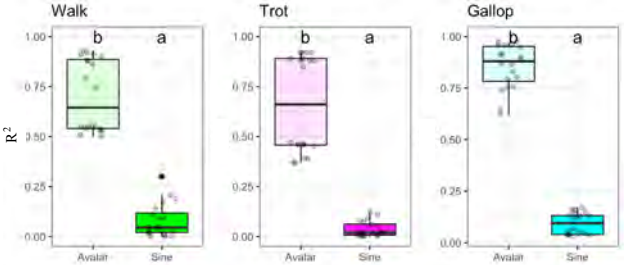

Figure 1: R^2 values of walking (green), trotting (magenta), and galloping (blue) using *in vivo* strain trajectories using both simulation protocols in "avatar" work loop experiments compared to sinusoidal length trajectories at the same frequency.

Additionally, *in vivo* rat relative work per cycle was accurately predicted by *ex vivo* work loops under most strain trajectories and stimulation protocols.

CONCLUSIONS

Results of "avatar" experiments demonstrate that viscoelastic responses to deformation from applied loads can be represented by strain and velocity transients in fasicles. These transients have large effects on muscle force production and regulation of work ouput. Our "avatar" experiments improve prediction of force in general, and particularly as frequency increases. This result suggests that muscles depend more heavily on intrinsic mechanical properties, such as titin, at higher frequencies, because tendons and sensory feedback are not present in "avatar" experiments.

INTRODUCTION

Humans and other animals adapt to expend the least amount of metabolic energy to complete a movement task, both over acute [1-3] and evolutionary timeframes [1,4]. Whether adaptations in locomotor economy occur in response to altered life history, especially during development (e.g. environmental fluctuations, or training in humans) remains less clear. Further, the mechanical underpinning to adaptations in locomotor economy that may occure during development have not been well explored.

We have previously demonstrated that chronic limb loading during development substantially alters locomotor economy; it was found that chronically limb-loaded animals (LL) cary additional limb mass remarkably more economically than control animal (CON) [5]. Here we test the hypothesis that a reduction in mechanical limb work contributes to the observed lower metabolic cost of carrying externally applied limb mass after chronic limb loading. Specifically, we hypothesize that (1) LL animals locomote with added limb mass using less mechanical power than CON animals, and (2) the increase in mechanical power between unweighted and weighted conditions will be smaller for LL animals than CON animals.

METHODS

To study the effect of load stimulus during development on locomotor mechanics, we applied an average load of 3.5% body mass unilaterally to the lower right limb of a group of guinea fowl, continuously from 1-16 weeks of age (limb-loaded group, LL; n = 10). CON birds were raised in the same conditions but with no external limb loading (n = 10). At 16 weeks old, half of the birds (N = 5 per group) were video recorded (100 Hz) walking on a treadmill in both unilaterally loaded and non-loaded conditions. An inverse dynamic formulation was used to analyse swing-phase kinetics. We compared mechanical data to previously collected metabolic data on the same animals in the same conditions [5].

RESULTS AND DISCUSSION

At 16-weeks old, LL animals used 24% less metabolic energy than CON animals to walk with 3.5% BM loading [5]. Our hypothesis that LL had lower mechanical power than CON was, however, refuted. Surprisingly, our data is suggestive of LL animals having even greater mechanical power than CON animals, although this difference was not statistically significant at an alpha of 0.05 ($p = 0.12$, ES = 1.18; figure 1).

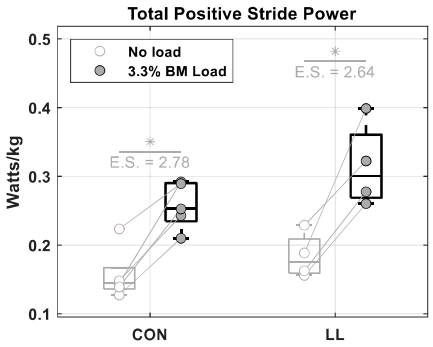

Figure 1 Total positive stride power (watts/kg) for both CON and LL animals. *significant difference due to loading ($p < 0.05$).

CONCLUSIONS

LL animals required no less limb power to carry additional mass compared to CON, despite the observed large reduction in metabolic energy consumption [5]. Increases in limb power in LL animals were isolated to the right (chronically loaded) limb, specifically driven by a larger increase in power at the ankle from unloaded to loaded walking. We propose that muscle-level adaptations may explain the improved locomotor economy in LL animals compared to CON animals. Further work is being conducted to investigate whether adaptations to muscular architecture explain how animals were able to achieve improvements in locomotor economy after growth-period loading. Preliminary findings indicate adaptations not only in muscle mass, but also in sarcomere properties after limb loading.

DOES THE *IN-VIVO* OR *IN-VITRO* ENVIRONMENT IMPACT THE TENDON FORCE-STRAIN RELATIONSHIP?

Introduction

By quantifying tendon properties, such as hysteresis and stiffness, we can improve our understanding of the functional capacity of the musculoskeletal system [1]. However, there is a great disparity in previously quantified tendon properties. For example, tendon hysteresis values obtained *in-vitro* are typically smaller and have less variation than the corresponding hysteresis obtained *in-vivo* [2]. It is unclear if these inconsistencies in tendon properties obtained *in-vivo* and *in-vitro* are caused by differences in methodology or if the mechanical properties of tendons are indeed different in *in-vivo* and *in-vitro* environments. The aim of this study was to determine the hysteresis of a sheep hindlimb tendon *in-vivo* and to compare the *in-vivo* results with those obtained from *in-vitro* experiments that replicated the *in-vivo* conditions. Based on data in the literature, it was hypothesized that the hysteresis obtained *in-vivo* is greater than the corresponding hysteresis obtained *in-vitro*.

Methods

Six sheep were trained to walk on a motor-driven treadmill after which the medial gastrocnemius tendon was surgically instrumented with a custom-made "E"-shaped buckle-type force transducer [3] and Sonomicrometry crystals [4] (Figure 1). All signals were transmitted by telemetry to a custom-built amplifier and synchronized with the use of an electronic synchronization pulse. Following post-surgical recovery, *in-vivo* muscle forces (1040Hz) and tendon lengths (520Hz) were collected while the sheep walked on a motor-driven treadmill (Figure 1). Results from one sheep and three steps walking at a speed of 1.96 m/s where good signals were obtained are presented. Force and sonomicrometry data were low pass filtered (10 and 50Hz, respectively) using a 4th order recursive Butterworth filter. The muscle tendon unit, including part of the calcaneus, was harvested for the *in-vitro* experiments which took place 24h post-mortem and included calibration of the tendon force transducer. The tendon was clamped in a mechanical testing machine with a 10kN load cell and preloaded with 14.9N (Instron). A 20-min rest period was followed by 101 conditioning cycles to 1% strain at 0.5 Hz, and 51 test cycles using strain rates and peak forces that had been measured during the *in-vivo* walking conditions. The tendon was kept hydrated using a 0.9% saline solution that was generously applied every 2-min. Tendon strain was calculated as (length-length$_{ref}$)/length$_{ref}$)*100. *In-vivo* tendon strains were measured for a segment of the tendon length (length$_{ref}$ = shortest segment length observed *in-vivo*), while *in-vitro* tendon strains were measured for the entire tendon length (length$_{ref}$ = tendon length at zero strain). Hysteresis was defined as the difference in area between the force vs strain loading and unloading curves relative to the area under the force vs strain loading curve. This study was approved by the University of Calgary Veterinary Sciences Animal Care committee.

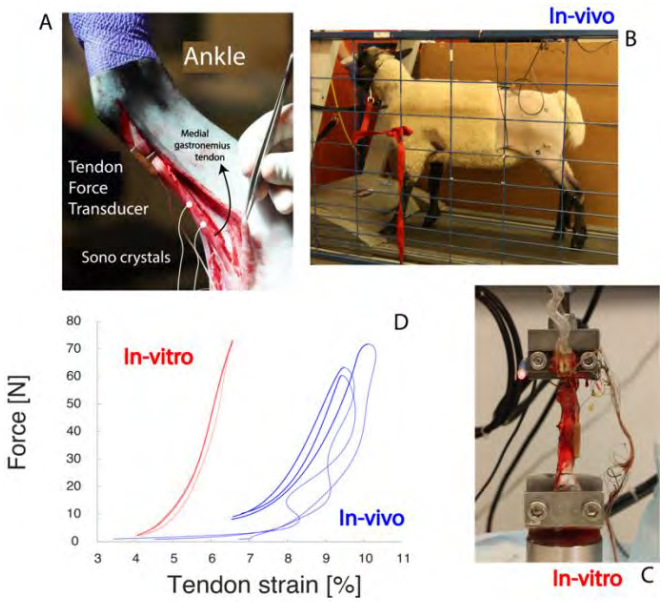

Figure 1: (A) surgically instrumented medial gastrocnemius tendon, (C) tendon clamped in Instron, (D) Force vs strain curve for 3 step cycles of a sheep walking on treadmill at 1.96 m/s (B)(blue line) and replication of the *in-vivo* strain rate and peak force *in-vitro* (red dashed line)(thick lines represent the loading and thin lines the unloading phases).

Results and Discussion

In agreement with published research, we found that the hysteresis for the sheep MG obtained for *in-vivo* conditions (Mean±SD; 57±8%) were greater than those obtained *in-vitro* for comparable loading conditions (14±1%). While our *in-vitro* results agree in magnitude with previous *in-vitro* studies, our *in-vivo* hysteresis values exceed previous estimates from *in-vivo* human studies [2]. Average tendon hysteresis values in humans typically do not exceed 40%, but they often vary greatly between step cycles (e.g., 2-45% [5]). These results suggest that muscular contractions and the *in-vivo* environment may impact the force-strain relationship of tendons.

Significance

The difference between *in-vivo* and *in-vitro* tendon properties for comparable loading conditions warrants caution when relating *in-vitro* tendon properties to *in-vivo* tendon function. Further research examining the detailed reasons for these differences is needed.

INTRODUCTION

Fast impulsive behaviors are some of the most challening for animals to perform given the high forces that are necessary to produce these movements [1,2]. Movements that predominantly occur in the horizontal plane present an additional challenge on flat substrates due to slip occurring if the ratio between the horizontal and vertical components exceeds the coefficient of friction [3,4]. Additionally the surface's coefficient of friction and geometry can influence the angle that slip occurs. Striking snakes propel a large fraction of their anterior body forward with high accelerations [5]. Snakes are found in a wide range of substrates with highly variable surface friction and geometries which can be difficult to strike from. We hypothesize that snakes will strike faster and with more force on a surface with vertically-oriented walls than on an open platform.

METHODS

We obtained four wild-caught blood pythons (*P. brongersmai*) from a commercial provider. This species is suitable for strike studies due to being easily obtainable, non-venomous, and readily strikes defensively. We constructed a rigid strike platform out of a 30.5x30.5x0.7 cm carbon fiber sandwich panel of DragonPlate with a coefficient of friction of 0.3±0.09. Two setups were made, an open setup and a walled setup where we attached two walls on one corner of the strike platform. The strike platform was attached to a 6-axis force sensor (Nano 43). We recorded the strikes at 500 images s^{-1} in dorsal view using an overhead SC1 Edgertronic high-speed camera. Trials were performed in sets of three to five per 24 h and individuals were allowed a minimum of 5 minutes of rest between trials to prevent fatigue. A total of 47 trials were recorded (24 open setup, 23 walled setup). We measured 13 variables: maximum (max.) fore-aft force, max. lateral force, max. vertical force, max. total force, max. head velocity, max. head acceleration, fore-aft impulse, strike distance, max. tail velocity, max. tail acceleration, max. tail displacement, max. fore-aft to vertical force ratio, and percent of the strike above the slip threshold. Last we ran a mixed model ANOVA for each variable with setup, individual, and setup*individual.

RESULTS AND DISCUSSION

Contrary to our hypothesis, snakes displayed high strike performance in both setups (Fig. 1). Our results displayed high individual variability within and between individuals and setups. As a result, the open and walled setups were statistically indistinguishable in most variables measured. Only max. lateral force, max. tail distance, max. fore-aft to vertical force ratio, and percent of the strike above the slip threshold were significantly affected by setup. Our results match what would be expected if the tail and posterior body were being used as an inertial appendage based on the ratio of fore-aft to vertical forces which exceeds the coefficient of friction for a small portion of the strike (~6%) in the open setup which increased dramatically in the walled setup (~39%). This suggests the snakes tail movement is keeping this ratio at or just below the coefficient of friction in the open setup.

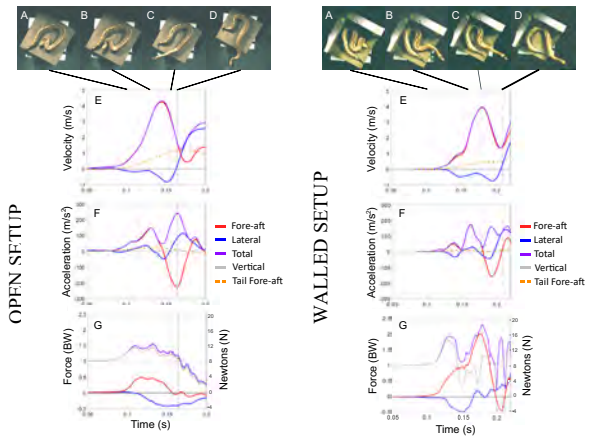

Figure 1. Snake strikes showing the snake during the strike (A-D), velocity (E), acceleration (F), and Force (G).

CONCLUSIONS

We found almost no statistical difference between the majority of variables analyzed for the blood python strikes between an open and walled setup. These results might be explained by the movement of the tail during the strike acting as an inertial appendage. A large variety of snakes encounter open habitats and this mechanism would allow them to exploit a wider range of microhabitats to successfully capture prey.

Creating musculoskeletal models of humans and animals with OpenSim Creator

Adam Kewley[1], Julia van Beesel[1,2], and Ajay Seth[1]
[1] Biomechanical Engineering, TU Delft, Delft, Netherlands.
[2] Dept. of Human Origins, Max Plank Institute for Evolutionary Anthropology, Leipzig, Germany.

INTRODUCTION

Musculoskeletal modeling is an important tool for investigating the biomechanics of human and animal movement. To study patient- or species-specific mechanics, researchers rely on anatomical information from cadavers or biomedical imaging (CT, MRI and Cryo scans). Therefore, there is a growing need to develop specimen-specific musculoskeletal models to predict patient outcomes and to understand how species evolved at a comparative level. While models with specimen-specific musculoskeletal geometries may yield more accurate results [1], the creation of specimen-specific models remains a huge challenge.

METHODS

We developed OpenSim Creator [2] to provide graphical tools to rapidly create, edit and analyze OpenSim [3,4] musculoskeletal models by interfacing directly with the OpenSim API. Model building tools include importing high-resolution meshes (e.g. from CT scans), landmark identification for joint axis and muscle path definition, and adding associated joints and muscles. Whilst editing, live plotting enables model builders to visualize how muscle paths, lengths and moment-arms change with respect to changing landmark selection. Furthermore, OpenSim Creator provides a workflow based on morphometric transformations [5] to morph existing musculoskeletal models to specimen-specific anatomy. We used OpenSim Creator to build and compare specimen-specific shoulder models. Beginning with a generic shoulder model [6] we fit subject-specific CT and MRI scans (superimposed in Fig.1) using its morphometric-transformation tool. We defined the line of action for each muscle from MRI-based muscle volumes and adjusted them to align with the moment arm curves from the generic model. Similarly, OpenSim Creator was used to enhance an existing gorilla model [7] with scapulothoracic joint kinematics as described in the human shoulder model (Fig 2), so that shoulder kinematics could be directly compared.

RESULTS AND DISCUSSION

OpenSimCreator's mesh importer tool enabled real-time placement and orientation of subject-specific bodies and joints based on boney landmarks, which automatically produced an OpenSim model. OpenSim Creator's live plotting provided real-time visual feedback on the effect of attachment points and wrapping surfaces on each muscle's moment arm (Fig. 1 right panel). (Fig. 2). We can now analyze species-specific differences through comparison of the biomechanical capacity of both models (Fig 2).

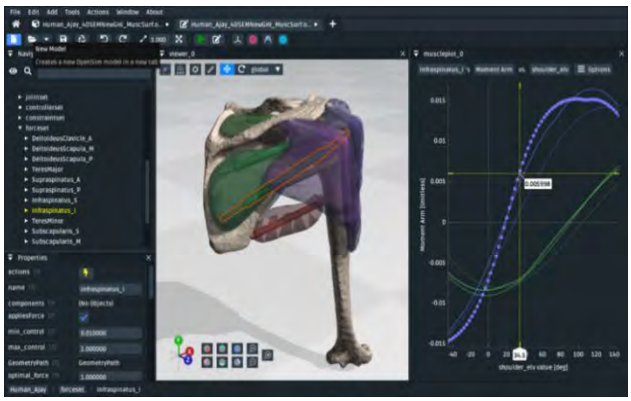

Figure 1: OpenSim Creator tools for creating a subject-specific shoulder model. The navigator (left) presents the composition of the model, model viewers (middle) provide the 3D visualization, and model output plotters like the muscle plotter (right) are updated whenever the model is modified.

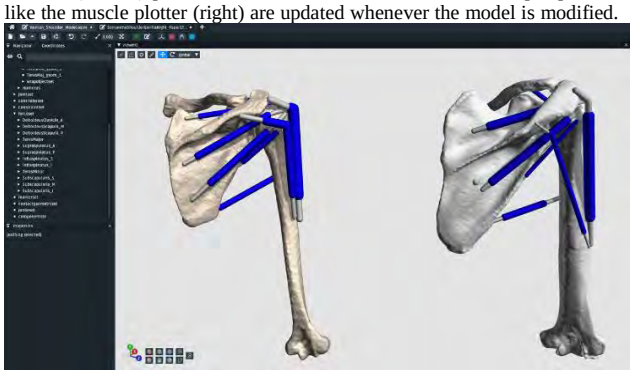

Figure 2: A specimen-specific human model (left) is used to update a gorilla model (right) in OpenSim Creator.

CONCLUSIONS

We developed a graphical model building tool, OpenSim Creator, that includes graphical editing and a morphometric transformation workflow to create new specimen-specific musculoskeletal models. We believe OpenSim Creator, as free and easy to use opensource software [2], will enable more studies with larger numbers and variety of specimen-specific models.

RESIDUAL FORCE ENHANCEMENT: ACTIVE VERSUS PASSIVE CONTRIBUTION

Wejdaan Faridi, Venus Joumaa, Shuyue Liu and Walter Herzog
Faculty of Kinesiology, University of Calgary, Calgary, Canada
Email: Wejdaan.Faridi@ucalgary.ca

INTRODUCTION

Residual force enhancement (rFE) is the increase in isometric force observed following active stretch compared to purely isometric contractions at the same final muscle length and level of activation [1]. rFE is thought to be caused by an active component, associated with actin-myosin cross-bridges, and a passive component, associated with titin [1]. The relative contribution of the active and passive components to rFE is currently unclear.

In the muscle rigor state (devoid of ATP), all possible cross-bridges are attached to actin [2] in a uniform post-power stroke conformation, and therefore, the contribution of cross-bridges to force in the rigor state is thought to be the same following active stretch and purely isometric contractions. Any remaining difference in rFE in the rigor state would be attributable to the passive component.

Our purpose was to investigate the contribution of the active and passive components to rFE by exposing single muscle fibres in the force-enhanced and isometric reference states to rigor conditions. We hypothesized that the rFE in rigor would decrease but would not be abolished.

METHODS

Single fibers (n=8) from rabbit psoas muscle were harvested, skinned, and prepared for mechanical testing as previously described [e.g., Liu et al., 2022]. Fibres were then activated at an average sarcomere length of 2.4 um, stretched to a sarcomere length of 3.0 um, and then exposed to a rigor solution for 90s. For reference trials fibers were activated at an average sarcomere length of 3.0 and then exposed to the rigor conditions for 90s (Figure 1). rFE was compared between the two trials before and after incubation in the rigor solution.

RESULTS AND DISCUSSION

Contrary to our hypothesis, rFE increased from 8.5±4.5% to 17.1±4.0% (0.042±0.020 to 0.073±0.023 mN) following submersion in the rigor solution.

Assuming that the active component contribution is similar for the isometric reference and the force-enhanced conditions in the rigor solution, a possible explanation for the increase in rFE may come from an increase in titin stiffness when the number of cross-bridges increases in rigor solution [3].

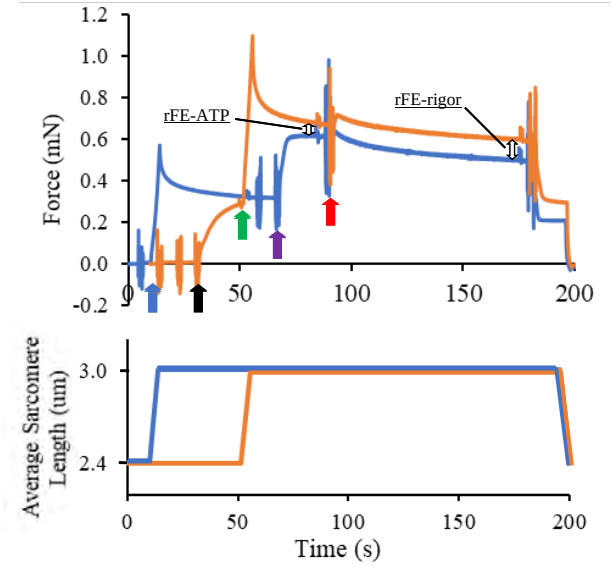

Figure 1 Force and average sarcomere length as a function of time for an active stretch (orange) and a purely isometric (blue) reference contraction performed with a single fibre from the rabbit psoas muscle. For the active stretch condition, the fibre was activated at a sarcomere length of 2.4 um (black arrow), and then actively stretched to a sarcomere length of 3.0 um (green arrow). For the purely isometric contraction, the fibre was passively stretched to a sarcomere length of 3.0 um (blue arrow), and then activated (purple arrow). At steady-state for both conditions, the fibre was transferred into a rigor solution (red arrow). rFE was measured in the activating (rFE-ATP) and the rigor (rFE-rigor) solutions (double headed black arrows).

CONCLUSIONS

The results of this study suggest that the passive component primarily contributes to the development of rFE. However, this conclusion relies on the assumption that the active component was effectively controlled with the induction of a rigor state. Further research is required to better understand the behaviour of cross-bridges in a rigor state.

Kinetics of a collective load carrying in ants

J. Drapin[1], V. Fourcassié[1] and P. Moretto[1]
[1] Centre de Recherches sur la Cognition Animale (CRCA)- Centre de Biologie Intégrative (CBI), Toulouse, France.
Email: pierre.moretto@univ-tlse3.fr

INTRODUCTION

Cooperative performances of social insects are transforming robotics perspectives because of their remarkable organisation to solve complex tasks. A cooperative transport occurs when a group of individuals works together to move an otherwise unmanageable object. Yet, the phenomenon of collective transport among worker ants is still poorly understood, although its existence has been reported in at least 40 genera of different subfamilies of Formicidae [1]. Advances in technology allow to acquire precise kinematics of the whole-body segments as well as detailed morphometric data [2]. A 2D kinematic analysis of a collective transport observed in *Paratrechina longicornis* has been performed. It enables us to attempt a first estimation of the forces and momentums applied by ants to move and turn a carried item.

METHODS

A camera and 3 infrared strobe spots all synchronized and sampled at 300Hz recorded the kinematic of a group of 4 ants that collectively carry a load (Fig.1a). The Vicon Motus (v10) software enabled calibration with a Lego® brick and to define a 2D external frame. The corners of the carried object, as well as the mandible distal (m_d) and head proximal extremities (neck) of each ant, were tracked to build a poly-articulated model including the 4 ant's heads and the load they transport. The forces ($\vec{F}_i=m_i.\vec{a}_i$) and momentum ($\overrightarrow{Mz}_i=Obj.\vec{m}_d\wedge\vec{F}_i$) applied by ants were determined from their body masses (m_i), as well as the accelerations ($\vec{a}_i$) of the head and object center of mass (Obj). The Fundamental Principle of Dynamic (PFD) enabled us to verify the accuracy of the estimates by comparing the sum of ant forces then momentum to the linear and angular accelerations of the object having its own mass and inertia momentum.

RESULTS AND DISCUSSION

It occurred that ants first moved the object to the left during 2.5" then rotated it clockwise. Our results are in good agreement with the observations and would enable us to precise the coordination and synergies across ants. During the first "translation" phase to the left, the ant's forces were negative in X and similar for all ants (Fig.1b). The negative momentums of ants 1 and 4 induced counter-clockwise rotation compensated by ant 2 (yellow, Mz > 0) while ant 3 was neutral (red, Mz ~ 0). The Mz of ant 2 (yellow, Fig.1d) decreases after 2.5" to become negative after 3.5" inducing the clockwise rotation of the object while all ants were acting in the same way.

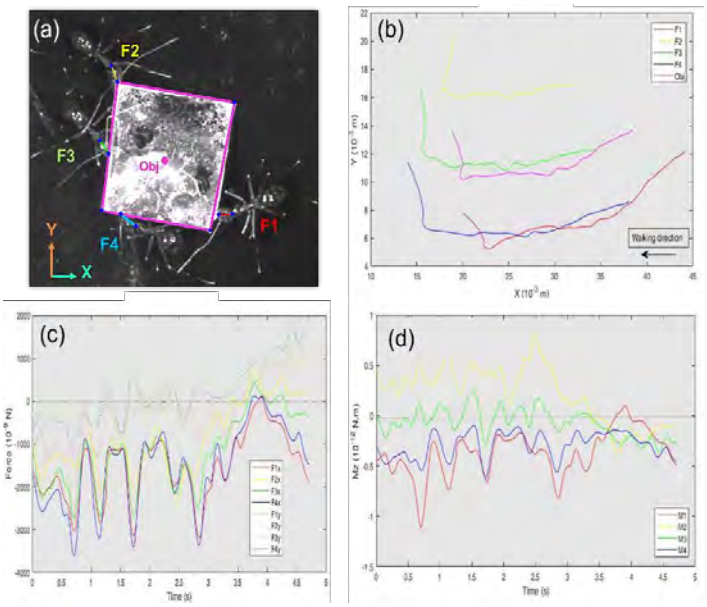

Figure 1 (a) Locations of the tracked points (i.e., mandibles and ant's necks, 4 corners of the load). Ants were moving towards the nest located on the left, which explains the negative values of the X coordinates. **(b)** Ant's and load center of mass trajectories. Time course of the forces **(c)** and momentum **(d)** respectively on the X, Y and Z axis.

CONCLUSIONS

The purpose of this study was to test a method to estimate the forces applied by four ants on a load they collectively carry to measure the 6 components of the torso applied by each ant. Our estimates in respect to the PFD appear accurate and the method seems to enable us to discern the action forces applied by ants on the object they collectively carry. It is confirmed by the moment of forces they apply, which is in agreement with the object rotation around its center of mass. Further investigations will enable us to precise the method to consider both 3D translations and rotations and finally address the synergies and the efficiency of the ant team.

Characterizing residual and passive force enhancements in cardiac myofibrils

Introduction

Residual force enhancement (RFE) is defined as the increase in the steady-state, isometric force of a muscle following an active stretch compared to the corresponding (same length, same activation) force of a purely isometric contraction. RFE has been consistently observed in skeletal muscle. However, there are conflicting observations regarding the occurrence of RFE in cardiac muscle [e.g., 1, 2]. The presence of RFE in cardiac muscle may not necessarily improve cardiac function but may provide insight into the possible mechanism of RFE. It has been suggested that the molecular spring, titin, plays a major role in RFE in skeletal muscle. Cardiac muscle has shorter titin isoforms than skeletal muscle, and thus might show different RFE properties compared to skeletal muscle. The purpose of this study was to re-examine RFE in cardiac myofibrils, thereby resolving the controversy that exists in the literature, and gain novel insights into cardiac RFE based on the eventual findings.

Methods

The experimental setup is demonstrated as previously [3]. Briefly, single myofibrils were prepared from the left ventricle of rabbits, and mounted on a custom-built setup on an inverted microscope. RFE was measured following active stretching of rabbit cardiac myofibrils across three different sarcomere length (SL) ranges, 1.8, 2.0, and 2.2 µm, while the stretching amplitude was kept the same, at 0.2 µm (n = 8 for each). We then repeated the same measurement at the final SL of 2.2 µm when actively stretching 0.4 µm (n = 8), to see the effect of stretching magnitude to RFE in cardiac myofibrils.

Results and Discussion

All 32 myofibrils that were tested in this study exhibited RFE. Following stretches of 0.2 µm/sarcomere, the total stresses after active stretching were significantly greater than the reference stresses, ranging from 13% - 19% (Fig 1A). There was no statistical difference in the magnitude of RFE among the three different sarcomere length rages (p = .20; Fig 1A). When the stretching magnitude was different (i.e., 0.2 µm or 0.4 µm) while the final SL was the same (2.2 µm/sarcomere), greater magnitude of RFE was observed with increasing stretching magnitude (p = .038; Fig 1B).

RFE is thought to be caused by a stiffening of titin upon muscle activation, by either calcium binding to titin and/or titin binding to actin [e.g., 4]. Since cardiac muscle clearly produced RFE in our study, we suggest that cardiac titin can lead to RFE, by interacting with actin filament. The specific mechanism by which titin indeed regulate active force needs further investigation.

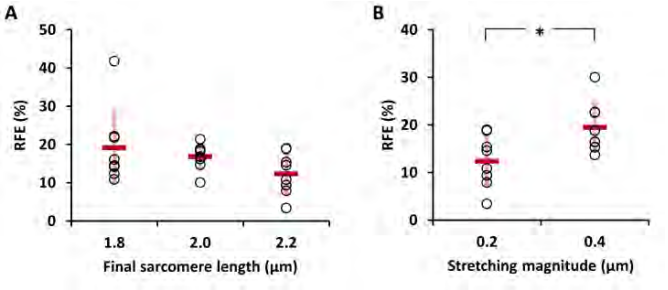

Figure 1. (A) RFE (%) at each final sarcomere length (SL) when the myofibrils were actively stretched by 0.2 µm. (B) RFE (%) at the same final SL (2.2 µm) when the stretching magnitude was different. The opened circle represents each data point measured from a single myofibril, and the red horizontal and vertical bars represent the average and one standard deviation, respectively.

A few studies observed the opposite findings to ours that they found no RFE in cardiac myofibrils/fibre bundles after active stretching. We believe that it is because of the different methodologies used in each study, such as the different speed of stretching of myofibrils, or different timing of active stretching during their experimental protocols.

Conclusions

We conclude from the results of our study that cardiac myofibrils have RFE properties similar to those found in skeletal muscle. Therefore, whatever the mechanisms are for these properties, they are likely contained in both cardiac and skeletal myofibrils, suggesting (but by no means proving) that RFE are caused by the same mechanism(s) in all striated muscles.

THE INTRINSIC AND NEURALLY-MEDIATED CONTRIBUTIONS TO THE BALANCE-CORRECTING TORQUE RESPONSE DIFFER BETWEEN THE ANKLE AND HIP

Kristen L. Jakubowski[1*], Giovanni Martino[1], Owen N. Beck, Gregory S. Sawicki[2], Lena H. Ting[1]
[1] Wallace H. Coulter Department of Biomedical Engineering, Emory University & Georgia Institute of Technology, Atlanta, USA [2] George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, USA *Email: kjakubo@emory.edu

INTRODUCTION

To maintain balance in response to a perturbation (e.g., not fall), one needs to produce a corrective torque rapidly. The torque arises from the musculoskeletal system's intrinsic mechanical properties—including muscle short-range stiffness—at the time of the perturbation and from delayed muscle activation from neurally-mediated sensory feedback pathways, with the delay varying depending on the feedback pathway (e.g., short-latency, long-latency, or volitional responses) [1]. While these mechanisms are well-established, to our knowledge, no one has independently quantified the intrinsic and neural contributions to the balance-correcting torque response across different joints. Thus, this study aimed to quantify the intrinsic and neural contributions to the torque response at the ankle and hip.

METHODS

We assessed reactive leg joint torques to backward support surface perturbations in 7 healthy young adults (25 ± 4 years). Participants maintained standing balance during randomized ramp and hold perturbations at 12 cm or 75%, 85%, and 95% of their step threshold, each tested four times. Whole-body kinetics and kinematics were used to estimate ankle, knee, and hip torques using the OpenSim Inverse Dynamics (ID) tool [2].

To differentiate the intrinsic and neural contributions, we implemented a modified version of the previously developed sensorimotor response model (SRM) [3]. Similar to previous work, center of mass (COM) kinematics were used as the input into the SRM [3]. Parallel loops were added to the SRM to predict 1) non-negative signals, as prior versions only estimated positive signals, like electromyography (EMG; and 2) the response to both CoM acceleration and deceleration since torque is the net effect of muscle activation (Fig 1). Our modified SRM model can differentiate the intrinsic and neural contributions by evaluating the time delays (λ) of the parallel loops since the intrinsic components will have a nearly zero-delay. In contrast, the neurally-mediated components will have delays specific to the feedback pathway.

RESULTS

At all perturbation magnitudes, we found that the intrinsic and neural contributions to the reactive torque response differed between the hip and ankle. Namely, we observed an intrinsic component at the hip (blue) but not at the ankle (red; Fig 1). At the hip, two loops occurred at nearly "zero-delay", with one occurring in sync with the positive peak in COM acceleration (solid blue line) and the other with the negative peak in COM acceleration (dashed blue line). However, we did not observe a "zero-delay" loop at the ankle.

At the hip and ankle, two delayed loops were required to accurately model the response, separated into a "short" and "long delay" component. Since the delays associated with the short and long-delayed loops are different, they likely arise from different sensory feedback pathways (e.g., long-latency vs. volitional).

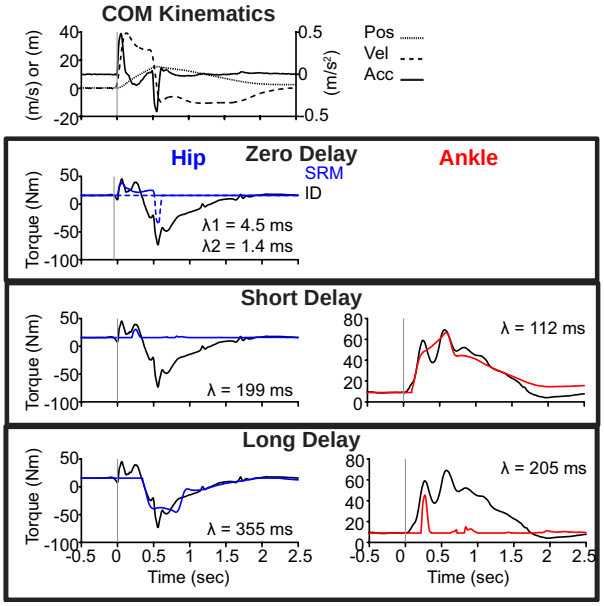

Figure 1 Exemplary data from a perturbation at 95% of step threshold. For the hip (blue) and ankle (red), a multi-loop SRM model was implemented to reconstruct the inverse dynamics (ID) derived joint torques. Center of mass (COM) acceleration (solid), velocity (dashed), and position (dotted) were used as the input into the SRM. The SRM loops were separated based on their delays (λ). The grey line represents the start of the perturbation.

DISCUSSION & CONCLUSION

The lack of an intrinsic (zero-delay) component at the ankle may occur because the compliance of the Achilles tendon is attenuating the short-range stiffness response. However, there is an intrinsic contribution to the hip response since the tendons are stiffer. This results in both intrinsic and neurally-mediated components contributing to the response at the hip, while the neurally-mediated components primarily dictate the response at the ankle.

Summary

The hand and wrist present some of the most challenging structures in the study of biomechanics, as well as in the evaluation of many biomechanical principles. Historically, biomechanics research of the hand and wrist has been underdeveloped when compared with that into other areas of the musculoskeletal system. While numerous biomechanical studies have been initiated by surgeons and engineers, cooperative efforts among scientists, anatomists, engineers, and clinicians in surgery and therapy are required to progress research avenues and further improvement of treatment modalities and functional outcomes. The symposium for hand and wrist biomechanics was first held in Brussels, Belgium 30 years ago in 1992. In 2012, Hand and Wrist Biomechanics International (HWBI) was founded with the aim to provide opportunities for global scientific exchange of knowledge in this field and to promote collaborative, interdisciplinary work to better understand and treat these complex joint systems. As a Technical Group of the ISB we are hosting a one-day Symposium within the 2023 ISB Congress. The four sessions consist of keynote and short talks, representing research from across the globe, and continuing our tradition of reporting on the latest research. The day will also provide opportunities to discuss tools and techniques, review challenges, and celebrate successes in this intriguing area of biomechanics.

Recovery of thumb joint movement for patients with severe carpal tunnel syndrome

Hiroshi Kurumadani[1], Akira Kodama[2], Teruyasu Tanaka[2] and Toru Sunagawa[1]

INTRODUCTION

Carpal tunnel syndrome (CTS) is a common entrapment neuropathy of the upper extremity that causes the symptoms, such as numbness, pain, and paralysis of thenar muscles. In severe CTS cases, the thenar muscle paralysis results in a loss of the thumb joint movement, which affects the activities of daily life. Previous reports have indicated that the surgical treatment, such as carpal tunnel release, reduces the symptoms of CTS[1]. Although surgical treatment, such as carpal tunnel release, reduces numbness or pain in severe CTS cases[2], it is unclear whether the thumb joint movement is improved by the surgical treatment. The purpose of this study was to examine the recovery of thumb joint movement in patients with severe CTS.

METHODS

16 hands of 12 patients with severe CTS (Padua classification: severe 8 hands, extreme 8 hands) and 16 hands of 8 healthy adults participated in this study. Data of the severe CTS patients were collected before, 6 months after, and 12 months after surgical treatment by carpal tunnel release. For thumb joint movement, the thumb joint angles were obtained during the thumb circumduction movement as a task. Ten spherical reflective markers were attached to the thumb tip, proximal phalanx, metacarpal, and dorsal surface of the middle metacarpal. A three-dimensional motion capture system recorded the displacements of the markers during the task. From the marker displacements, the joint angle of flexion/extension, abduction/adduction, and pronation/supination in the thumb carpometacarpal (CM) joint, and that of flexion/extension in the thumb metacarpophalangeal (MP) and interphalangeal (IP) joint were calculated using Euler angles. The joint angle ranges of each joint during the task were calculated. From the markers on the thumb tip, the trajectory area and perimeter of the thumb tip during the task were calculated, and the roundness was also calculated from the area and perimeter. The results were compared between healthy adults and patients with severe CTS by ANOVA.

RESULTS AND DISCUSSION

The joint angle range of the abduction/adduction of thumb CM joint in severe CTS did not differ from that in healthy adults at 12 months postoperatively. The joint angle range of flexion/extension of the MP joint in severe CTS was significantly improved at 12 months postoperatively compared with preoperatively and 6 months postoperatively; however, it was lower than that in healthy adults (Figure 1). The joint angle range of the thumb CM joint flexion/extension, pronation/supination, and IP joint flexion/extension was significantly lower in severe CTS than in healthy adults both preoperatively and postoperatively. The thumb MP joint movement may be improved due to recovery of tendon gliding disorder. The trajectory area of the thumb tip was significantly greater at 12 months postoperatively than at preoperatively and 6 months postoperatively (Figure 1). The roundness was significantly improved at 12 months postoperatively than at preoperatively. There were no significant differences in the perimeter. The recovery of the trajectory area may reflect the improvement in the MP joint movement.

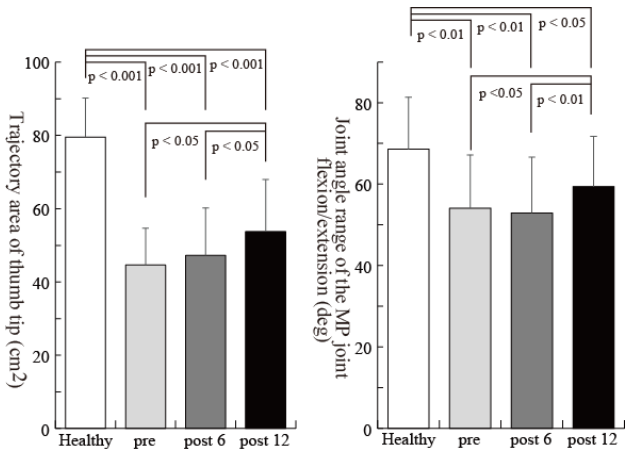

Figure 1 Results of trajectory area (left) and flexion/extension angle range of the MP joint (right).

CONCLUSIONS

Patients with severe carpal tunnel syndrome may have improved thumb joint movement due to recovery of thumb MP joint movement rather than thumb CM joint movement.

MEDIAN NERVE DEFORMATION INCREASES DURING REPEATED EFFORTS OF A PULP-PINCH GRIP TASK

Denise Balogh[1] and Aaron M. Kociolek [1]

[1] Department of Physical and Health Education, Nipissing University, North Bay, Canada.
Email: dbalogh798@my.nipissingu.ca

INTRODUCTION

Carpal tunnel syndrome (CTS) is a common peripheral neuropathy in workers exposed to occupational risk factors, including repetitive and forceful gripping **[1]**. The development of CTS is therefore quite multi-faceted, with several injury mechanisms contributing to the compression of the median nerve within the carpal tunnel **[2]**. Increased carpal tunnel pressure is a well-established injury mechanism, which increases with grip force magnitude during a pulp-pinch grip **[3].** This increase and redistribution of pressure in the carpal tunnel may further result in displacement and deformation of the median nerve.

Several studies have used ultrasound to investigate the effects of occupational risk factors on carpal tunnel dynamics **[4,5].** Turcotte & Kociolek **[4]** investigated the effects of non-neutral wrist postures and grip force magnitude on both median nerve deformation and displacement **[4].** However, there remains a need to assess the effects of repetitive gripping tasks including varying rates of force development.

METHODS

Twelve healthy participants performed a repeated grip task using a digital dynamometer (MIE Medical) while their carpal tunnel was scanned with ultrasound (L15, Clarius). The grip task involved pulp-pinching 3 consecutive times from 0% to 40% of maximal voluntary force (MVF), which was also performed at 3 different rates of force development (RFD): acquiring the 40% MVF target over 1sec; 2sec; and 5sec. A custom program (LabView, National Instruments) provided visual feedback of the force matching profiles and collected grip forces at 1000Hz.

Static images were extracted from ultrasound Cineloops at intervals of 10% MVF (from 0% to 40% MVF) along the ramp up phases of the grip tasks as well as .5sec before the start of each ramp and .5sec after 40% MVF was reached. From the images, deformation measures of median nerve circularity, width, and height as well as displacement were calculated (ImageJ, National Institutes of Health). A 3-way repeated measures ANOVA tested the effects of grip force magnitude, ramp (pinch) number, and RFD on all outcome measures of the median nerve (α=0.05).

RESULTS AND DISCUSSION

Median nerve width significantly decreased as a function of grip force magnitude ($F_{1,11}$=10.85, p=.007) and ramp number ($F_{1,11}$=8.35, p=.015; Figure 1). There was also a main effect of ramp number on median nerve height, with increased height in ramp three vs. ramp one ($F_{1,11}$=7.98, p=.017). These results indicate that the nerve continued to deform with increasing force and repeated pinch grips.

Median nerve displacement also increased with grip force magnitude from 0% to 40 % MVF ($F_{1,11}$=8.62, p=.014). However, displacement of the median nerve was greatest during the first ramp ($F_{1,11}$=13.89, p=.003), with very little displacement in the second and third ramps. These results indicate an initial re-arrangement of structures within the carpal tunnel upon initiation of a repeated grip task. There were no significant differences between the three RFD.

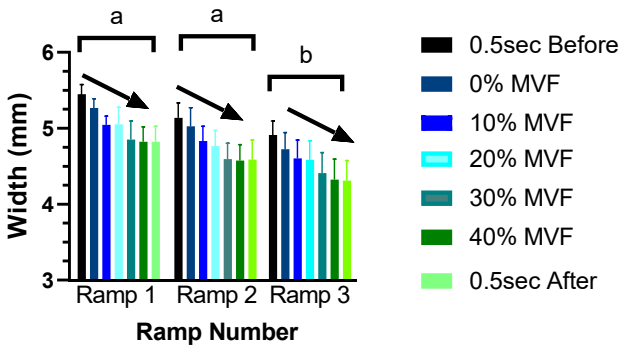

Figure 1. Mean (± SEM) median nerve width as a function of grip force and ramp number. Letters (a,b) indicate significant differences between ramps 1 to 3. Downward arrows indicate a significant decreasing linear trend of width with increasing force magnitude.

CONCLUSIONS

Median nerve displacement and deformation increased with grip force magnitude and repetition (i.e., pinch ramp number). We believe increased localized pressures during the grip task may lead to median nerve deformation as well as entrapment within the carpal tunnel during a repeated grip task.

STABILITY OF THE MIDCARPAL JOINT POST SCAPHOIDECTOMY IN DIFFERENT WRIST TYPES

Nicholas Parody, MSc; Catherine Petchprapa MD; Steven Glickel MD; Ronit Wollstein, MD
Orthopedic Surgery, NYU Langone Health

INTRODUCTION

Partial scaphoid excision has been employed to treat arthritis of the scaphoid-trapezium-trapezoid and radioscaphoid joints [1-4]. Because some patients developed midcarpal instability, utilization of this technique has been limited [2, 5, 6]. Recent studies have identified two distinct structural patterns of the midcarpal joint. Type 1 wrists have a lunate-capitate facet, and type 2 wrists have a lunate-hamate-capitate facet [7]. The structure of the midcarpal joint affects the transfer of forces through the wrist [8, 9]. We hypothesize that midcarpal joint structure will affect force transference through wrists with distal and proximal pole excision. Understanding these mechanical patterns may help in identifying those wrists that are prone to develop significant midcarpal joint instability following partial scaphoid excision, allowing a more personalized approach to scaphoid nonunion and wrist arthritis.

METHODS

Sixteen wrist CT scans were anonymized and converted to .stl files to be used with Fusion360 (Autodesk, v.2.0.14109). Ten were categorized as type 1, with the remaining six being type 2. Five wrists were selected at random from each group to be used in the simulation. Each bone was made into a separate body and given the mechanical properties of cortical bone. The scaphoid was split into proximal and distal halves by cutting the bone at a 40° angle from its base with the ulna. A 100N load was applied to the dorsal crests of the trapezoid and capitate. The displacement of the trapezoid, trapezium, scaphoid, capitate, and hamate were recorded in the x, y, and z directions after the load was applied. These displacement values were then averaged across each bone. The two-sample t-test was used to compare the displacement values between both wrist types and wrists that have and have not undergone a scaphoidectomy.

RESULTS AND DISCUSSION

The transfer of force through the trapezoid/STT joint and hamate was significantly different after proximal scaphoidectomy. There were no statistically significant differences in the displacements of the evaluated bones in type 1 and 2 wrists ($p = 0.05$) that underwent scaphoidectomies when compared to each other. It is likely we were underpowered to detect significant differences in a distal partial scaphoidectomy.

CONCLUSIONS

1) Partial excision of the scaphoid was found to affect the transfer of forces through the STT and midcarpal joints in type 1 wrists.
2) Further study is needed to better understand the transfer of forces in these two procedures and observe any potential trends.

INTRODUCTION

The Eaton-Littler stress-view radiography has been widely used to measure joint laxity and subluxation of the thumb carpometacarpal (CMC) joint for assisting in the diagnosis and severity classification of osteoarthritis. However, recent studies have shown its disadvantages, such as inconsistent or poor intra-observer or inter-observer reliability and a lack of compelling correlation with patients' clinical characteristics[1]. Furthermore, the scientific evidence regarding our understanding of the relationships among the extent of CMC joint subluxation, joint contact pattern, amount of applied stress, and assessing postures when performing a thumb CMC stress-view radiograph is still scant. Besides, sex and age may affect joint mobility. Therefore, this study aimed to assess the effect of age and sex on the subluxation of the thumb CMC joint via a novel stress-view measuring system, in which the amount of stress applied to the joint and the subsequent joint subluxation would be recorded and analysed, respectively.

METHODS

Twenty-eight healthy participants were recruited in this study. They were divided into three groups, the young group (20-39 years old; 5 males & 5 females), the middle-aged group (40-59 years old; 3 males & 5 females) and the elderly group (over 60 years old; 5 males & 5 females). The custom stress-view evaluation system(SvES)[2] collected the stress applied to the CMC joint and the subsequent joint subluxation. The SvES includes a hand-supported frame and a force transducer. Three-hand postures were set to induce subluxation of the first metacarpal bone respective to the trapezium by conducting a stressed force on the thumb. They were determined as follows: (1) MP_S: the participants positioned their thumbs, with the nails parallel to each other, and pressed against the transducer using their metacarpophalangeal joints at the lateral side of both thumbs with the frame(Fig.1); and (2) KP_S: the participants held the force transducer between their thumb pad and the proximal interphalangeal joint of the index finger in the key pinch posture with hand on the frame; and (3) KP: the similar posture as KP_S without the frame and the palm side was touching the table. A fluoroscopic system obtained real-time moving images of the hand, with the main focus on the CMC joint. The image recording frequency was set at 10 Hz. The fluoroscopic images and the force data were collected synchronously.

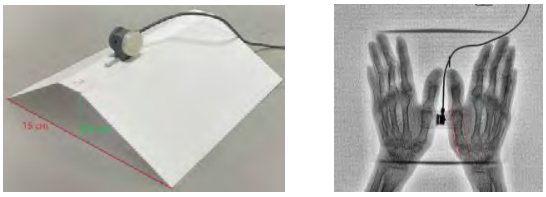

Figure 1 The main body of the custom stress-view evaluation system(left). The radiographic image used to determine the CMC joint radial subluxation ratio, where A indicates the amounts of the first metacarpal subluxation from the trapezium, and B represents the total width of the base of the first metacarpal bone (right)

RESULTS AND DISCUSSION

Table 1 shows the subluxation ratio occurring at the pressed force reaches maximal. Preliminary results suggested that the subluxation ratio of MP_S in the elder group was lower than in the other two age groups. This result might be caused by the soft tissue characteristics related to ageing. The effect of gender shows no particular trend, which may be due to the limited cases.

Table 1: The subluxation ratio of different age groups and gender.

	Male						Female					
	MP_S		KP_S		KP		MP_S		KP_S		KP	
Group	M	SD	M	SD	M	SD	M	SD	M	SD	M	SD
young	55.4	16.9	41.1	15.4	38.9	8.5	46.6	19.6	31.5	12.1	33	8.3
middle-aged	47.9	4.5	28.8	11.4	29.7	16.5	42.2	7.6	17.4	10.9	30.1	7.3
elderly	33.5	17.2	22.2	19.6	30.2	11.7	38.6	14.1	26	17.5	36.4	10.4

CONCLUSIONS

The study's result suggested that age affects the status of joint subluxation, and the effect of age should be considered in future clinical analysis. For future work, we will continue collecting data from subjects for more evidence.

USING AN RGB-DEPTH CAMERA FOR MARKER-LESS ESTIMATION OF CONTACT BETWEEN HAND AND HANDRIM DURING IN-LAB WHEELCHAIR TENNIS PROPULSION

INTRODUCTION

The present work investigates marker-less measurements using vision systems for contact detection between hand and hand-rim in wheelchair propulsion. Measurement wheels or instrumented ergometers are good ways to measure kinetics, but lack the position of the hand in space.

METHODS

17 able-bodied participants with no prior experience in wheelchair propulsion pushed the wheelchair on the ergometer in six tests divided in two blocks: Byr (holding a tennis racket) and Bnr (free hands). Each block was tested in three different conditions: C1 (4 km/h for 90 s), C2 (5.4 km/h for 90 s), C3 (max speed for 10 s). The used measurement systems were an ergometer collecting torque and speed on both sides at a frequency of 100 Hz and a camera collecting both RGB and depth images at a frequency of 60 Hz, placed on the right side of the participant. For each RGB frame collected by the camera, the hand was identified by means of Mediapipe (MP) [1], able to detect 21 landmarks, as shown in (Figure 1). Using the maximum and the minimum value of the coordinates of each landmark, a region of interest (ROI) was located around the hand. The depth data of this ROI, obtained from the corresponding depth frame, were used to identify the hand point-cloud. The position of the hand had to be expressed with respect to the wheel. To do so, the centre and the circle of the hand-rim were recognized on the RGB image. Using the values of the corresponding pixels in the depth image, the best fitting plane in the hand-rim was then computed with a RANSAC method. Five features are extracted: radial and normal distance of the hand with respect to the wheel, their derivates and the ratio between the ROI height and width. These features were used to train different classifiers with two classes: Contact and No-Contact, whose ground-truth was obtained by the analysis of the torque applied, recorded by the ergometer [2]. The most accurate (MLP with 10,100 and 10 neurons, accuracy = 83%) was validated with a 5-fold validation on the 5 days of test. Finally, after a post-processing phase, the detection error in time was used to estimate the uncertainty.

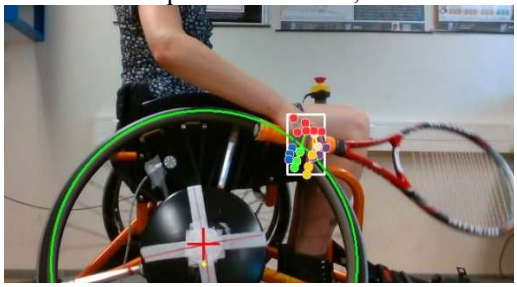

Figure 1: Hand recognized by Mediapipe during the propulsion of a wheelchair while holding a tennis racket

RESULTS AND DISCUSSION

The distributions of errors in contact detection for all the blocks and conditions was the following: -0.01 ± 0.12 s for start and 0.00 ± 0.12 s for end of contact, RMSE = 0.12 s for both). A distinction between the different test situations is presented in (Table 1). Since every frame in which the hand is not recognized by MP implies a gap for the contact detection algorithm, a relation between the performances of the two was expected. A lower RMSE for the tests executed with the racket (Byr) suggests that the contact detection algorithm performs better when the hand is holding the racket, even though the percentage of frames in which the hand is not recognized by MP is similar for the case with and without racket (≃9%). On the contrary, the percentage of frames not recognized by MP is proportional to the speed of the wheel, (and consequently the speed of the hand) but this does not affect the performances of the algorithm: the RMSE is similar for C1C2 and C3.

CONCLUSIONS

The present work shows the feasibility of the development of an algorithm able to detect the start and the end of the contact between hand and hand-rim using the relative position between the two obtained by means of marker-less vision systems. Further analysis should be carried out on the relation between the performances of the hand recognition algorithm (MP or an equivalent), and the contact detection algorithm.

Investigating the Long-Term Impacts of Hand Tractor Operation on the Upper Limb of Farm Operators

Josefa Angelie D. Revilla[1], Clarissa M. Pesigan[1], Stephanie Caridad DR. Landicho[1], and John Kenneth P. Punongbayan[1]
[1] Department of Industrial Engineering, College of Engineering and Agro-Industrial Technology, University of the Philippines Los Baños, Laguna, Philippines.
Email: jdrevilla@up.edu.ph

INTRODUCTION

In the Philippines, agriculture is one of the major sectors that provide livelihood to the people. Farming various crops is the most common activity. This uses different agricultural machinery such as the hand tractor or the two-wheel tractor. This is an equipment, driven or controlled by an operator, that helps in cultivating the farm land. A hand tractor is powered by either a diesel or gasoline engine. It is pushed forward by an operator on a puddy field. During operation, a downward push or vertical lift of the handle is sometimes necessary for easy maneuverability. The engine creates vibration of around 21 m/s^2 [1] that is proven to be transmitted to the handle. There have been little reports on how this level of vibration affects the operators in the long run. Hence, this investigation aims to identify how such vibration level influences the hand functionality of farm operators who have used a hand tractor for a long time.

METHODS

The study investigated 15 farm operators with a mean age and working experience of 36.7 ± 11.6 years old and 20.1 ± 12.2 years. Basic measurement such as height, weight, hand anthropometry, and handedness were recorded. Afterwards, grip strength (GS), pinch strength (PS), finger sensitivity, finger dexterity, and subjective discomfort along the upper limb were measured. Grip and pinch strength were measured using a Vernier hand dynamometer and Lab Quest 2 data logger. Finger sensitivity was assessed using the two-point discriminator test (TPDT) while finger dexterity was evaluated using the 9-hole peg board test (NHPT). The perceived discomfort along the upper limbs was rated using the Wong-Baker FACES scale. All tests were done for both the dominant and non-dominant hand side. The results were compared with related studies which determined a reference GS and PS value, NHPT performance, and TPDT result of healthy individuals with the same age range as the participants.

RESULTS AND DISCUSSION

Hand Strength

The mean GS of the experienced farm operators is 21.98 ± 5.79 kgf for the dominant and 19.46 ± 5.33 kgf for the non-dominant hand. Meanwhile, the mean PS is 12.13 ± 2.45 kgf and 10.89 ± 2.13 kgf for the dominant and non-dominant hand. Related studies determined that the GS of healthy men of the same age range is around 46-53 kgf and 42-50 kgf for the dominant and non-dominant side [2, 3, 4]. In addition, PS of healthy males is about 9-10 kgf and 9 kgf for the dominant and non-dominant side [4].

Finger Dexterity

Using the NHPT, the result led to 17.37 ± 1.38 seconds and 19.11 ± 1.99 seconds for the dominant and non-dominant hand. A similar study found that the NHPT of healthy males is 17-18 seconds and 18-20 seconds for the dominant and non-dominant hand [5].

Finger Sensitivity

Table 1 presents the TPDT results for the dominant and non-dominant hand. From related research, the normal minimal distance for the fingertips is 2-6 mm [6, 7].

Table 1. Median TPDT value (in mm)

Hand side	Thumb	Index	Middle	Ring	Small
Dominant	3	3	3	3	3
Non-dominant	3	2	2	2	3

Synthesis

Although the testing method may be different across the studies, the resulting GS of exposed farm operators is evidently lower than those of healthy men while PS and NHPT did not present a clear difference. Additionally, the TPDT values fell within the normal range. Subjectively, the upper limb discomfort perceived by the farm operators ranged from none to mild discomfort.

CONCLUSIONS

In conclusion, the long-term impact of constant exposure to hand tractor vibration is most evident on the reduction of grip strength. This signifies a strong tendency to develop upper limb MSD.

Dr Suh received her medical degree and residency training at the Schulich School of Medicine & Dentistry at Western University. She then completed two years of fellowship training, subspecializing in wrist and hand reconstruction and trauma. Her first fellowship was completed at the Hospital for Special Surgery, New York, New York and her second at the Mayo Clinic in Rochester, Minnesota. She returned to Western in 2014 to join the Department of Surgery and in 2021 she relocated to Emory. Dr Suh's clinical interests encompass disorders of the wrist and hand, while her research interests include both biomechanical and clinical outcomes.

Unsolved Clinical Mysteries in the Hand and Wrist

The hand and wrist are composed of numerous bony and soft tissue elements, contributing to it being one of the most complex anatomical regions in the body. Musculoskeletal injuries of the hand and wrist also comprise the most common areas of injury with significant functional morbidity to the patient. Despite the gains in identifying and characterizing clinical conditions, there remains an incomplete understanding of the pathomechanics of injuries and the biomechanical impact of treatment options. The role of biomechanical investigation is increasingly being utilized to provide foundational work for the clinician given the anatomical complexity and is being leveraged to delineate the interplay of the various hand and wrist structures. This talk will discuss the current unsolved clinical mysteries in the hand and wrist that would benefit from further biomechanical investigation.

THE DIFFERENCE IN THE EFFICIENCY OF REACTIVE GRIP FORCE ADAPTATION DURING STATIC AND DYNAMIC TASKS BETWEEN CHILDREN AND ADULTS

INTRODUCTION

Daily activities are full of unexpected perturbations. Manipulating the objects with fingertips in an unpredicted context requires well-reactive grip force adaptation, which immediately adjusts the grip force based on adequate sensory feedback. Analysis of reactive grip force adaptation has been considered an indicator of hand sensorimotor control ability in response to environmental perturbation [1]. The use of the adaptation strategy is less efficient in younger children. With age, this strategy will become mature. The difference in the efficiency of force adaptation between children and adults was studied purely in one context[2]. However, perturbations in daily living may emerge during static or dynamic tasks. It has never been investigated separately. Thus, this study aimed (1) to understand if there is any difference in adaption strategies used in static and dynamic movements and (2) to investigate the efficiency of force adaptation between children and adults in static and dynamic tasks.

METHODS

This study recruited five adults (age = 23.8±1.9 years) and five children (age= 4.3±0.5 years). A novel pinch apparatus was used for measuring reactive grip force adaptation in static and dynamic tasks.

The novel pinch apparatus is made of a 3D-printed cuboid (size = 25×25×65 mm^3 weight = 90g) which contains a force sensor to record grip force. It is connected to a fixed-base platform that contains a 35g block with a string and is controlled by a button that releases the block to cause a perturbation.

In the static task, subjects grip and lift the pinch apparatus to 15cm and hold for 15s. In the 5^{th} second, the examiner presses the button unexpectedly to release the block. The other task is the dynamic task in which subjects lift the apparatus to 25cm and hold it for 10s. At 15cm, the perturbation is released. There are three trials in each task.

The efficiency of force adaptation was represented by (1) reaction time: the time delay between the impact and peak grip force; and (2) grip force rate: the ratio of peak grip force and the maximum grip force.

RESULTS AND DISCUSSION

In Table 1, comparing the reaction time and grip force rate between static and dynamic tasks, there was no significant difference found for children. However, for adults, no significant difference in reaction time but in grip force rate was found between static and dynamic tasks. Besides, children showed a significant delay in the reaction time and higher values of grip force rate in the dynamic task compared with adults.

CONCLUSIONS

We found that the grip force rate in the static task is larger than in the dynamic one for adults. The reason may be the amplitude of the grip force exerted is relatively small in the static task. Thus, the perturbation seemed to have a higher magnitude of impact on maintaining grip stability in the static task.

Moreover, children perform longer latency of reaction time and a higher percentage of grip force rate. It is consistent with the previous study in which age effects are evident in the delay to max grip force and a larger percentage of maximal grip force[2]. Therefore, the efficiency of utilizing forces is less efficient in children. However, the number of subjects in this study is still insufficient and limited to a specific age group. Therefore, it still needs further investigation to identify the difference better.

INTRODUCTION

The thumb is essential for manipulating objects and performing tasks such as pinching and grasping. Its strength and dexterity stem from the interaction of 9 thumb muscles, particularly at the carpometacarpal (CMC) joint with 3 degrees of freedom. Unfortunately, when CMC osteoarthritis (OA) occurs, it can cause debilitating pain, diminished strength, and limited range of motion. [1]. Despite the importance of the thumb muscles, limited research has been conducted on healthy or pathologic cohorts [2-4] due to the challenges posed by the size and location of these muscles and the constraints of surface electromyography. Currently, there is a gap in our understanding of muscle activity in patients with CMC OA, including how these muscles may (or may not) compensate for pain and its impact on hand biomechanics. The purpose of this study was to investigate differences in muscle activity across the clinical spectrum of CMC OA.

METHODS

Women with clinically diagnosed CMC OA [n = 16; age 65.6 ± 11 years] and healthy, pain-free thumbs [n = 15, age 62.1 ± 12 years] were recruited for this IRB-approved study. Participants completed self-reported questionnaires on pain and function, including the Australian/Canadian Osteoarthritis Hand Index (AUSCAN). Disease severity was classified from radiographs using the Eaton-Littler scale. Muscle activity was recorded during range of motion (ROM) tasks: flexion/extension, ad/abduction, opposition, and circumduction. Each task was performed three times. Muscle activity was recorded from 4 extrinsic and 4 intrinsic muscles using fine-wire electromyography (fEMG) sampled at 3,000 Hz. Data were filtered, rectified, amplitude normalized, and time normalized to percent task completion. Analyses evaluated differences in muscle activity across participants.

RESULTS AND DISCUSSION

No clear differences in muscle activation existed between the two recruited cohorts. However, imaging and self-reported pain data demonstrated an overlap between the recruited cohorts (Fig. 1A), suggesting little correlation between pain and disease severity. To determine if there were any muscle activation patterns that separated participants into meaningful subgroups, various clustering methods were employed, including dynamic time warping (DTW), functional principal component analysis (fPCA), and non-negative matrix factorization (NMF). Results were examined to decide if self-reported pain, disease severity, or other measured characteristics could describe the identified clusters.

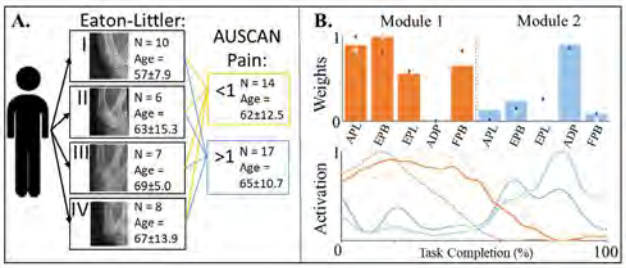

Figure 1A. Patient groups based on disease (Eaton-Littler classification) or pain severity (AUSCAN). **B.** Average muscle synergy using two modules (blue and orange) with examples of individuals with early- (light) versus end-stage (dark) disease.

When presented with 8 muscle activation patterns for each participant, both fPCA and DTW failed to identify meaningful subgroups. This outcome and the variability in muscle activation patterns across and within participants highlight the complexity and redundancy of thumb muscle actions. Clusters could be identified when examining each muscle individually, but valuable information about muscle coordination and co-activation was lost. Importantly, NMF analysis of muscle synergies, revealed that participants with diverse pain and disease severity levels could be grouped together. NMF results also showed agonist and antagonist muscles were activating simultaneously (Fig. 1B), emphasizing the significance of accurately measuring co-activation. To further understand the biomechanical changes in CMC OA, adding more features to clustering analysis, such as kinematic data and co-activation indices, is of immediate interest.

CONCLUSIONS

Our results elucidate the complex presentation of CMC OA and indicate a need for feature extraction techniques capable of analyzing multimodal datasets. Through these efforts, a more comprehensive understanding of CMC OA may be achieved.

INTRODUCTION

Pinch grip is a basic hand motion that allows string instrumentalists to perform music. However, muscle fatigue degrades their performance and can lead to overuse syndrome (OS)[1]. Muscle fatigue can be detected by increases in surface electromyographic (EMG) signals, since muscles are prone to electrically activate to compensate for decreases in muscle capacity[2]. We aimed to define muscle fatigue by changes in EMG signal and maximum endurance time (MET), used in a computational model to define decreases in muscle capacity. We hypothesised that (1) the EMG signals of muscles, induced by the requirements of the fingers' motions, would increase during maximum pinch force (MPF) tasks due to muscle fatigue; (2) the relative increase in EMG signals would increase with required pinch force; (3) fatigue, expressed as MPF following a trial divided by initial MPF, would increase with required pinch force.

METHODS

Twenty-two participants performed five static pinch trials to exhaustion, with the required force defined as a percentage of the individual's initial MPF. EMG sensors were attached on the left arm to monitor the flexor digitorum profungus (FDP), flexor digitorum superficialis (FDS), flexor pollicis longus (FPL), extensor digitorum communis (EDC), extensor indicis (EI), extensor pollicis longus (EPL), abductor pollicis longus (APL), abductor pollicis brevis (ABP) and first dorsal interosseous (DI) muscles. A second MPF task was performed immediately following the endurance task. At least 5-minutes of rest after each task ensured recovery from any fatigue.

RESULTS AND DISCUSSION

The EMG signals for all muscles increased from the baseline amplitude recorded during the first MPF task, when MPF was less than 50% (Figure 1). These increases agreed with increases in the post-task MPF ($p<0.01$, Table 1). In contrast, MET exponentially decreased in order of the level of the task (Table 1). Both EMG signals and MET demonstrated the level of muscle fatigue. However, eight of nine muscles did not indicate differences in EMG signals from 50 to 70% MPF; the exception being APL ($p<0.05$). Since APL is not a prime mover in flexing or extending the thumb, participants might have different techniques to stabilise their joints. The EMG signal was not sufficient to indicate the level of muscle fatigue from 50 to 70% MPF task while the MET showed differences for all levels of pinch ($p < 0.001$).

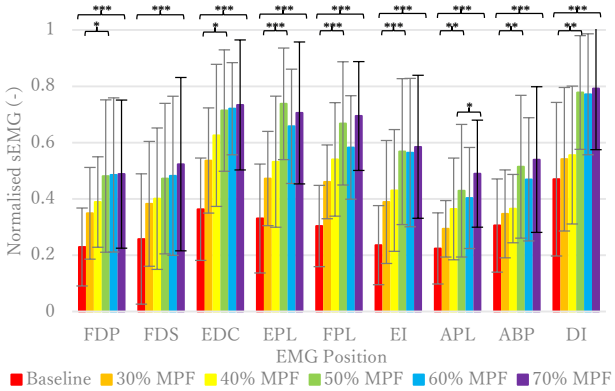

Figure 1 Normalised EMG signals during maximum voluntary contraction after static endurance tasks of varying %MPF

CONCLUSIONS

Muscle fatigue was related to decreasing post-task MPFs, which agreed with both rise of EMG signals and drop of MET for 30 to 50% MPF tasks. EMG was not sufficient to differentiate levels of fatigue from 50 to 70% MPF tasks, whereas the METs were able to show this. Combining these two factors will, therefore, be able to predict the decrease in MPF. These factors may be included to a computational model to calculate decreases in muscle capacity and applied to activities of instrumentalists.

METHOD FOR ASSESSING THE FINE MOTOR SKILLS SYNERGIES BASED ON COMPUTER VISION

Andrey Pomerantsev
Independent researcher
Email: a.pomerantsev.1981@gmail.com

INTRODUCTION

The coordinated work of the fingers is an indicator of human health and the key to professional skill. The aim of the work was to create a method for quantitative control of fine motor synergies based on computer vision. The study of fine motor skills is actual theme at different ages and for different purposes. At preschool age, fine motor skills allow to estimate the degree of child readiness for school. Cognitive abilities, memory, speech, logic, mathematical abilities, concentration, imaginative thinking evolves concurrently with fine motor skills. Fine motor skills determine the level of skill in many professions. Musicians (conductors, pianists, accordionists), doctors (dentists, surgeons), cyber sportsmen, IT specialists, jewelers and representatives of many other professions have well-developed and specific fine motor skills.

METHODS

The proposed method is based on the MediaPipe open source framework, exactly the Mediapipe Hands neural network. Computer vision allows to determine the palm by analysis of the video stream. First, neural network detects the palm area in the frame, and then localizes 21 nodal points to determine the gesture (Figure 1). Due neural network and the author's method of assessing fine motor skills [1], computer application FingerFit 4.0 was developed. During changing gestures, certain synergy is used [2]. The possible combination of straightened and bent fingers of one hand is 2^5 =32. The number of gestures changes combinations is $2^5x2^5=2^{10}$=32x32=1024. From this number, it is necessary to exclude 32 repetitive gestures and 160 gestures when only one finger is involved in the work. Thus, the final number of synergies is 832. The app fixes the synergy only if all fingers participate in the gesture construction at once. The time to rebuild the gesture is 1 second. If a person does not have time, the app asks to return to the original gesture. The complexity of synergy is estimated by the total time that a person spends on changing a gesture.

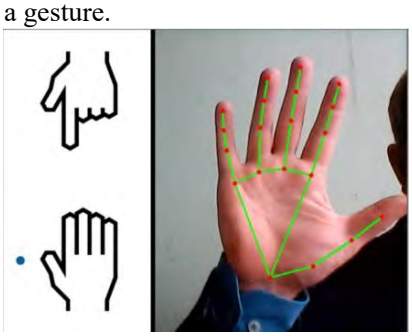

Figure 1 Computer application interface.

RESULTS AND DISCUSSION

A 7-year-old girl with no health abnormalities or delays participated in the method approbation. We evaluated 145 synergies by a sequence of 32 random gestures. The most complex synergies are presented in Table 1.

CONCLUSIONS

A fine motor skills assessment method was developed with using the MediaPipe framework. The method is based on the definition and quantity control of synergies. The presented approach will be advisable to use for the control of professional skills, assessment of the child's readiness for school, as well as the diagnosis of neurological diseases. The accumulated test results in the future will allow to establish the boundaries of the norm and draw objective conclusions about fine motor skills level.

Coordinated muscle activity during chopstick manipulation

Kazuya Kurauchi, Hiroshi Kurumadani, Shota Date and Toru Sunagawa
Graduate School of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan.
Email: kazu.hiro.bmk@gmail.com

INTRODUCTION

Chopsticks manipulation is one of the skillful finger movements. In rehabilitation, reacquisition of chopstick manipulation for disabled hands includes exercises such as manipulating chopsticks and picking up objects. Many intrinsic and extrinsic hand muscles are involved in chopstick manipulation. Previous reports of hand-muscle coordination have indicated that the intrinsic and extrinsic hand muscles have intermuscular coordination between these muscles[1]. Highly skilled finger movements require intrinsic hand muscle activities, such as the lumbrical muscle, and intermuscular coordination between intrinsic hand muscles[2]. Hand muscle activities may thus have several intermuscular coordination during chopsticks manipulation. This study aimed to examine the intermuscular coordination between the intrinsic and extrinsic hand muscles during chopstick manipulation.

METHODS

Twenty healthy right-handed adults performed six object-grasping tasks by using chopsticks. The grasping tasks consisted of three object widths (1, 2, and 3 cm) and two weights (10 and 40g). Each task was conducted in 10 trials. The surface electromyography measured 12 muscle activities during the task with a sampling frequency of 1000 Hz. The tested muscles were eight intrinsic (first, second, and third lumbrical muscles, first, second, and third dorsal interosseous muscles, flexor and abductor pollicis brevis) and four extrinsic (flexor digitorum superficialis, extensor digitorum, flexor carpi ulnaris, and extensor carpi radialis muscle) hand muscles.

Furthermore, the movements of the chopstick tips were measured with a three-dimensional motion capture system to identify the opening and closing movements of the chopsticks. The obtained electromyographic signals were filtered and smoothed and then extracted from the initial chopstick opening to the end of the closing movement. The muscle activity waveforms during the chopstick opening/closing movement were extracted for five trials for each task. Next, muscle synergy analysis using non-negative matrix factorization was performed on all muscle activity waveforms for all tasks, and the muscle weighting components and time-varying patterns with a variance accounted for above 90% were extracted. Muscle-weighting components greater than 0.4 were defined as those with high contributions to the extracted synergy.

RESULTS AND DISCUSSION

Five muscle synergies were extracted from the opening to closing chopstick movements (Figure 1). The five synergies were divided into three main categories. The first was intrinsic intermuscular coordination, such as between the lumbrical muscles and between the thenar and the interosseous muscles. The second was extrinsic intermuscular coordination between the extensor digitorum and extensor carpi radialis. The third was intermuscular coordination between intrinsic and extrinsic muscles, such as between the interosseous muscle and the flexor digitorum profundus. This coordination may be due to the same or close location of the nerve roots innervating the respective muscles.

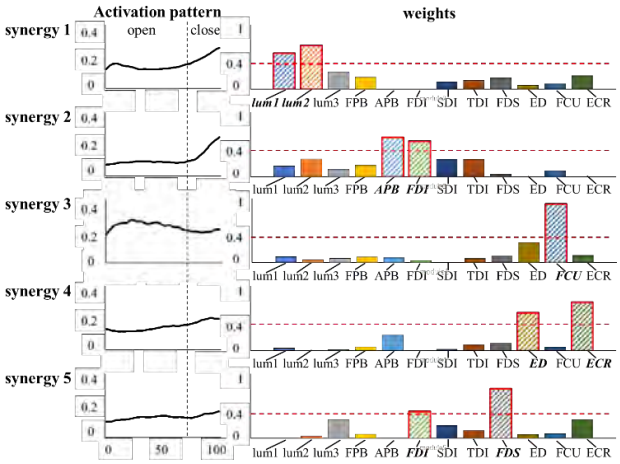

Figure 1 Results of non-negative matrix factorization. Basic pattern (left) and contributions of muscles (right). lum1: first lumbrical muscle, lum2: second lumbrical muscle, lum3: third lumbrical muscle, FDI: first dorsal interosseous muscle, SDI: second dorsal interosseous muscle, TDI: third dorsal interosseous muscle, FPB: flexor pollicis brevis muscle, APB: abductor pollicis brevis muscle, FDS: flexor digitorum superficialis muscle, ED: extensor digitorum muscle, FCU: flexor carpi ulnaris, ECR: extensor carpi radialis

CONCLUSIONS

We found three intermuscular coordination during chopstick manipulation: coordination between intrinsic hand muscles, extrinsic hand muscles, and intrinsic and extrinsic muscles. The results of this study may lead to the establishment of an efficient method for improving chopstick manipulation.

Non-Surgical Carpal Arch Space Augmentation for Median Nerve Decompression

The carpal tunnel is a tightly bounded space, making the median nerve prone to compression and eventually leading to carpal tunnel syndrome. Carpal tunnel release surgery transects the transverse carpal ligament to expand the tunnel arch space, decompress the median nerve, and relieve the associated symptoms. However, the surgical procedure unavoidably disrupts essential anatomical, biomechanical and physiological functions of the wrist, potentially causing reduced grip strength, pillar pain, carpal bone instability, scar tissue formation, and perineural fibrosis. It is desirable to decompress the median nerve without surgically transecting the transverse carpal ligament. This talk is to review several approaches we have developed for nonsurgical carpal arch space augmentation (CASA), namely, radio ulnar wrist compression, muscle-ligament interaction, palmar pulling, and collagenolysis of the transverse carpal ligament. Briefly summarized is the research work on the CASA topic about theoretical considerations, in vitro and in situ experiment, computational modeling, and human subject studies with asymptomatic and carpal tunnel syndrome hands.

CHALLENGES IN DEVELOPING A HEALTHY FINITE ELEMENT WRIST MODEL: LIGAMENTS

Andrés Mena[1], Ronit Wollstein[2], and James Yang[1*]
[1]Texas Tech University, Lubbock, Texas 79409, USA
[2]New York University, New York, USA
*Email: james.yang@ttu.edu

INTRODUCTION

The wrist is a complex human joint that participates in most functional daily activities and is thus prone to pathology and injuries. Understanding how the wrist operates under normal conditions is crucial to study novel treatments and prevention, but wrist biomechanics remains vastly unexplored. Experimental methods have been used extensively to study the wrist [1]. However, the expensive equipment and natural limitations of *in vivo* and *in vitro* testing pose a challenge for the study of the wrist. Numerical methods like the finite element method (FEM) have been used to study other human joints [2] and are now being considered as a viable option to analyze important mechanical variables of the complex wrist joint. Since there is no accepted universal methodology to create finite element models, authors have opted for different modeling techniques, making comparison and validation extremely difficult. A fundamental part of most models is ligaments, but the number included in each work and their material properties vary depending on the authors [3]–[4]. Therefore, a study is performed to investigate the effects of different ligament configurations on the wrist's stress distribution and load transfer.

METHODS

Several finite element models were developed using computed tomography (CT) scans from a healthy right wrist (68-year-old male). The CT images were imported into 3D Slicer [5], manually segmented, and smoothed to create surface meshes of each bone. The bones considered were the distal radius, ulna, eight carpal bones, and a section of the metacarpals. The surface meshes were then imported into IA-FEMesh [6] to create volumetric meshes of each bone using 8-node brick elements. The volumetric meshes were imported into LS-DYNA (Livermore Software Technology Corporation, Livermore, CA, USA) to assemble the model. Cortical bone was modeled by extruding specific bone surfaces with shell elements with constant thickness. Linear elastic isotropic material properties were assigned to cortical (E=18 000 MPa, ν= 0.2) and cancellous (E=100 MPa, ν= 0.25) bone [5]. Soft tissues like cartilage and ligaments were manually incorporated into the model after consulting the original CT scans and other sources [7]. Cartilage was modeled using 8-node brick elements by extruding specific regions of the bone surface. Ligaments were implemented in the model using multiple linear springs. An original healthy model containing sixty ligaments [4] is considered as a control model. Then several modifications based on different experimental and computational studies [8] were evaluated. The following regions are evaluated: metacarpal, carpometacarpal, ulnar wrist, and radial wrist. Loads accrued from in vivo studies were applied to the metacarpal heads/carpometacarpal joints. As boundary conditions, the bottom ends of the radius and ulna were fixed. Further constraints were applied to the metacarpals and carpals to prevent displacement in the final model [4]. Contact was considered in the models using a frictionless or frictional surface-to-surface [9] scheme.

RESULTS AND DISCUSSION

The variables that will be retrieved from the simulation are stress distribution, contact pressure, and load transfer. These variables will be obtained for the whole model, important wrist regions (radial and ulnar side), and individual carpal bones.

CONCLUSIONS

The effects of completely removing ligament groups will be investigated to understand their contribution to computational stability and wrist biomechanics.

INTRODUCTION

Trapeziometacarpal (TMC) joint osteoarthritis (OA) is characterised by the degeneration of bone and cartilage in the basal thumb joint [1]. However, potential biomechanical factors that contribute to the onset and progression of OA are difficult to measure *in vivo*. We have developed image-based data driven methods to compare TMC joint morphology between OA-affected and healthy subjects. Dynamic multi feature-class Gaussian process models (DMFC-GPMs) [2] are used to model variation in the shape, pose, and intensity feature classes of the first metacarpal (MC1) and trapezium and anatomical features indicative of the onset and development of OA in the joint are determined.

METHODS

Three feature classes (shape, pose, and intensity) were extracted from the CT scan data of 38 participants (12 with TMC OA). Each participant was imaged in a series of standardized positions which allowed for the subject-specific pose variation as a feature class. This feature class cannot be represented in a single-object model. The bones were segmented semi-automatically to reconstruct 3D bone surface meshes and tetrahedral volume meshes. Dense correspondence within surface meshes and volumetric-shape-intensity meshes was established and latent space computation was used to build the individual DMFC-GPMs. Three DMFC-GPMs were built representative of the healthy, TMC OA, and the combined datasets.

The differences in the mean morphologies of the TMC OA and healthy groups were evaluated through the comparison of five anatomical features. A custom-written MATLAB code was used to determine the shortest distance between the articular surface of the trapezium and MC1 for each model. An anatomical 3D CAD software package was used determine the planes of best fit to manually measure both the volar beak angle and trapezial inclination of the mean shape of the MC1 and trapezium, respectively. The surface area of the articular facets was measured manually by delineating the edge of the facet. A custom-written sphere-fitting python code was used to calculate the average local curvature along the volar-dorsal and radio-ulnar axes of each bone. Preliminary models of the healthy and TMC OA datasets were built comprising of 3 participants each in a series of standardized positions.

RESULTS AND DISCUSSION

Four additional samples taken from each model were used to analyse the differences between datasets using a two sample, two-tailed T-test assuming equal variance (Table 1). TMC joint space was decreased whilst the surface area of the articular facets was increased for both the MC1 and trapezium bones of TMC OA. The trapezial inclination of TMC OA patients showed a more obtuse angle, indicating possible growth of osteophytes along the contour of the trapezial articular facet in late-stage OA. Analysis of the curvature of the articular facets indicates an increased radius of curvature along the radial-ulnar axis and the dorsal-volar axis of an OA-affected trapezium and MC1, respectively.

CONCLUSIONS

The DMFC GPM of TMC could be effectively used to assess five quantifiable anatomical features which are associated with TMC OA using standard CT scans.

INTRODUCTION

Anatomical frames for upper limb segments have previously been proposed by the International Society of Biomechanics (ISB) [1]. However, a limitation of creating anatomy-based frames is the need to denude to locate and digitize unique features on bones; introducing both intra- and inter-user variabilities that hamper reproducibility across research groups. Therefore, the purpose of this study was to quantify and validate the use of a new Motion-based Coordinate System (MCS) functional frame definition for finger joints using helical axes (HA) in an *in-vitro* setting. This model was directly compared to the standardized ISB anatomical frames.

METHODS

Eleven digits from 4 fresh-frozen upper extremities were utilized. Active finger flexion was controlled using a previously reported finger motion simulation protocol with flexor tendons moving in displacement control at a rate of 0.6 in/sec against a constant 10 N extensor antagonist load and vice versa for finger extension [2]. Joint kinematics was tracked using an electromagnetic transmitter system where rigid fixation of the trackers in bone was achieved by an interference tolerance fit. Discrete motion pathways of each segment were dictated in each bone segment to obtain the associated mean helical axis orientations required for coordinate system building. Two sets of frames were constructed: the landmark definition corresponded to implementation of ISB' anatomical frames whereas functional frames included a functional joint axis. Both constructed frames were further validated with goniometer measurements. Finger joint flexion/extension were measured and mean differences and deviations between methodologies were computed for all digits. A three-way repeated measures ANOVA (factors: Joint (MCP, PIP, DIP); Axes (X, Y, Z); Frame Definition (MCS, ISB)) was conducted to evaluate differences in each cardan angle. Furthermore, a paired t-test and a linear regression for correlation were also computed for a further validation of the local frame definition in the Z-axis (i.e. flexion/extension).

RESULTS AND DISCUSSION

The mean joint angle about the X-axis (add-abd), Y-axis (int-ext rot), and Z-axis (flex-ext) were computed (Figure 1). Non-significant differences were reported for both MCS and ISB compared to goniometer readings at 95% CI. Unlike ISB, all joints under MCS and goniometer readings were strongly and significantly correlated. Average joint angle deviations of about 2.7° were measured for both MCS and ISB across all three axes. Largest deviations were observed at the PIP and DIP joints along the int-ext rot and abd-add axes, with flexion-extension axes achieving the lowest deviations in all joints. In addition, A three-way ANOVA resulted in an insignificant mean difference of 0.151° between MCS and ISB (p=0.923). Repeatability of MCS and ISB along the flexion-extension axis following 5 motion cycles were measured to be 0.64° and 0.86°, respectively.

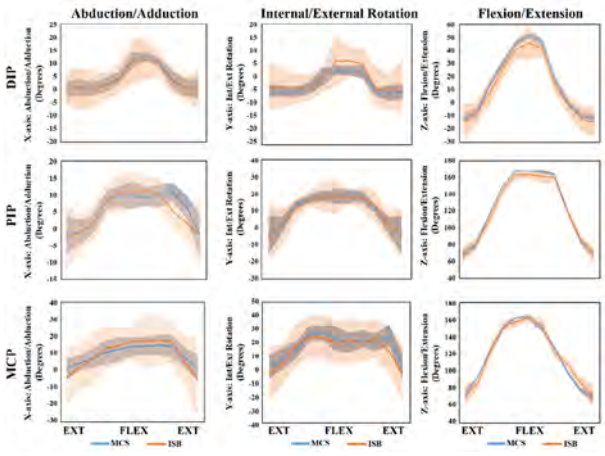

Figure 1 Mean angles measured by MCS and ISB local frames for each joint (DIP, PIP, MCP) along its respective X-, Y-, and Z-axes throughout one full active motion cycle are illustrated above. MCS are denoted by blue lines where ISB are denoted by orange lines.

CONCLUSIONS

Our findings support the use of the MCS methodology presented in this study in measuring accurate and reproducible finger joint kinematics, compared to ISB recommendations. To our knowledge, this is the first study that evaluates the accuracy of helical axes during active in-vitro finger motion without the use of virtually constructed motion pathways of bone segments in computed tomography (CT) scans.

FAMILIARITY EFFECT ON HANDWRITING PERFORMANCE IN SCHOOL-AGED CHILDREN

Wen-Feng Huang[1], Pin-Chen Hung[1], Tien-Ni Wang[1], Hao-Ling Chen[1]
[1] School of Occupational Therapy, National Taiwan University, Taipei, Taiwan, R.O.C
Email: hlchen@ntu.edu.tw

INTRODUCTION

Handwriting is very important for school-aged children. Children in Taiwan have to keep learning to write different characters in their early school years. Considering the busy schedules of school-aged children, efficiently producing handwritten scripts is essential for them. Children who are unfamiliar with the newly learned characters are considered to write inefficiently. However, relevant research was insufficient. Therefore, this study aimed to investigate the familiarity effect of characters on handwriting performance from the kinematic and kinetic perspectives for school-aged children in Taiwan.

METHODS

A convenience sample of 30 lower-grade children was recruited. They were asked to perform copy tasks at their own pace while copying characters as legibly as possible. To investigate the familiarity effect on handwriting kinematics and kinetics, two copy tasks, namely the *familiar task* and the *unfamiliar task,* were administered using a newly-developed tablet-based evaluation of Chinese handwriting (TECH) [1]. The TECH was shipped in a pressure-sensitive tablet with a wireless pen. The *familiar task* consisted of 20 high-frequency Chinese characters taught in the first-grade curriculum in Taiwan. The *unfamiliar task* consisted of 20 Hanguls (i.e., Korean characters) that have similar visual-spatial features to Chinese characters (e.g., square arrangement, multiple compounds, sharp turns, complex stroke directions, etc.). The assembly of the copy tasks considered the visual-spatial features of the construction of a copying character to ensure the equity of task difficulties. Additionally, the average stroke number of a copying character was identical in the two tasks. The TECH recorded the *On-surface* and *In-air movements* (Figure 1) of the pen-tip to obtain the temporal, spatial, and force measures [2]. The familiarity effects were examined using paired samples T-test. The significance level was .05.

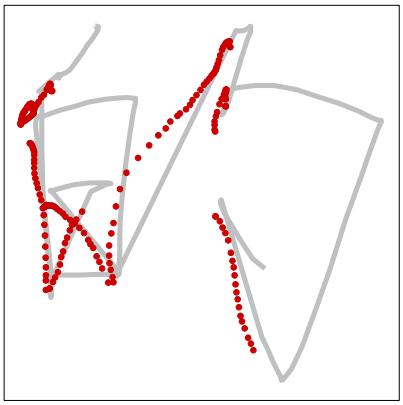

Figure 1 Illustration of the pen-tip movement. The gray-solid and the red-dotted lines respectively represent the trajectories of *On-surface* and *In-air movements.*

RESULTS AND DISCUSSION

The stroke velocity was comparable in the two tasks, suggesting that familiarity with characters might not significantly affect the time efficiency. When copying Hanguls (i.e., the *unfamiliar task*), children represented more peaks of stroke velocity, higher ratio of elapsed time in the air, higher ratio of excursion length in the air, and longer inter-stroke time. The tremble strokes and redundant *In-air movement* indicated that fluency and automaticity of handwriting were compromised. Additionally, stronger pen-tip force and more varied pen-tip force also indicated less efficient motor control during copying unfamiliar characters.

CONCLUSIONS

The familiarity with characters was important for children as it could influence the motor control of handwriting, including fluency, automaticity, and force regulation. To help children enhance familiarity to characters, handwriting instruction that involved direct practice of copying characters might be suggested.

linc@ncku.edu.tw

INTRODUCTION

Parkinson's disease (PD) can significantly impair a patient's daily life. Assessing hand movement is an important part of the motor examination to understand the severity of PD. Accurate assessment can be challenging due to motor fluctuation or symptom variation throughout the day, resulting in incomplete characterization of the disease's actual condition during clinical examination. Therefore, a continuous sensing method to quantify the hand motor symptoms is needed. Channel state information (CSI) refers to the combined impact of the propagation of Wi-Fi signals from the transmitter to the receiver. The Wi-Fi-based sensing is passive , contactless, and privacy preserving. Studies have shown the capability of Wi-Fi CSI to capture human subtle motion, such as respiration [1]. Therefore, this paper proposes a method to continously detect subtle changes in the hand motor symptoms of PD, particularly tremor and bradykinesia and extract quantitative information for assessing the disease progression.

METHODS

A single Tx-Rx pair of Wi-Fi devices was used to collect CSI data during hand movements performed, and the environmental settings followed our previous study [2]. We first divided complex-valued CSI sequences gathered by two antennas to obtain the CSI ratio [1], which could eliminate the random phase offset that may occur. Second, The Butterworth filter was applied to remove low and high-frequency noise. After that, the principal component analysis was conducted to find the best presentation of signal response to the target motion. Finally, the Savitzky-Golay filter was used to smooth the data.

A processed sequence of complex-valued CSI ratio was analyzed in two steps. First, the data sequence was converted into magnitudes and the peaks were identified as the number of movements for determining the duration and frequency. Secondly, the data points of the sequence should visualize the movement as an arc in the complex plane, theoretically. By fitting the data points to a circle, the proportion of the arc (L_{arc}) to the circle's circumference C can be calculated by Eq. 1, where a and b are half of LoS length and the perpendicular distance from LoS to action point; λ is wavelength of carrier frequency (5.765 GHz), providing an estimate of the displacment of the movement (Δb).

$$\frac{L_{arc}}{C} * \lambda = 2 * (\sqrt{a^2 + (b + \Delta b)^2} - \sqrt{a^2 + b^2}) \quad (1)$$

RESULTS AND DISCUSSION

In the analysis of finger tapping, the amplitude graph (Figure 1) of a tapping action displays two distinct peaks that correspond to the opening and closing actions of the index finger and thumb. The frequency of approximately 1.12 Hz can be quantified by computing the number of peaks presented in the graph with average action duration 0.16 second.

Figure 2 illustrates the complex plane representation of an opening action in a finger-tapping test, which controlled the maximum opening to 5 cm. Another two finger-tapping tests were conducted with the maximum opening between two fingers set as 4 and 7 cm. In the former case, the complex plane representation showed a semicircular arc. In the latter case, the data points on the complex plane formed an approximately 0.8 full circle. The results suggested that the movements of fingers during tapping could be distinguished and measured in the tested range of opening action, i.e., 4 – 7 cm.

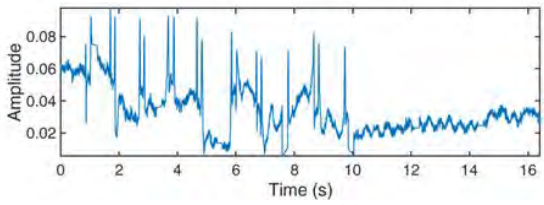

Figure 1 Amplitude plot of finger tapping

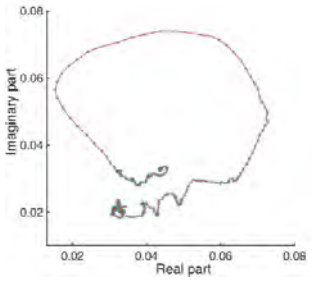

Figure 2 Finger tapping in complex plane

CONCLUSIONS

The proposed method successfully detected and quantified the frequencies and displacement of finger tapping. With continuous detection, the patient's daily condition can be tracked to understand the disease progression and drug efficacy, which help the doctor prescribe more accurately.

Keynote speakers

Toshiyasu Nakamura, MD, PhD

Department of Orthopaedic Surgery, School of Medicine, International University of Health and Welfare, Tokyo, Japan

Dr Nakamura graduated from Keio University School of Medicine in 1988, and from the Graduate School of Medicine specializing in Orthopaedic Surgery in 1994. His PhD addressed the functional anatomy of the triangular fibrocartilage complex. He completed research fellowships at the Mayo Clinic, Rochester, Minnesota and the Hand Center of Western New York, Buffalo, New York. In 2000 Dr Nakamura joined the academic staff of Keio University, where he taught until 2014, when he moved to the International University of Health and Welfare.

Biomechanics of the Distal Radioulnar joint (DRUJ)

The human wrist is a complex joint allowing six freedom motion including flexion-extension, radial-ulnar deviation and forearm pronosupination. The wrist consists of radiocarpal, midcarpal and distal radioulnar joints. The carpometacarpal (CMC) joints are also included into the wrist, and especially the thumb CMC joint allows multidirectional motion to achieve opposition. In this presentation, the author presents biomechanics of the distal radioulnar joint (DRUJ).

Functional anatomy

The DRUJ consists of the triangular fibrocartilage complex (TFCC), sigmoid notch of the radius, ulnar head and joint capsule. The TFCC is the 3-D structure and characteristics of the radioulnar ligament (RUL) indicated nearly vertical insertion to the fovea of the ulna. Some fibers of the RUL also attach to the base of the ulnar styloid. The vertical insertion of the RUL fibers allows easy twisting during pronosupination and provides adequate stability of the DRUJ during motion.

Static analysis of stability

The TFC has been considered the primary stabilizer of the DRUJ. Several studies revealed that attaching fibers of the RUL to the fovea is the most important part among the TFCC. As the TFCC is a 3-D structure, care should be taken that its 3-D structure is maintained during biomechanical studies. The author presents that sectioning the TFCC can affect static stability of the DRUJ. Also, importance of the fovea attachment of the TFCC and lesser function of the ulnar styloid process are presented.

Dynamic analysis using wrist simulator

Stability contributions of the fovea attachment and styloid attachment of the RUL for DRUJ was examined using static MTC machine analysis and dynamic wrist simulator, indicating fovea attachment of the RUL was much important compared to the styloid attachment, which was consistent with the clinical findings that ulnar styloid is not necessary to fix in distal radius fracture when the foveal attachment of the RUL remained intact.

How to repair and reconstruct the RUL or TFCC to the ulna

Functional anatomy and biomechanical studies in this presentation suggest that the avulsed RUL should be introduced to the central lesion of the fovea, with stitches (arthroscopic or open repair) or tendon(s) (reconstruction). Once the RUL is reattached or reconstructed to the fovea, patient indicates full of forearm rotation with adequate stability of the DRUJ.

THE IMPACT OF BODY COMPOSITION ON STAND-TO-SIT BIOMECHANICS AND MUSCLE ACTIVITY OF NURSES – A QUANTITATIVE-EXPLORATIVE STUDY

INTRODUCTION

Manual patient handling is one of the most significant challenges leading to musculoskeletal burden among nurses, who are already at high risk for physical impairments like muscle weakness, overweight, or obesity. Technical innovations can enhance traditional working techniques, e.g., a robotic system providing physical relief by collaboratively assisting nurses [1]. Worksite-tailored exercise training is another option to prevent physical burden in care [2, 3]. Traditional stand-to-sit (STS) tasks are promising exercises as they are easy to understand, reduce the risk of injury, and provide sufficient intensity for bodyweight resistance training. In addition, they can be easily integrated into daily routines, being elementary components of many activities of daily living and various actions in the day-to-day caregiving processes. However, research and evidence on STS tasks' biomechanical and muscular characteristics are limited – especially for nurses. Therefore, this explorative study aimed to quantify nurses' STS movement strategies in a laboratory setting to provide initial insights on identifying physical deterioration by data.

METHODS

We analyzed 292 STS transitions of eleven nurses (two male). The total number of STS transitions was counted, and ground reaction forces and non-invasive surface electromyography were collected. The displacement of the center of mass (COM), its velocity and acceleration, and the displacement of the center of foot pressure (COP) was calculated to quantify balance control. Muscle activation of the knee extensor, knee flexor, and lumbar erector muscles was quantified by root mean square. Individual data set elaboration led to group classification according to BMI characteristics (WHO: BMI ≥ 25 kg/m^2 is considered overweight).

RESULTS AND DISCUSSION

Compared to the normal-weight subjects, a BMI ≥ 25 kg/m^2 resulted in lower STS repetitions in 60 s (Tab. 1), a slower pace, and a longer cycle duration: Mean STS cycle duration took 0.59 s longer in the last 15 s of the STS movement compared to the normal-weight group. In the first 15 s of the movement, the mean difference between both groups was 0.32 s. COM displacement was extended in the anterior-posterior direction (Fig. 1a), and the COP range was ten times higher in the medial-lateral direction (Fig. 1b).
Movement strategies were adapted for balance control, increasing the muscle activity of the biarticular knee extensor, knee flexor, and lumbar erector. These findings imply that adapted trunk flexion due to overweight or obesity increases knee extensor activity as a compensatory mechanism for balance control.

Table 1. Descriptive data of the study participants (mean ± SD).

	BMI < 25 kg/m^2 (n = 8)	BMI ≥ 25 kg/m^2 (n = 3)
Age [years]	32 ± 11	36 ± 12
BMI [kg/m^2]	22.10 ± 1.24	30.93 ± 4.39
60 s STS repetitions [n]	28 ± 3	24 ± 6

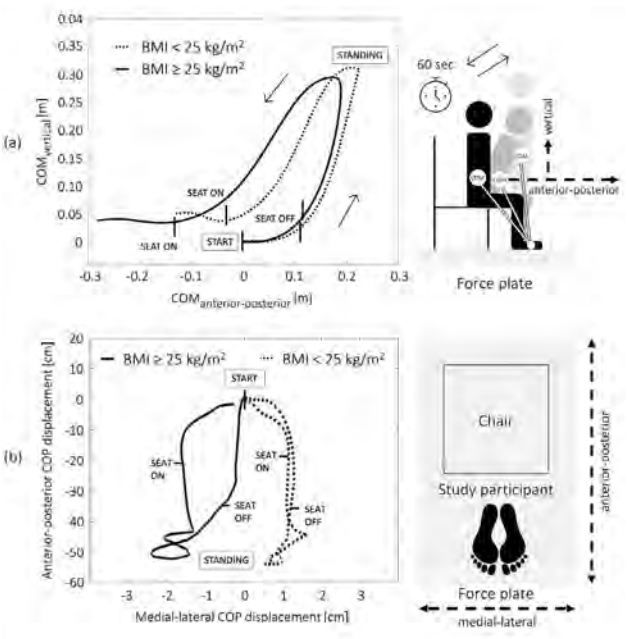

Figure 1. (a) COM trajectory in the anterior-posterior and vertical direction and (b) COP trajectory in the medial-lateral and anterior-posterior direction during the STS cycle.

CONCLUSIONS

In our data set, the functional performance of nurses in STS transitions is decreased with physical deteriorations (BMI ≥ 25 kg/m^2), resulting in lower STS repetitions in 60 s, a slower pace, and longer cycle duration. In this context, movement strategies were adapted for balance control, altering the velocity and acceleration, knee extensor, knee flexor, and lumbar erector muscle activity. These findings provide initial insights into STS performance strategies of nurses and can be used to conceive future worksite-tailored exercises.

THE EFFECT OF CHANGING BICYCLE SADDLE POSITION ON SUBMAXIMAL CYCLING BEHAVIOUR.

Cristian Riveros-Matthey[1], Glen A. Lichtwark[1], Mark J. Connick [1] and Timothy J. Carroll [1]

Email: c.riverosmatthey@uq.net.au.

INTRODUCTION

According to optimal control theory, we organise our movements to maximise motor performance according to specific objectives (like economy and precision). Meeting these behavioural objectives can also be thought of as minimising the costs of movement. In walking, for example, people select a stride length and rate that are aligned with the minimum energy consumption [1]. However, in tasks such as cycling, other criteria may drive the selection of a preferred cadence. The amount of muscle activation has been proposed as a cost that regulates movement in cycling. Computer simulations and experimental cycling suggest that people tend to minimise the amount of muscle activation in each pedal stroke, rather than minimising the total energy expenditure. However, it is not clear whether a cost function based on EMG activations can explain cycling behaviour when the mechanical conditions of cycling change. This question is important because if a cost function explains behaviour under novel conditions, there is greater evidence that the function helps to determine behaviour rather than merely correlating with it. Here we tested whether changes in cycling behaviour driven by altering saddle height are consistent with various cost functions for optimising movement.

METHODS

Twelve level 3-4 cyclists took part in three days of assessments (normal, low, and high saddle conditions). They exerted 3min cycling bouts at submaximal power output (2.5 $W \cdot kg^{-1}$) under 7 cadences (from 50 to 110rpm plus the self-selected cadence (SSC)). Breath-by-breath gas analysis, 3D motion capture, surface electromyography (EMG) and force-instrumented pedals were included. The net metabolic power was calculated based on VO2 and CO2 uptake. The sum of normalised muscle activations squared (CF1) and the sum of the volume-weighted muscle activations (CF2) were calculated from EMG [2]. The EMG-based cost functions and metabolic power data were fitted with a second-order polynomial nonlinear regression. This study was approved by the local ethics committee (2022/HE001934) and participants provided written informed consent.

RESULTS AND DISCUSSION

Preliminary results show that saddle changes affect metabolic power (Fig. 1) and EMG-based cost functions across cadences. Changes in SSC were also observed (normal saddle: 94 rpm, low saddle: 102 rpm, high saddle: 83 rpm), with the CF1 tending to be minimised under all saddle height conditions (Fig. 2).

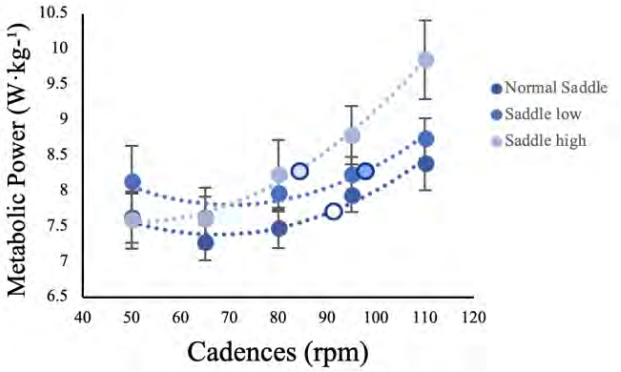

Figure 1: Metabolic power across cadences at 2.5 $W \cdot kg^{-1}$(n=9). Circles with borders represent the SSC in each mechanical condition.

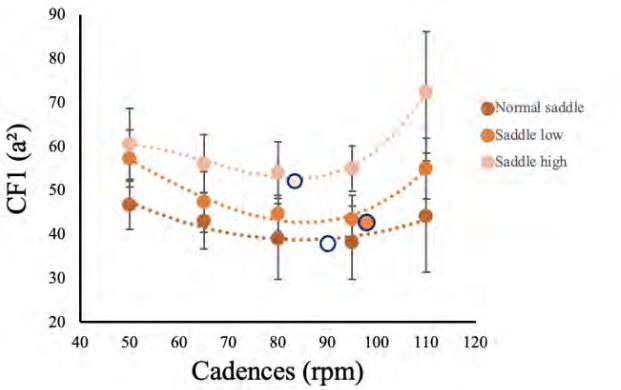

Figure 2: Mean "fatigue-like" CF1 per task cycle across cadences at 2.5 $W \cdot kg^{-1}$(n=6). Circles with borders represent the SSC in each mechanical condition.

CONCLUSIONS

Preliminary findings indicate that saddle height variations provide a sufficient change in mechanical conditions to substantially affect SSC, metabolic power, and EMG-based cost functions. Critically, the "fatigue-like" CF1 was minimized in all saddle conditions, whereas the "effort-like" CF2 was reduced only in normal and low saddle conditions. These preliminary data suggest the CNS prioritises avoidance of high muscle activation irrespective of the volume of muscle tissue that is activated.

EFFECTS OF AGE-RELATED MUSCLE DEGENERATION ON DYNAMIC STABILITY DURING WALKING: A MUSCULOSKELETAL COMPUTER SIMULATION STUDY

INTRODUCTION

Age-related deficits in muscle function have been considered to negatively affect dynamic stability during walking and increase the risk of falls [1]. Older adults exhibit reduced muscle strength, slower rate of muscle force development, and prolonged twitch contractions compared to younger adults [2]. However, it remains unclear how and to what extent these deficits of muscle property affect dynamic stability. The purpose of this study was to quantify the effect of age-related deficits in muscle function on dynamic stability during walking. A musculoskeletal computer simulation was utilized to alter specific muscular parameters.

METHODS

Walking movement was simulated by using two-dimensional musculoskeletal models, which consists of seven rigid bodies (trunk, thighs, shanks, and feet) and 18 Hill-type muscles (m. iliopsoas, mm. glutei, hamstrings, m. rectus femoris, mm. vasti, m. biceps femoris short head, m. gastrocnemius, m. soleus, and m. tibialis anterior in each leg). Maximum isometric muscle force (F_{iso}), maximum muscle contraction velocity (V_{max}), and deactivation time (T_{deact}) in the model's muscle properties were adjusted to assess the effect of age-related deficits in muscle function on the dynamic stability during walking.

Five models which differed in their muscle properties were created: young adult (YA) and older adult (OA) models, and the models with reduced F_{iso}, reduced V_{max}, and prolonged T_{deact} (ΔF, ΔV, and ΔT models, respectively). The muscle parameters for the YA model were adapted from the previous study [3]. The OA model was defined as the model with 30% reduced F_{iso}, 20% reduced V_{max}, and 20% extended T_{deact} from the YA model [2]. Each of these adjustments for F_{iso}, V_{max}, and T_{deact}, was independently applied for ΔF, ΔV, and ΔT models, respectively.

Numerical optimization was executed to find the muscle activation patterns that yielded successful three steps of walking with minimum energy expenditure. Optimizations were executed with a modified version of the algorithm of [4], implemented in MATLAB (MathWorks Inc., Natick, MA).

The margin of stability (MoS) [5] in the anteroposterior direction at toe-off instant was calculated as a measure of dynamic stability during walking. The MoS value was compared between the models.

RESULTS AND DISCUSSION

The MoS was 0.059 m and 0.020 m for the YA and the OA model, respectively. This indicates that the OA model performed walking with less dynamic stability than the YA model. The MoS was 0.001 m, 0.043 m, and 0.014 m, for the ΔF, ΔV, and ΔT model, respectively. These results indicate that the walking was less stable when the muscle force was adjusted than when the muscle contraction velocity or deactivation time was adjusted. These findings suggest that the degeneration in isometric muscle force would have the most adverse effect on the dynamic stability during walking.

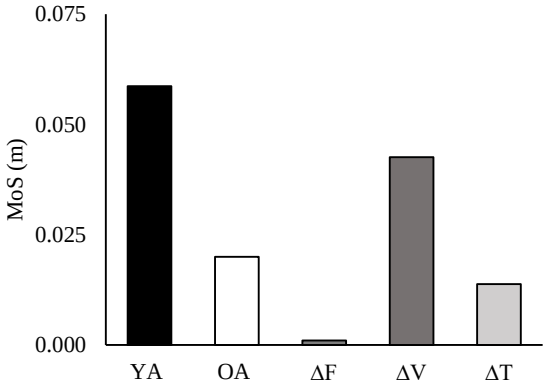

Figure 1 Margin of stability during walking for each model condition.

CONCLUSIONS

Age-related degeneration of muscle properties impaired the dynamic stability during walking. It appeared that the isometric muscle force had a larger effect on dynamic stability than muscle contraction velocity and deactivation time. These findings would be useful for developing an intervention program to effectively reduce the fall risk in older adults.

Anatomical knee model for forward dynamics gait simulation

Beomsoo Shin[1], Seungbum Koo[1]
[1] Department of Mechanical engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea.
Email: skoo@kaist.ac.kr

INTRODUCTION

Ligaments provide passive constraint and stability to the knee. Roles of individual ligaments are controversial [1]. Abnormal kinematics and instability have been reported from patients with ligament ruptrue durting walking [2]. Clinical meausrements could show deviations by different ligament states such as reconstruction [3]. However, the kinematics of uninjured and injured knee conditions are difficult to obtain for the same subject. A dynamics model of the knee with ligaments and muscles would help understand the roles of individual ligaments. A forward dynamics simulation with muscle exctiation controller for walking could predict the kinematics of injured conditions. The objective of this study is to quantify the change of knee joint kinematics according to knee ligament injuries during level walking.

METHODS

A dynamics musculoskeletal model with 25 degrees of freedom (DOF) and 92 lower limb muscles were created [4]. The knee joint was made as a six-DOF joint and constrained with thirty-one ligaments. Ligament force was determined according to its strain. Ligament strain, stiffness, and attachment location were obtained from cadaveric anatomy data in a previous study [5]. The knee model was validated by comparing its kinematic response to external forces and torques [5]. A gait controller that determines temporal muscle excitations was made of a deep neural network and was trained by reinforcement learning to track a measured walking motion of a healthy participant. In the knee, only the flexion-extension angle was provided and the other five-DOF knee kinematics were not constrained during the training. The knee joint kinematics in the simulation of walking of a normal knee were compared with those in a previous study using bi-planar fluoroscopic system [6]. One of the anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), lateral collateral ligament (LCL), and medial collateral ligament (MCL) was removed for each individual ligament injury simulation. The injured knee kinematics were compared with those of the intact knee simulation.

RESULTS AND DISCUSSION

Ligament strain and attachment locations were adjusted less than 9.52% and 8 mm, respectively, with respect to a reference model [5]. Walking motion was generated with a trained neural network, whose root mean square error of knee flexion was 5.6 deg during a gait cycle. Each injury simulation gave produced altered knee kinematics (Figure 1). ACL deficient model (ACLD) showed larger anterior translation during the stance phase. PCL deficient model (PCLD) showed larger posterior translation during the terminal swing phase. LCL deficient (LCLD) model showed varus rotation during the stance phase. MCL deficient (MCLD) model showed valgus rotation during the initial swing phase.

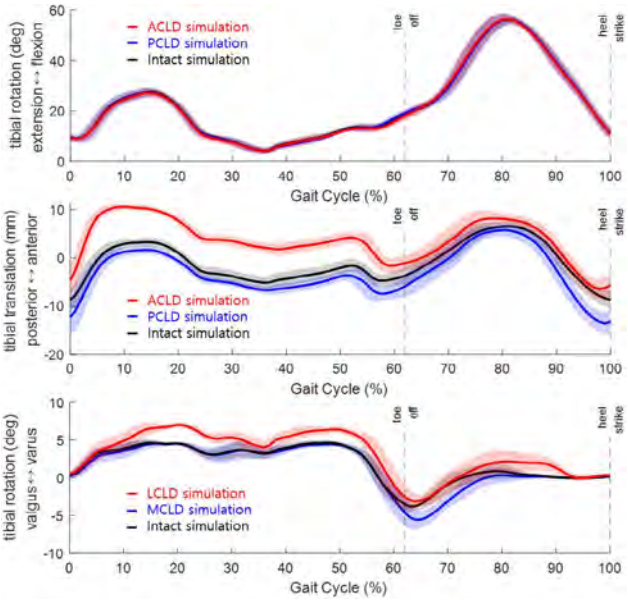

Figure 1 Knee flexion (Top), tibial translation (Mid) and tibial rotation (Bot) among ligament injury simulations during gait cycle

CONCLUSIONS

Six-DOF knee kinematics of normal knee could be reproduced in our forward dynamics simulation [6]. Temporal changes of the knee kinematics could be observed by individual ligament injuries. Cruciate ligaments provided translational stability and collateral ligaments provided rotational stability during gait cycle. It shows a role of ligaments in pure gait dynamics. Human response and adaptation to injury would make the prediction of kinematics changes complicated [2].

INTRODUCTION

The iliotibial band (ITB) is commonly injured in runners due to overuse, yet little is understood about the conditions that cause this syndrome. Typically, peak strain responses of the ITB to changes in gait kinematics have been modelled via musculoskeletal (MSK) models that only consider the ITB as a passive ligamentous structure originating on the iliac crest. However, these simplified models have ignored the potentially large strains transmitted through the ITB by its two in-series muscles; tensor fascia latae (TFL) and gluteus maximus (GMax) [1]. Here, we use an EMG-driven MSK model to assess the mechanical behaviour of the ITB during walking and running with perturbations chosen from literature aimed at increasing the strain in the ITB (i.e., changes in inclination and stance width). We hypothesized that narrower stance width and moving downhill would increase the strain in the ITB (both the ligamentous component and tendonous components).

METHODS

Fifteen healthy participants (4f, 11m, age:30±7 years, Height: 178±8 cm, Weight: 76±12 kg) provided informed, written consent to participate in this study. We recorded fine-wire electromyography (superior region of GMax-GMS), and three-dimensional kinematic and kinetic measures, which were used to drive an OpenSim musculoskeletal model during walking and running for each gait condition (wide stance, narrow stance, uphill, and downhill). We converted a lower body model by Eng *et al.* [1] from SIMM to OpenSim (SimTK, USA) and combined the ITB muscle tendon units (MTUs) of both TFL and GMS) with the Rajagopal *et al.* [2] model. We computed ITB ligamentous strain, and for each MTU we computed the force and length in response to the EMG stimulation during each walking and running condition. We performed separate repeated measures two-way ANOVAs (α=0.05) to test the effect of stance width and inclination on peak EMG and peak muscle force in the TFL and GMS as well peak strain in the ITB ligament structure. Pairwise differences were determined using a Bonferroni-Holm post-hoc comparison (α=0.05).

RESULTS AND DISCUSSION

A summary of the key statistical findings are shown in Figure 1. We found that uphill walking and running increased the demand on all three ITB trajectories (ligamentous, TFL and GMS MTUs) through increasing muscle activity, MTU force, and ITB ligament strain consistently. Additionally, we found limited effects of changing stance width on the MTU behaviour but found that increasing stance width resulted in lower ITB ligament strain.

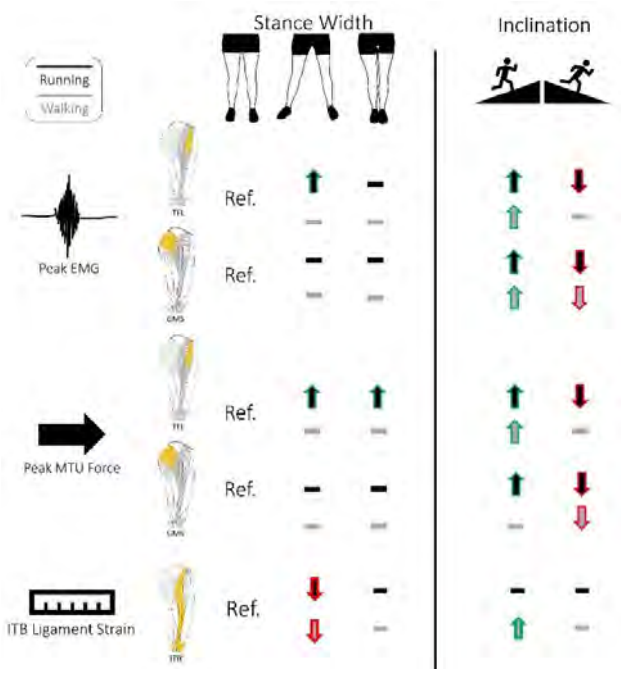

Figure 1 General summary of EMG, ITB MTU forces, and ITB ligament strain findings compared to normal level ground conditions for both walking (grey) and running (black).

CONCLUSIONS

Using our novel experimental and modelling approach, we found that surface inclination had a substantial influence on TFL and GMax activations and force in the ITB portion of these MTUs. During uphill walking and running, peak muscle activation was increased by an average of 51%, and during downhill running was decreased by an average of 33%. In contrast, little evidence of changes in passive ITB ligamentous strain were found due to changes in inclination angle. This work shows new insights into the contrasting mechanical behaviour of the passive (ligamentous) and active (MTU) components of the ITB, and these vary with gait modifications associated with ITB syndrome.

INTRODUCTION

Gait symmetry is one of the most informative aspects of gait quality. Quantifying gait symmetry contributes to the identification of deficits in typical and pathological locomotion. Many metrics have been proposed based on different data sources and approaches [1]. However, no consensus exists on their appropriate biomechanical interpretation and whether gait speed has an effect on symmetry indices computation.
The aim of this study is to compare two different gait symmetry indexes adopted in the literature, based on different data sources and approaches (from the whole-body centre of mass (BCoM) trajectory [2], and the accelerations measured by an inertial sensor located on the pelvis [3]) during walking at different speeds.

METHODS

Ten healthy participants (4 women, 1.71±0.08 m height, 68.2±10.2 kg body mass, 34.5±8.5 years old; mean±SD) walked for 60 s on a treadmill at seven different speeds (from 0.28 to 1.95 m/s with steps of 0.28 m/s) in a randomised order. Each participant was then asked to simulate an asymmetric walk at 0.83 m/s (ASYM). The position of 18 markers located on the main joint centres was recorded (200 Hz) with a Vicon system and the 3D BCoM trajectory was computed as a weighted mean [4]. For each stride, the BCoM trajectory was closed in a 3D loop and described by a 10-harmonic Fourier series, whose coefficients were used to calculate the Symmetry Index (SI) for each anatomical axis (antero-posterior (AP), medio-lateral (ML), and cranio-caudal (CC)) [2]. Simultaneously, lower trunk 3D linear accelerations were collected (200 Hz) by an inertial measurement unit (IMU) (APDM Opal) located at the L1-L2 level. To guarantee a repeatable system of reference among participants, the IMU was verticalized, and the resulting axes were considered to approximate anatomical axes. Gait symmetry was obtained for each stride by computing the improved Harmonic Ratio (iHR) [3]. SI and iHR ranges from 0%, total asymmetry, to 100%, perfect symmetry. The influence of speed and index on symmetry was assessed with a two-way repeated measure ANOVA after checking for data normality.

RESULTS AND DISCUSSION

Perfect symmetry (100%) was never achieved. In both indexes, symmetry increased significantly ($p<0.001$) with walking speed in AP and CC axes, whereas in ML axis, symmetry slightly decreased (SI) or increased (iHR) (Figure 1). Symmetry values were substantially different between indexes ($p<0.001$), with iHR showing higher values in AP and CC, and lower in ML. ASYM deviation from typical walking was highlighted by both indexes in AP and CC axes only ($p<0.05$). The difference in symmetry values between indexes can be ascribed to the different data sources (position vs. acceleration, and BCoM vs. pelvis) and analysis (harmonic content in SI vs. harmonic power in iHR).

CONCLUSIONS

Although a similar trend is shown by both indexes in the AP and CC axes at increasing speed, iHR systematically described a more symmetrical gait. This suggests caution when comparing values obtained by different metrics. Moreover, since symmetry indices are influenced by walking speed, particularly at low speeds, any comparison (e.g. among age-groups or diseases) should be performed only by matching the speed.

INTRODUCTION

Understanding mechanical phenomena underlying the initiation of gait is essential to better prevent risk of falling. Thus, mechanical variables such as kinematics of the center of mass or whole-body angular momentum evolutions have been demonstrated to be related to anticipatory adaptations of the body while stepping [1,2]. A degradation of these adaptations could therefore reveal an increased risk of falling and has been observed in motor-impaired population [2]. However, in spite of encouraging results, the transfer towards real-time applications for prevention or monitoring is hindered by the complexity of the proposed indicators in both their interpretability and their quantification process. In this abstract, we proposed to test the feasibility of using a mechanical-based index: the distance of the Body Center of Mass (BCoM) to the Minimal Moment Axis (MMA) of the external contact wrench, referred hereafter as $d_{BCoM-MMA}$ [3]. This index should overcome the above-mentioned difficulties while keeping a discriminating nature when comparing young and elderly stepping.

METHODS

15 healthy young (mean age: 25 years old; range: 19-29) and 15 healthy old (mean age: 69 years old; range: 63-77) adults volunteered. They were asked to initiate gait 10 times at a self-selected preferred (Pref) and at a fastest speed (Fast). Each participant performed this stepping and $d_{BCoM-MMA}$ was then obtained at each instant of time using: $d_{BCoM-MMA} = \frac{\|\boldsymbol{F} \times \boldsymbol{M_{BCoM}}\|}{\|\boldsymbol{F}\|^2}$ where $\boldsymbol{F} \times \boldsymbol{M_{BCoM}}$ is the cross product between the external forces and the external moment computed at the BCoM, $\boldsymbol{M_{BCoM}}$ being equal to the variation of the angular momentum ($\boldsymbol{K}$) at the BCOM obtained as described in [5]. Two parameters were then extracted for each trial and each participant: the norm of $d_{BCoM-MMA}$ (d_{norm}) and the value of the Antero-Posterior algebraic distance d_{AP}. Under the hypothesis of normal distribution, t tests were performed to compare the values of the range across groups and across conditions.

RESULTS AND DISCUSSION

Whereas average velocities were close for both groups for the Pref condition, the ranges of the norm and the antero-posterior component of $d_{BCoM-MMA}$ were significantly higher ($p<0.05$) for the group of old adults compared to the group of young adults. On the contrary, for the Fast condition, even if their average velocity was greater, the values of both parameters remained significantly lower for young compared to the old people (Table 1).

This study is the first to quantify the ranges of parameters extracted from $d_{BCoM-MMA}$ during stepping. The values of the ranges are consistent with the ones retrieved during gait of healthy adults. The magnitude of the increase with speed and age is also consistent with the tendency of the distance to be higher for motor-impaired people or in destabilizing situations [5]. Finally, the evolution of the proposed parameters with age is in direct relation with the larger angular momenta exhibited in this population [3]. It therefore confirms that this indicator could be used to monitor gait dynamics in real-time.

CONCLUSIONS

In this abstract we compared stepping instability using the distance between the BCOM and the MMA on old and young population at spontaneous and fast speed. Our results demonstrate that the distance tends to increase for older population at both cadences. This tendency is consistent with the higher instability of older adults during stepping and the distance could be used to quantify it.

EFFECTIVENESS OF CO-CONTRACTION IN MITIGATING THE EFFECT OF AGE-RELATED INCREASE IN PASSIVE MUSCLE STIFFNESS

Tiina Murtola and Christopher Richards
Department of Comparative Biomedical Sciences, Royal Veterinary College, London, UK.
Email: tmurtola@rvc.ac.uk

INTRODUCTION

Ageing causes changes in the musculoskeletal system and its control. These changes include increasing the passive stiffness muscles [1], which has been observed to cause deterioration of reaching performance in simulations when studied independent of other ageing changes [2]. Older individuals have also been observed to utilise increased co-contraction of antagonistic muscles [e.g. 3]. In the present work, we use computational simulations to investigate the extent to which this co-contraction strategy has the potential to mitigate the effects of increased muscle stiffness.

METHODS

A three joint, six muscle model of the human upper limb is used in conjunction with a predictive PD controller which computes muscle excitations for horizontal reaching movements [2]. In order to introduce planned co-contraction into the model with minimal changes to the controller, each of the muscles (i=1,…,6) is set to produce force f_i according to

$$f_i = f_{a,i}a_i + f_{p,i} + f_{c,i},$$

where $f_{a,i}$ is the active force-velocity-length relationship, a_i is the active state, $f_{p,i}$ is the length dependent passive force, and $f_{c,i}$ is the co-contraction force for muscle i. Three cases of $f_{p,i}$ are considered: (i) no passive stiffness, (ii) slight passive stiffness representing young adults (YA) and (iii) severe passive stiffness representing older adults (OA). Co-contraction forces are kept constant throughout simulations, and three levels are compared: (i) no co-contraction, (ii) co-contraction at 5% of the isometric strength of the weaker muscle in an antagonistic pair, and (iii) co-contraction at 10% of the weaker muscle strength. Control parameters are optimised for each case separately, and accuracy of reaching towards four different targets is studied.

RESULTS

The deteriorating effects of increasing muscle stiffness can be seen both in average accuracy of the final endpoint position (Table 1) as well as for each individual reach (Figure 1). This deterioration is particularly large for contra-lateral reaching (target 2), where the final position error for the OA model is 700-fold compared to the YA model. Increasing co-contraction force had variable effects: it reduced accuracy in the model with no passive stiffness, caused target-dependent improvement or deterioration in the YA model, and resulted in a minor loss of accuracy for targets in the OA model except for target 2, where both 5% and 10% co-contraction levels improved accuracy significantly.

Table 1: Average reaching accuracy (mm) for the three passive stiffness and three co-contraction conditions considered.

f_c	No f_p	YA	OA
None	0.0087	0.0493	6.8133
5 %	0.0404	0.0602	2.1209
10 %	0.0588	0.0635	3.1615

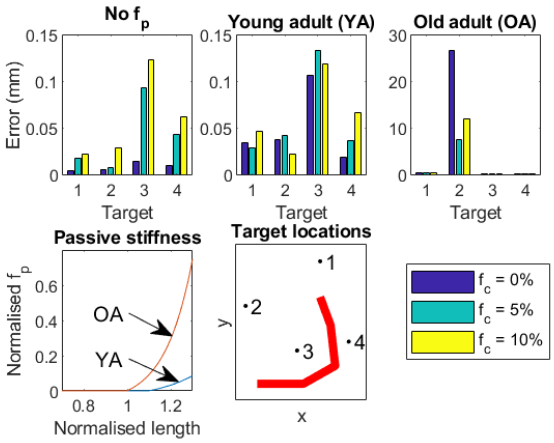

Figure 1 Accuracy of reaching towards four targets under three passive stiffness conditions and co-contraction force levels.

CONCLUSIONS

Our simulations indicate that age-related muscle stiffening causes deterioration in reaching accuracy, but this effect can be partially reversed in some movements by co-contraction of antagonistic muscles. However, in other cases, co-contraction may lead to reduced accuracy, suggesting that increased co-contraction observed in older adults serves a more complex purpose than simply compensating for muscle stiffness.

INTRODUCTION

Predictive neuromechanical simulations are useful for estimating the biomechanics of the human body in the absence of experimental data. These simulations are usually set up as optimal control problems aiming at finding the simulation parameters that optimize the movement of a neuromechanical model of the human body by minimizing a task-dependent cost function. A common approach is that of using the optimal control problem for estimating the parameters of a neural controller that can, or not, be biologically inspired. In this work we propose a novel biologically-inspired neural controller for predictive simulation of cycling. The controller we developed pairs descending, rythmic activity, with reflexes to obtain a physiological cycling motion.

METHODS

The biomechanical model used in this work was adapted from a standard gait biomechanical model developed in Opensim. The neural controller used in the simulations is a composite controller constituted by a feedforward synergistic controller and a reflexive feedback controller. The feedforward controller consists of 10 synergies (5 per side). The synergies are shaped as synergy modules, where the contribution of a muscle to the module is reflected by a weight value, activated by a time-varying activation signal. The contribution of the muscles to the modules of the synergies was restricted by those observed experimentally in [1]. Specifically, each module was constituted by 2-4 muscles of unknown weight, selected as the muscles considered more active in an experimental synergy, while the weights for all the other muscles was set to zero. The activation signals of the synergies were modelled as sine waves with zeroed negative phase. All the 10 synergies shared the same frequency for the cosine, while each synergy has its own phase. The optimization procedure estimates the weights of the muscles in each synergy, the common frequency of the 10 synergies activation signals and the amplitude and phases of the activation of the single synergies. To minimize the parameters to be optimized, the amplitude and phases were estimated only for the synergies on the left side. The amplitudes for the right side were the same as the left, and the phases were delayed by π. The reflexive controller was modelled as a controller that inhibits the activation of a muscle if its antagonistic muscle is active. The optimization was carried out using the CMA-ES algorithm [2] by estimating the synergy parameters minimizing a cost function which penalizes ankle dorsi-flexion angles outside the [-30;20] degrees range and minimizes the energy expenditure, the interaction forces between the pedal and the foot and the difference between the actual and target speed (75 rpm). The simulations were set to last 8 seconds. The muscular activations obtained in these simulations were compared with those obtained during a baseline cycling task performed at 75 rpm in a previous work [1]. The simulations were performed using the Hyfydy simulation engine and the SCONE software [3]. We performed 15 simulations with random initial parameters. The parameters of the simulation better minimizing the cost function were then used as initial parameters for 10 post-hoc simulations, that have been analyzed using custom Matlab code.

RESULTS AND DISCUSSION

The optimization procedure resulted in simulations which synthesized kinematic data consistent with a physiological normal cycling pattern (not shown) and muscular activations that are similar to the experimental ones (Figure 1).

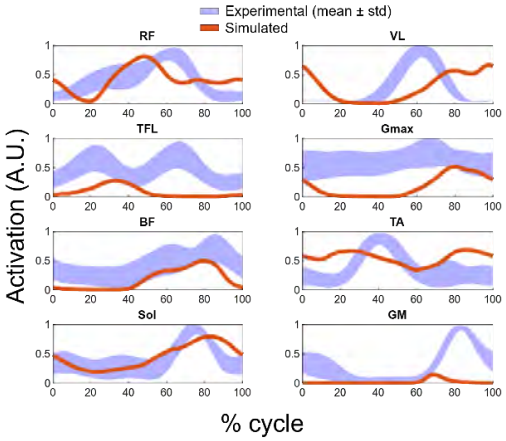

Figure 1 Comparison between experimental (blue) and simulated (red) muscular activations.

CONCLUSIONS

Here we show that a simple synergistic/reflexive controller, paired with a general cost function, can replicate cycling kinematics and, to a degree, the physiological muscular activations. Further work will test improved cost functions, and the ability of the controller to generalize to different cycling scenarios.

INVESTIGATING THE EFFECTS OF PATELLOFEMORAL GEOMETRY INCONGRUENCE ON JOINT FUNCTION USING COMPUTATIONAL MODELLING

Annagh Macie[1], Allison Clouthier[1]
[1] School of Human Kinetics, University of Ottawa, Ottawa, Canada.
Email: amaci014@uottawa.ca

INTRODUCTION

Bone and cartilage geometry varies widely among people and these morphological differences have implications for risk of injury and pathology. In the knee, geometrical features have been associated with patellofemoral (PF) pain and instability, and knee osteoarthritis. Furthermore, changes to bone geometry that occurs in knee surgeries like trochleoplasty (sulcus deepening) have been noted to increase PF contact pressure and shear stress [1]. Investigations into how incongruent PF geometry affects joint function can provide insight into why certain variance in bone geometries may put a person at risk for injury or pathology. This research seeks to use computational modelling to demonstrate the effects of PF geometry incongruency in regards to changes in PF kinematics and cartilage contact pressure during gait.

METHODS

A statistical shape model was generated from magnetic resonance images of the right knee of 14 asymptomatic participants [2]. Meshes of the femur, tibia and patella bone and cartilage were created [2]. Principal component (PC) analysis was then applied to the whole joint [2]. For PC2 (trochlear groove (TG) depth), new knee geometries for the femur and patella were created by adding ± 3 standard deviations of the PC2 score multiplied by the loading vector for PC2 to the mean mesh. This resulted with 3 geometries of TG depth (shallow, mean and deep) as well as a congruent patella for each TG. Combinations of one femur and one patella were then created to produce models with congruent and incongruent geometries (i.e., deep TG with deep patella and deep TG with shallow patella), for a total of nine knee models. These models where then integrated into a previously validated musculoskeletal model and the same overground walking trial was simulated using each model. The cartilage contact pressure and knee kinematics were simulated for the walking trial using the Concurrent Optimization of Muscle Activations and Kinematics (COMAK) routine [3]. The resulting knee kinematics and contact mechanics from the different models were compared throughout the gait cycle to assess the influence of PF incongruence on functional knee mechanics.

RESULTS AND DISCUSSION

The findings from this research indicated that a lack of bone geometry congruency results in changes in joint kinematics and cartilage contact pressure during gait. With the models using the deep patella there was an increase in lateral patellar translation and patellar tilt as bone congruency decreased. Furthermore, contact pressure also increased and presented more laterally as bone congruency decreased (Fig. 1). With the models using the shallow patella, lateral patellar translation and patellar tilt was greater using the congruent shallow TG and decreased with less congruent femur models, with the least amount of patellar translation and tilt being present with the deep TG. Similarly, for contact pressure the shallow patella also showed that the highest and most lateral pressure occurred with the congruent femur and this reduced and presented more medially as incongruence increased. These results indicated that instances where the shallow TG was used resulted in the most lateral translation and largest amount of contact pressure regardless of congruency.

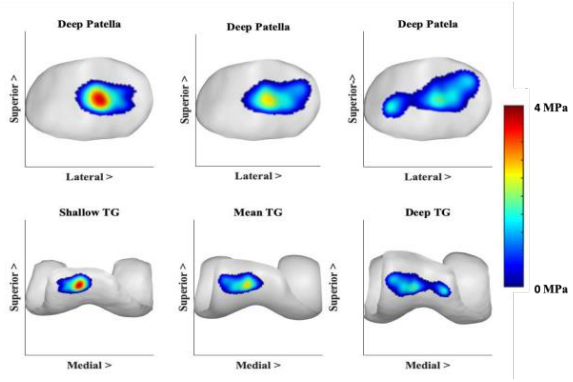

Figure 1 Instant of maximum contact pressure for models using a shallow, mean and deep TG and a deep patella during gait.

CONCLUSIONS

This research explores the effects of bone geometry and congruence on PF function. Changes in PF geometry congruency did result in altered PF joint kinematics and cartilage contact pressure in all of the models. However, in the scope of decreasing lateral patellar translation and patellar tilt as well as decreasing and medializing cartilage contact pressure, the absence of a shallow TG was the key component for this outcome. Understanding the effect of congruence on function could provide insight into treatment effectiveness or the likelihood of an individual experiencing a knee injury or degenerative knee disorder.

INTRODUCTION

In musculoskeletal modeling, the path of a muscle is represented as a series of straight and curved lines, defined by origin, via, and insertion points as well as obstacles around which the lines wrap [1]. A correct configuration of muscle path is crucial for simulation accuracy as it determines muscle moment arm, on which a muscle's kinetic capacity is dependent. However, muscle path modeling can be laborious, where a large number of path-related parameters must be tuned; often manually. In this work, we propose a method that automatically calibrates muscle path, with high speed and accuracy.

METHODS

We formulate the process of parameter tuning as a least-squares problem with the following cost function:

$$\delta(\boldsymbol{p}) = \sum_{n=1}^{N} \|\boldsymbol{r}_{\text{data}}(\boldsymbol{q}_n) - \boldsymbol{r}_{\text{model}}(\boldsymbol{q}_n, \boldsymbol{p})\|_2^{\,2} \rightarrow \min$$

where $\boldsymbol{p}$ denotes muscle path parameters, including locations of origin, via, and insertion points, as well as the size, location, and orientation of the wrapping obstacle(s), and $\boldsymbol{r}(\boldsymbol{q})$ is the moment arm at joint position $\boldsymbol{q}$. Note that $\boldsymbol{r}$ and $\boldsymbol{q}$ are vectors with the dimension of DoF number, whereas N is the size of the dataset.

To reduce computational load, we first take a geometric approach to compute $\boldsymbol{r}_{\text{model}}(\boldsymbol{q})$ from the muscle path defined by $\boldsymbol{p}$, and then specify the gradient of $\delta(\boldsymbol{p})$ in its analytical form. To this end, we revise the muscle path algorithm in [1] into a continuous form, such that the derivative $\partial \boldsymbol{r}_{\text{model}}(\boldsymbol{q}, \boldsymbol{p})/\partial \boldsymbol{p}$ exists for all $\boldsymbol{p}$.

For result quantification, we use a 12-DoF human shoulder-arm model [2] as a reference to examine algorithm performance in replicating the geometry of all 42 muscle paths. Measurements of $\boldsymbol{q}$ in [3] are put into the reference model to generate artificial $\boldsymbol{r}_{\text{data}}(\boldsymbol{q})$ for calibration and validation.

RESULTS AND DISCUSSION

On a 2.9-GHz Intel Core i9 (64 GB RAM), the path calibration of all 42 muscles took 37.2 min; with parallel computing, the total time decreased to 5.5 min. For most muscles, the calibration took less than 1 min. Muscles with multiple via points and wrapping obstacles are configured with more than 18 parameters, requiring more iterations, but were still calibrated within 5 min.

The calibrated muscle path geometry shared much resemblance to the reference model (Figure 1, top). In validation, most muscles contain less than 1 mm of absolute error in moment arm about any actuating DOF (Figure 1, bottom); the mean is 0.37 mm.

With the analytical form of the gradient specified, our muscle path calibration method achieves speed and accuracy beyond manual capability. A major challenge in muscle path modeling is that a muscle may span multiple joint DoFs and have multiple moment arms, each determined by all actuating DoFs. Importantly, our method is not limited to fit moment arm–angle curves or surfaces but is designed to fit hypercubes. The path calibration we demonstrate is based on a vector of moment arms about 12 DoFs, which dependents on a vector of 12 generalized coordinates ($\boldsymbol{r}(\boldsymbol{q})$: $\mathrm{R}^{12} \mapsto \mathrm{R}^{12}$). This is an impossible task for manual tuning.

Though the performance is demonstrated in silico, the method is conveniently compatible with experimental data, since the only mandatory input is the relationship between moment arms and joint angles. We also derived the gradient for a path coordinate–based cost function, which enables calibration with medical imaging data (e.g., MRI) and expands the possibility of application.

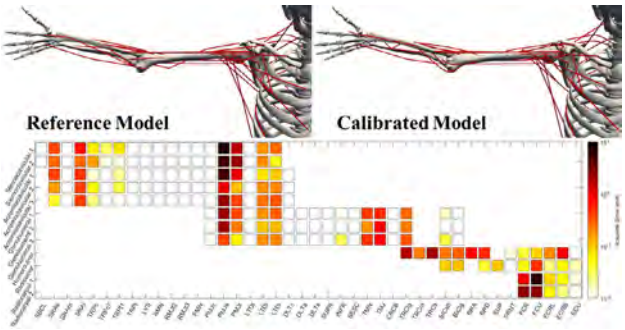

Figure 1 Top: Reference and calibrated muscle path geometry. Bottom: Absolute error of moment arm about each actuating DoF.

CONCLUSIONS

An automated method of muscle path calibration is developed with the gradient analytically specified, and its performance is demonstrated by fast and accurate replication of muscle path geometry.

INTRODUCTION

A large array of small and large muscles can control the foot and ankle to aid in locomotion across complex terrain. These muscles can control the foot by either co-activating muscles prior to a perturbation or rely on feedback to stabilize the foot and ankle. *In vivo* experiments to understand these mechanisms are limited by multiple factors such as having humans experience unsafe, unexpected perturbations that could lead to injury [1]. *In silico* experiments allow researchers to overcome these limitations imposed by *in vivo* studies. The purpose of this study is to determine how humans can compensate for peturbations to the foot-ankle complex using computer simulation and a neuromusculoskeletal model.

METHODS

Musculoskeletal model: We used a modified version of a musculoskeletal model [2] with 12 muscles that crossed a 3 degree of freedom (DoF) ankle with a 3 DoF bushing force representing a lumped ligament contributing force at the end range of motion.

Neural model: We added a simulated neural network consisting of motoneurons and basic reflex circuitry. Each muscle was controlled by a population of motoneurons; Ia spindle feedback calculated from the musculoskeletal model was connected to the neural network model to simulate Ia homonymous excitation (stretch reflex) and reciprocal inhibition to all antagonist muscles. Renshaw cells (exhibiting recurrent inhibition of the agonist muscles) and phasic presynaptic inhibition of Ia afferents were modelled. Motoneuron pools were activated by descending drives.

Task: We applied simulated torque perturbations to the ankle of the neuromechanical model that varied in amplitude and were consistent with locomotion literature. We used optimization (with a multi-objective version of covariance adaptation evolution strategy) to find connection weights (feedback, central, and drives) that minimize metabolic cost, angular accelerations, and ligament force in response to random perturbations into dorsiflexion (similar to stance phase of locomotion).

RESULTS AND DISCUSSION

Without the neural reflex model, the muscle activations in response to a novel perturbation resulted large angular deviations. With the additional of a neural feedback model, the perturbation was compensated resulting in an angular acceleration profile that was relatively smooth, creating increased stabilization of the foot. Figure 1 shows an example of the simulation with a 50 Nm perturbation to the foot with neural feedback.

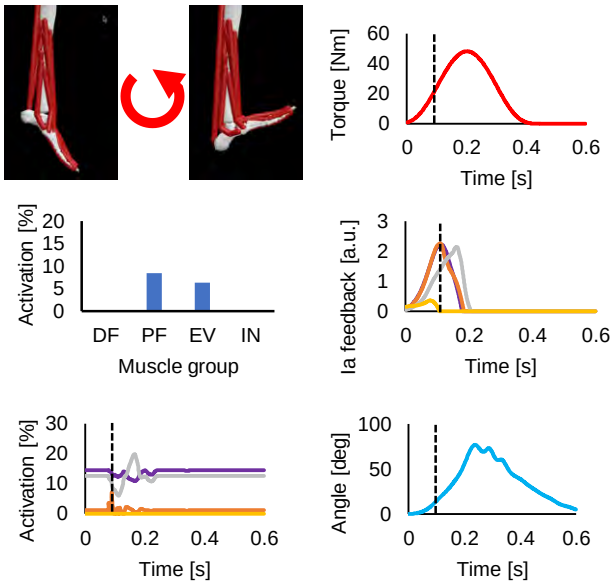

Figure 1: Top left panel shows the ankle model initial position and perturbation. Top right panel shows the torque perturbation time course. Middle left panel shows pre-activation of dorsiflexors (DF), plantarflexors (PF), evertors (EV), invertors (IN) prior to the perturbation. Middle right panel shows the Ia feedback from tibialis posterior (yellow), gastrocnemius medialis (orange), peroneus brevis (grey), and soleus (purple). Bottom left panel shows the activations from these same muscles. Bottom right panel shows the joint angle change from the perturbation.

Our preliminary findings showed that the combination of pre-activation of multiple muscles crossing the ankle followed by a coordinated activation of select muscles to produce force can oppose a rapid, applied perturbation to the foot similar to what is experienced during locomotion. During bipedal locomotion across varied terrain, humans can alter their foot posture and muscle activations to prepare for unexpected perturbations from the environment. Although there are other plausible mechanisms, these results provide a basis for understanding how humans can adapt to quick, unexpected perturbations to the foot and ankle via feedback similar to what occurs in locomotion.

CONCLUSIONS

Feedback is important for controlling perturbations to the foot and ankle and a combination of muscle pre-activation and the low-level neural circuitry are likely essential for controlling the foot during locomotion.

INTRODUCTION

Non-invasive modelling tools, such as *in-silico* and *in-vitro* studies, have been developed to predict shoulder biomechanics and to better understand the impacts of clinical challenges on it. Previous studies have developed musculoskeletal shoulder models however, the experimental validations were generally insufficient. The goal of this study was to investigate the impact of soft tissue injuries on shoulder joint mechanics using a musculoskeletal model validated against *in-vitro* data from an advanced cadaveric shoulder simulator.

METHODS

A subject-specific musculoskeletal model was developed using OpenSim [1]. The model (Fig. 1), expanded on previous published models [2], comprises a six degree of freedom (DoF) shoulder joint actuated by eight Millard 2012 Equilibrium type muscles {Anterior, Lateral and Posterior Deltoids (AD, LD, PD respectively), Subscapularis Superior (SBS) and Inferior (SBI), Supraspinatus (SSP), Infraspinatus (ISP), Teres Minor (TM)}. Concurrent Optimization of Muscles Activation and Kinematics (COMAK) algorithm [3] was used to predict muscle and joint contact forces for two ranges of motion (RoM) {Abduction (ABD) and Forward Flexion (FF)} under three conditions {healthy, supraspinatus tear, Type C tear (SSP, ISP, SBS tears) [4]}. Tears were simulated by setting up maximum isometric force to zero. The kinematics from our in-house eight muscle-actuated, six DoF advanced cadaveric shoulder simulator were input into the model for validation. Pearson correlation coefficients were calculated to compare the muscle forces from the model against the shoulder simulator forces during the different RoMs and thereby assess the validity of the *in-silico* study.

RESULTS AND DISCUSSION

For ABD and FF, forces in the dominant muscle groups estimated by the musculoskeletal model and those measured by the cadaveric shoulder simulator showed strong correlations (Pearson's r >0.5, Fig.1). However, for some non-dominant muscle groups (all conditions: PD; Type C: TM and SBI), Pearson's r <0.5 demonstrated weak correlation between the shoulder model and the experimental muscle forces. This may be explained by their low force magnitudes and the small changes in their activation patterns.

Our results indicated increases of AD and LD forces with the severity of the conditions tested (ABD results in Fig. 1, an average increase of 30% for the AD and 47% for the LD).

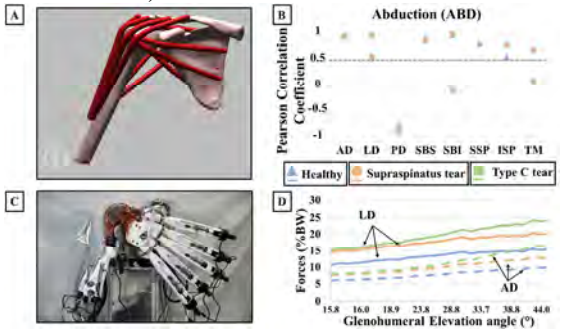

Figure 1 (A) OpenSim musculoskeletal model; (B) Correlation between muscle forces estimated by the model and the corresponding *in-vitro* data during ABD {Grey dashed line – Pearson's r = 0.5}; (C) Cadaveric shoulder simulator; (D) AD and LD muscle forces for ABD.

CONCLUSIONS

The results obtained from the shoulder model and those from the cadaveric simulator showed a good agreement for the dominant muscle groups. We found that the AD and LD forces increase when the rotator cuff muscles' function is compromised. This increase in muscle load may generate higher stress on the bones leading to potential fracture. Our *in-silico* approach provides a non-invasive tool for further investigations on shoulder pathologies and effectiveness of different surgical techniques.

INTRODUCTION

Cardiovascular disease (CVD) causes about 30% of global death (estimated 17.9 million) and about 80% of CVD is atherosclerosis-related diseases [1]. Vascular smooth muscle cells (VSMCs) are the major cellular components of arterial wall and perform the major function for arterial contraction and extracellular matrix (ECM) production. During atherosclerosis, VSMCs undergo phenotypic switching to a synthetic phenotype capable of proliferation and migration. The surrounding environment of VSMCs in vivo undergoes alterations in ECM stiffness and composition in addition to an increase in cholesterol content. Our work is focused on the analyzing difference in the mechanics of VSMCs isolated from western diet fed apolipoprotein-E knockout (ApoE$^{-/-}$) and wild type (WT) mice during atherosclerosis.

METHODS

VSMCs were enzymatically isolated from the descending thoracic aorta of male ApoE$^{-/-}$ and male WT mice [2]. VSMCs were cultured on elastically tunable substrates. Atomic force microscope (AFM) was employed to study N-cadherin (N-Cad) mediated cell-cell adhesion, integrin mediated cell-ECM adhesion forces, and stiffness of VSMCs. AFM was also used to examine live VSMC submembranous cytoskeleton organization. Two-way ANOVA was used to test statistical significance for all experiments.

RESULTS AND DISCUSSION

No significant difference in cell stiffenss was observed between normal diet-fed ApoE$^{-/-}$ and WT VSMCs. After three-month high fat diet, ApoE$^{-/-}$ VSMCs were found to have a significantly higher stiffness compared to WT VSMCs (Figure 1) [2]. Increased stiffness of ApoE$^{-/-}$ VSMCs correlated with a greater degree of stress fiber alignment as evidenced by AFM-generated force maps and stress fiber topography images. ApoE$^{-/-}$ VSMCs had a significantly lower adhesion force to N-Cad compared to WT on the 28 and 103 kPa substrates.

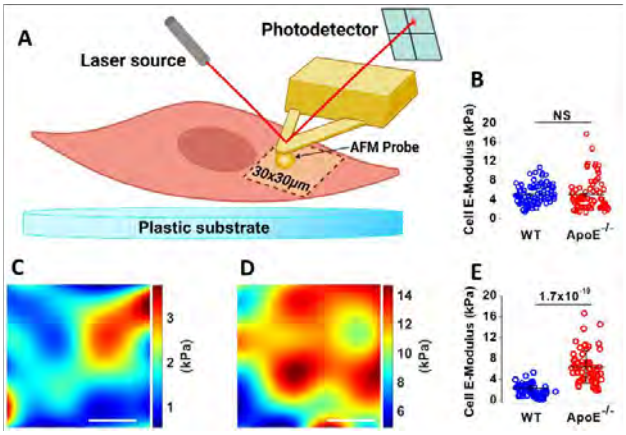

Figure 1 Live WT and ApoE$^{-/-}$ VSMC stiffness maps. **(A)** 30 × 30 μm cell surface areas were automatically scanned and indented at 6×6 positions with a glass bead. **(B)** Average stiffness for normal diet-fed ApoE$^{-/-}$ and WT VSMCs. **(C, D)** Stiffness force maps for WT and ApoE$^{-/-}$ VSMCs, respectively. **(E)** Average stiffness for Western diet-fed WT and ApoE$^{-/-}$ VSMCs. All data are presented as means ± SE (n > 60 cells across six different mice). Scale bar in lower right corner represents 10 μm. A was created with BioRender. com.

CONCLUSIONS

The results demonstrated a significant difference in cell mechanics, cytoskeletal organization, and migratory behavior of VSMCs isolated from WT and ApoE$^{-/-}$ mice. This supports our hypothesis that atherosclerosis alters the mechanical properties of VSMCs and provide insight into underlying mechanisms that may lead to future novel therapeutic approaches.

Identification of collective mechanical traits of an injured muscle model

Tae Yoon Kwon[1], Hyuntae Jeong[1], Youngbin Cho[1] and Jennifer H. Shin[1]

INTRODUCTION

Collective cell migration is essential in diverse biological processes, including wound healing, development, cancer metastasis, and tissue regeneration. Skeletal muscle tissues contain myoblasts and satellite cells, which are undifferentiated forms of muscle cells that help self-regeneration after muscle injury. Collective motions in skeletal muscle regeneration are composed of cellular heterogeneity due to the presence of undifferentiated cells. This migration of skeletal muscle cells is important for regeneration because it serves as targeted migration toward injured regions as well as an aligning motion for improved differentiation. However, little is known about the dynamic collective behavior of skeletal muscle regeneration.

In this study, we constructed in vitro injured muscle model which can mimic a skeletal muscle injury and regeneration environment with conditioned media. In addition, we identified the collective mechanical traits of the muscle cell clusters with the muscle model.

METHODS

C2C12 cells were obtained from American Type Culture Collection (CRL-1772) and cultured under a normal culture condition. Normal muscle (NM) and damaged muscle (DM) conditioned media were manually obtained by fully differentiated and scratch-damaged-differentiated C2C12 skeletal muscle cultured with base media (BM), respectively. Polyacrylamide gel (PA gel, 11kPa) and collagen type I were used to construct in vitro cell traction measurement platform. We cultured C2C12 cells on circular patterned (Diameter: 700μm) collagen, which was created by utilizing a PDMS stencil to allow selective attachment of the cells only inside the circular pattern. The stencil was then removed to induce the migration of cells toward free space. The displacements of the fluorescent beads contained in the PA gel were used to calculate traction and intercellular stress.

RESULTS AND DISCUSSION

We examined the migration behavior of the cell clusters under three different media conditions (DM, NM, and BM) for 24 hours. Distinct patterns were observed in the spreading area, velocity, and directionality under each condition. Furthermore, the traction and stress of migrating cells also showed uniquely different trends and were closely related to the migrating behavior. We identified that the heterogeneous population of skeletal muscle cell clusters exhibited distinct behaviors in the injured muscle-mimicking condition compared to the normal muscle-mimicking condition.

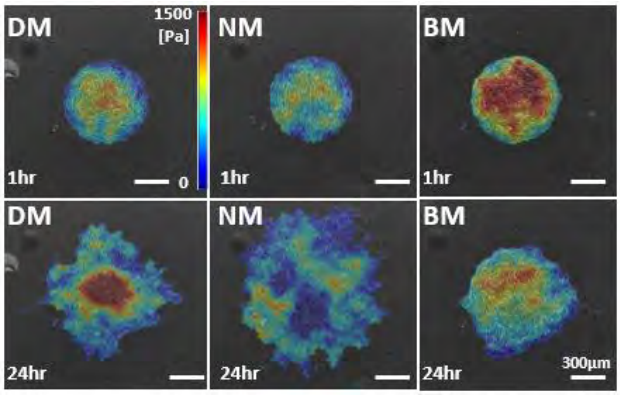

Figure 1 Temporal evolution of intercellular stress map.

CONCLUSIONS

In this study, we constructed in vitro injured muscle model which can mimic the skeletal muscle regeneration environment and measure cell traction to analyze the collective migration of muscle cells. As a result, we identified distinct patterns of migratory behavior and the mechanical traits of the cell clusters under different media conditions. Based on these findings, we suggest that biochemical cues from normal and injured skeletal muscles can induce these unique migratory patterns and mechanical properties by selectively activating specific cells at migrating clusters.

EFFECTS OF SOLUTE MOLECULAR SHAPES ON OSMOSIS ACROSS FIBROUS MEMBRANES: AN APPLICATION TO FLUID TRANSPORT IN AN ENDOTHELIAL GLYCOCALYX LAYER

INTRODUCTION

Endothelial glycocalyx layer (EGL) is a fiber matrix of proteoglycans and glycoproteins observed at vascular endothelial cell surfaces. Interaction between EGL and plasma globular proteins is believed to help preventing transcapillary fluid extravasation. Low level of serum albumins, for instance, is believed to cause hypovolemia and facilitate pulmonary edema [1]. The present work focuses on studying the effect of EGL-globular protein interaction on the abilities of globular proteins as osmotic agents due to their molecular shapes through a theoretical investigation.

METHODS

Volume flux (J_v) of the osmotic flow across a fibrous membrane can be written as

$$J_v = L_P\left(\Delta P_\infty - \sigma_0 \Delta\Pi_\infty\right) \qquad (1)$$

where ΔP_∞ is the hydrodynamic pressure difference across the layer and $\Delta\Pi_\infty$ is the osmotic pressure difference related to the external solute concentration difference (ΔC_∞) as $kT\Delta C_\infty$. L_P is the hydraulic permeability, and σ_0 is the osmotic reflection coefficient. Based on analysis of electron microscopic images showing that, near the endothelial cell surfaces of frog mesenteric capillaries, EGL structure was a quasi-periodic fibrous meshwork [2], EGL simplified geometry was that of a hexagonal array of rigid cylinders [3, 4]. In the present study, globular proteins are modelled as spheroids**.** Lubrication approximation can be employed and, using Green's second identity, σ_0 can be computed as [4,5]

$$\sigma_0 = 1 - \left\langle u_z \left\{ \exp\left(-E/kT\right) \right\} \right\rangle \Big/ \left\langle u_z \right\rangle \qquad (2)$$

where u_z is the axial velocity of Stokes flow in a hexagonal array of cylinders. E is the solute-fiber potential energy of interaction. To examine effects of solute molecular shape alone, E was assumed to be due to a solute-fiber steric interaction. The curved and angle brackets denote an average over all solute orientations and a cross-sectional average, respectively. u_z was obtained as a finite element solution and σ_0 was computed using Eq. (2).

RESULTS AND DISCUSSION

In Figure 1, σ_0 is presented as a function of the solute Stokes-Einstein radius (a_{SE}) scaled with the distance between two closest fibers (d). An increase in solute shape asymmetry (an increase in deviation of b/a from unity) causes an increase in σ_0. At a_{SE} = 3.6 nm (a_{SE} of serum albumins) and d = 6 nm (d of EGL [2, 4]), σ_0 of an uncharged sphere = 0.66. If the solute shape resembles that of an albumin (approximated as an oblate spheroid with b/a = 0.5), σ_0 = 0.81 [6], close to σ_0 of albumins obtained experimentally (σ_0 = 0.816 ± 0.027 for frog mesenteric capillaries and σ_0 > 0.9 for mammalians [7,8]) even without including charge effects.

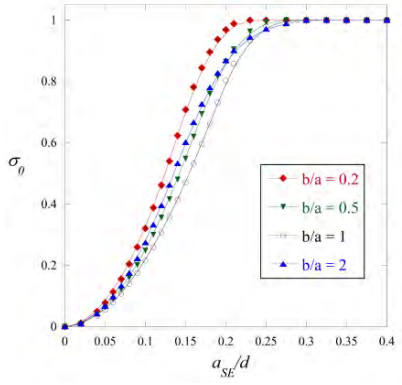

Figure 1 Osmotic reflection coefficient (σ_0) as a function of Stokes-Einstein radius scaled with a distance between fibers (a_{SE}/d). a is the spheroid equatorial radius, and b is the distance from center to pole along the symmetry axis of the spheroid [6].

CONCLUSIONS

Globular protein molecular shapes affect the osmotic fluid flux across a fibrous membrane and are likely to contribute to prevention of transcapillary fluid leakage. Figure 1 also shows a decline in σ_0 as a_{SE}/d decreases, indicating fiber volume fraction reduction caused by EGL damage (that is one of earliest signs of sepsis) can lead to transvascular fluid extravasation and edema.

Contribution of Titin to Passive and Active Forces in Single Myofibrils

Seong-won Han[1], Johanna K. Freundt[1], Wolfgang A. Linke[1]
[1] Institute of Physiology II, University of Münster, Germany.
Email: seongwon.han@uni-muenster.de

INTRODUCTION

Titin is a molecular spring and ruler that connects the Z-disk and the M-band in the sarcomere. Titin has been considered as the third component after actin and myosin, contributing to force generation of a sarcomere. Many attempts have been made to quantify the contribution of titin to passive and active forces, by removing titin through chemical degradation [1] or genetic impairment [2]. However, these approaches have limitations, because (i) other proteins are also affected by the chemical degradation, and (ii) most of the genetically modified animals exhibit secondary disease phenotypes, which complicate the interpretion of the results. Recently, the titin cleavage (TC) mouse model was established, where a cleavage site is cloned into I-band titin close to the A-band, and adding the tobacco etch virus protease to muscles allows for rapid and specific titin cleavage [3]. Using the TC model, we confirmed that titin contributes to passive and active force generation and also maintains sarcomeric structure organized [4]. However, even when all titin was cleaved, passive force did not drop to zero, but decreased by 50-55%, while titin was thought to contribute >90% of passive force previously [5]. One reason for this discrepancy could be the presence of stiff extracellular matrix proteins in the skinned muscle fibre bundles that were used [4]. Thus, we aimed at re-examining the contribution of titin to passive and active forces in single myofibrils, where the primary passive structure is clearly titin.

METHODS

Single myofibrils (n=3) from the psoas muscle of the TC mouse were attached to cantilevers (76 nN/µm) and set at an average sarcomere length (SL) of 2.4 µm. Then, the myofibril was slowly stretched to 3.0 µm, held for 30 s to measure passive force, and returned to the slack SL. The measurement was then repeated on the same myofibril, after titin was cleaved. Active force was quantified during activation with Ca^{2+} at an average SL of 2.4 µm. All force data were converted into stress considering the cross-sectional area of the myofibrils.

RESULTS AND DISCUSSION

After titin was cleaved, passive and active stresses were reduced by 59.2% and 47.8% on average, respectively (Fig 1A, B). Substantial changes in myofibrillar structure were observed during activation after TC (Fig 1C, D). Before the myofibril was activated, the Z-disks (red arrows) and the A-bands (blue arrows) were clearly defined (Fig 1C), but as the activation proceeded, the myofibril structures became indistinguishable (Fig 1D).

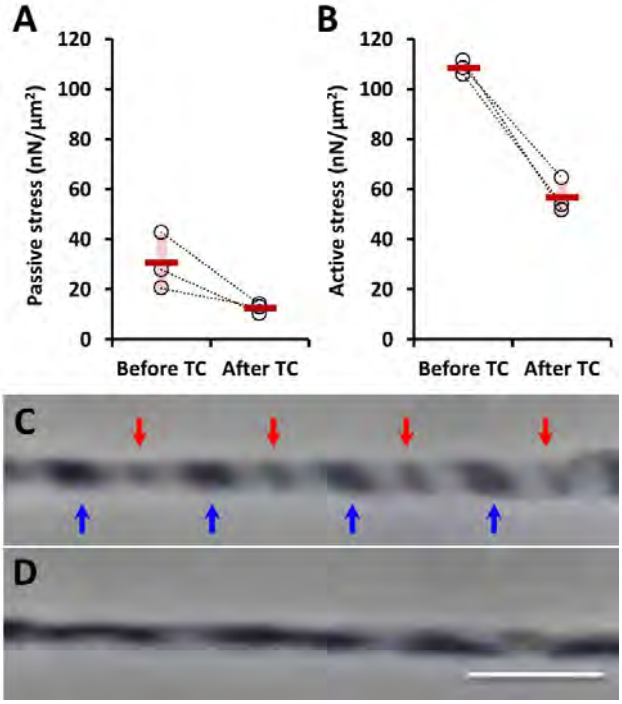

Figure 1 Summary of the results. Passive (A) and active (B) stresses are shown: each circle represents a result from a myofibril, and the horizontal bar and vertical bar represent the mean with 1SD, respectively. Structural changes in the myofibril before (C) and after (D) activation are shown when titin was removed. The red arrows point to the Z-disks, the blue arrows to the A-bands. The scale bar is 5 µm.

CONCLUSIONS

Our results confirm that cleaving titin reduces passive and active stress [4], but the decrease in stress reached no more than 67% in single myofibril preparation. Thus, further studies are required to determine the source of the remnant passive stress in myofibrils. Also, activating myofibrils is deleterious to the sarcomeric structures when titin was removed, resulting in substantial decrease in active stress.

INTRODUCTION

In skeletal muscle, titin proteins connect sarcomeric myofilaments together and are thought to be critical for contraction, especially during residual force enhancement (RFE) when force is elevated after an active stretch compared to a purely isometric contraction at the stretched final length [1]. We investigated titin's function during contraction using small-angle X-ray diffraction to track structural changes before and after 50% I-band titin cleavage using the titin cleavage transgenic mouse (TC) and the RFE-deficient, muscular dystrophy with myositis (*mdm*) mouse mutant [2-3].

METHODS

We used fast-twitch and permeabilized skeletal muscle fibers from TC (heterozygotes) and *mdm* (wild type and homozygous) mice. TC muscles have a splice site engineered into I-band titin [3] that allows for specific and rapid cutting of titins, and so decreases titin-based force and stiffness in the sarcomere. *Mdm* muscles have a small mutation in the titin gene that manifest as a small deletion in the I-band region that reduces RFE. Using these mutations, we ran typical mechanical experiments while also evaluating sarcomeric structures using small-angle X-ray diffraction. We captured mechanical and structural details of fibers during pure isometric contractions at short (Iso_{Short}) and long (Iso_{Long}) sarcomere lengths, as well as after an eccentric contraction from the shorter to longer sarcomere lengths (Iso_{RFE}). Full-factorial ANOVA with individual random effects were used on best Box-Cox transformed variables to test for differences in structure and function between titin treatments (TC) or genotypes (*mdm*).

RESULTS AND DISCUSSION

50% titin cleavage reduced RFE from 30.69 ± 3.35% to 17.44 ± 2.24% of reference force (Iso_{Long}; $P < 0.01$). We report that Iso_{RFE} is structurally distinct from pure isometric contractions, with increased thick filament strain and decreased lattice spacing compared to Iso_{Long} ($P < 0.01$). Furthermore, these distinctive RFE structural features were not detected in *mdm* fibers, but were present in wild-type fibers ($P < 0.01$). The results suggest that decreased lattice spacing and increased thick filament length, improving force production and transmission enough to account for ~40-70% of RFE. The remaining ~30-60% of RFE could be accounted for by an activation-dependent ~2-3-fold increase in titin-based stiffness before eccentric stretch (Fig. 1).

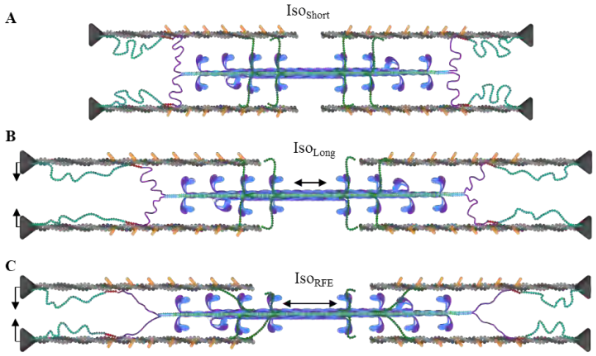

Figure 1 Possible mechanism of RFE. Configuration of sarcomeric proteins during (A) Iso_{Short}, (B) Iso_{Long}, and (C) Iso_{RFE} that may account for the distinctive mechanical and structural signatures.

CONCLUSIONS

These data demonstrate that titin is a critical regulator of sarcomeric tension, and as such, an essential contributor to RFE. The presence of RFE aligns with a distinctive structural state that is altered by titin cleavage and the *mdm* mutation. The analysis provides evidence that RFE is caused by increasing titin-based forces after eccentric stretch that also leads to decreased lattice spacing and elongated thick filaments. Finally, our data provide evidence for an activation-dependent increase in titin-based stiffness, but the mechanism remains unclear (possible mechanism shown in Fig. 1).

HOW COLLAGEN IX ALTERS THE MICROMECHANICAL PROPERTIES OF COLLAGEN II ARRAYS?

INTRODUCTION

Osteoarthritis (OA) is one of the most common skeletal diseases that can overshadow people's daily activities. This disorder is associated with the wear of the upper surface of the articular cartilage. Knowing the mechanical properties of the cartilage components by considering their structure can help to understand cartilage damage and regeneration. Thin collagen fibrils in the cartilage surface are heteromeric molecular structures composed of collagens type II, IX, and XI. Collagen type IX is fibril-associated collagen with interrupted triple helices (FACIT), which has remarkable properties. Type IX collagen is present not only in healthy fetal and mature cartilage but in OA-damaged cartilage at the edge of fibrillations. In this study mechanical properties of type II collagens with and without type IX collagen, have been investigated.

METHODS

Unlike fibrillar collagens, collagen IX is composed of three collagenous domains (COL1, COL2, and COL3) and four non-collagenous domains (NC1 to NC4). The NC1, NC2, COL1, and COL2 are vital in the mechanical properties of fibrils due to their special arrangement. Covalent bonds crosslinking type IX collagen with type II are unique. To consider these cross-links, Miles et al. [1] showed that COL2 and COL1 are anti-parallel. To assume the above features an array of 5 type II tropocollagens consisting of two periods with 67 nm lengths, first without collagen IX and then with collagen IX were designed (Figure 1). The persistence length of a 300 nm tropocollagen type II is 15 nm, and the number of its amino acids is known. Knowing the number of amino acids in COL1(IX), and COL2(IX), their corresponding persistence lengths and consequently their Young's moduli were calculated. By limiting the movement in one end along the fibre, a compressive force was slowly applied to the opposite end.

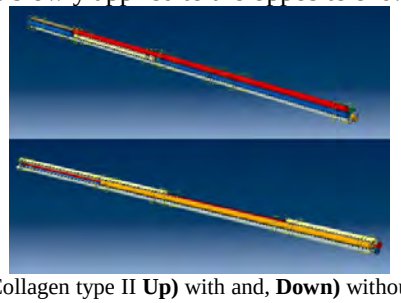

Figure 1 Collagen type II **Up)** with and, **Down)** without collagen IX models.

RESULTS AND DISCUSSION

The stress-strain curves are obtained for two opposite surfaces for each model (Figure 2). Two regions are observed: a primary region with a small Young's modulus, followed by a secondary region with a higher slope. The change in the slope is caused by a conformational change and the gradual growth in collagens' resistance against increasing tension. The primary Young's modulus with collagen IX (227 MPa) is approximately 30 percent stiffer than the model without (175 MPa). The secondary Young's modulus of the model with type IX collagen (315 MPa) is also 9 percent lower than the model without collagen IX (289 MPa). Since the molecular arrangement of collagens is asymmetrical, after applying the compressive load, it bends. Increasing the force makes the model buckle. The buckling load of the model with collagen IX (79 pN) is less than the model without collagen IX (87 pN). The results obtained for Young's moduli are consistent with previous investigations on collagens [2].

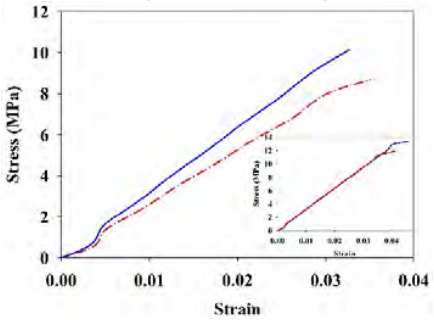

Figure 2 The stress-strain curve after applying pressure to the model results for the array with and, **Inset)** without collagen IX.

CONCLUSIONS

The presence of collagen IX can reduce the buckling force; hence we hypothesize that collagen IX acts as a barrier against collagen-degrading enzymes such as matrix metalloproteinases (MMPs) and delays the interaction of enzymes with fibrillar collagens. As a result of the remarkable effect of type IX collagen in the process of remodelling, growth, and destruction of collagen fibrils, it seems that this collagen can be used as a target molecule for the prevention and treatment of OA.

INTRODUCTION

Bone is a complex and unique tissue that is capable of responding to its mechanical environment by adapting its own morphology in response to external loading. Exposing the direct relation between the mechanostimuli and the remodelling of bone that follows will be immensely valuable as it may facilitate both the prediction and prevention of bone strain issues and potential bone failure injuries. In order to understand this form-function relation between stimulus and response, accurate assessment of how the bone is loaded is crucial. To simulate both the external and the internal loading conditions of bone in response to the realistic joint loading, we present an integrated finite element (FE) – micro FE (µFE) approach to assess both external, articular bone stress and internal bone strain based on physiologically relevant boundary conditions.

METHODS

Our custom FE pre- and post- processing software suite is used to generate parametric FE models based on CT imaging of the joint in standardized loading positions. Joint loading conditions are used to simulate the inter-articular loading patterns during realistic joint interactions. Using our custom suite, these articular loading patterns are extracted and integrated in µCT based, whole bone µFE models that assess bone strain values at the level of the of the trabecular bone architecture. The disassociated bone models are aligned with ISB convention standards for intuitive interpretation. The approach was developed for the primate thumb joint, specifically the trapeziometacarpal joint, but is intended for broader implementations in other joints and taxa. In bonobos, gibbons, and macaques, various grasping types with different thumb positions were CT scanned as input joint positions. The FE approach yields articular loading patterns in which differences per position of the thumb can be identified. These loading patterns are then applied as boundary conditions to the trapezium bone and solved to assess internal bone strain using µFE. Bone strain values were evaluated in five bonobo thumb specimens and for five different types of grasping

RESULTS AND DISCUSSION

The µFE results indicate that strain distributions between different simulated grasps are highly similar, showing dissipation towards the proximo-ulnar cluster of trabeculae regardless of trapezial bone microarchitecture. Strain levels deviating from this pattern are shown to be likely related to the dissimilar, possibly pathological, external bone morphology rather than trabecular differences. The simulated bone strain values fall within realistic boundaries of a healthy response to habitual loading. The average mean strain value of 62.11 µε ± 18.05 µε and peak strain value of 578.36 µε found across all simulations do not exceed bone yield values based on even the lowest reported elasticity modulus (ε_{yield} = 3500 µε).

CONCLUSIONS

This approach offers a method to integrate realistic boundary parameters into the assessment of internal bone strain values. Our research collaboration is working on expanding, validating, and further developing the approach with the aim of addressing the relation between the stimulus and the response in bone functional adaptation. Currently, the project is being further developed into an open source software suite to study the fundamentals of bone functional adaptation in the bipedal model of Guinea Fowl.

INTRODUCTION

Knee osteoarthritis (KOA) is a major cause of disability in older adults [1] , with more than 240 million adults suffering KOA [2]. However, approved therapies that modify the onset or progression of KOA remine elusive. Therefore, it is essential to identify the risk factors of KOA for early intervention. Quadriceps weakness has become an important predictor for knee pain, with strength training suggested as the first-line treatment by international guidelines. Nevertheless, it is noted that the mechanism underlying the association of quadriceps strength with knee pain is not clear.

In the knee, bone marrow and synovium are the source of pain due to their rich nociceptive innervation. Our team previously found that quadriceps weakness has the potential to cause the effusion-synovitis. An effect of quadriceps weakness on pain could be due to the intermediate effect of quadriceps weakness promoting effusion-synovitis which then cause pain. This is under urgent need to be investigated.

Using observational data acquired from the Osteoarthritis Initiative (OAI) cohort (an open-source database), we quantified the relation of muscle weakness and knee pain and then examined whether the association of muscle weakness with worsening pain was mediated by worsening effusion-synovitis.

METHODS

A longitudinal observational study was performed in 1050 participants (623 women and 427 men) included from the OAI, with complete records of quadriceps strength, effusion-synovitis, and knee pain at baseline, 1- and 2-year follow-ups. Quadriceps strength was measured at baseline, with subjects required to perform maximal voluntary isometric contraction. The highest value (Nm) was selected from three repetitions and normalized to body mass (Nm/kg). Effusion-synovitis was assessed in intercondylar region through Magnetic Resonance Imaging Osteoarthritis Knee Score (MOAKS) system based on MRI. Knee pain was evaluated according to Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain sub-scale. Other demographic characteristics and potential confounding factors were collected.

The relationship between WOMAC pain and quadriceps weakness was calculated by linear models, adjusted for age, sex, BMI, race, baseline WOMAC pain, Center for Epidemiologic Studies Depression Scale (CESD) score and Physical Activity Scale (PASE) score. Mediation models were used to assess the indirect effect of effusion-synovitis in the association of quadriceps weakness with worsening pain with adjustment for confounders. Given sex differences in strength, we further perform a sub-analysis stratified by sex.

RESULTS AND DISCUSSION

We found that the significantly negative association between baseline quadriceps strength and worsening pain in the primary and sub-group analyses at 1- and 2-year follow-ups (β: -0.87 - -0.26, $p<0.05$). These results were consistent with previous studies, indicating that quadriceps weakness was a critical risk factor for knee pain. In addition, mediation analyses showed that the association of quadriceps weakness with increased knee pain over 1 year was substantially mediated by the effusion-synovitis change in the whole population and females (**Figure 1**). We did not find similar results in males. This may be attributed to the lower quadriceps strength in females, which means that females are more prone to approach the strength threshold needed to protect the knee.

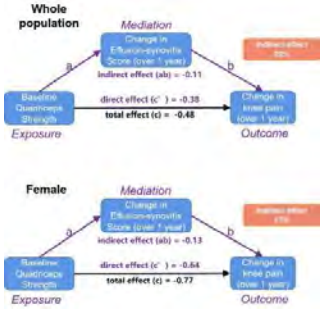

Figure 1. Schematic diagram of the mediating effect of effusion-synovitis changes on baseline quadriceps strength and knee pain changes.

CONCLUSIONS

In conclusion, quadriceps weakness is significantly associated knee pain worsening and this relation appears to be partially mediated by effusion-synovitis change, especially in females. These results remain to be verified in future interventional experiments.

INTRODUCTION

Knee osteoarthritis (OA) is a significant chronic disease that leads to more years lived with disability and imposes a devasting health care burden [1]. Identifying deleterious changes in cartilage status and health are critical for developing effective strategies to reduce risk of progressive degradation of articular cartilage and knee OA development. Evaluating articular cartilage deformation following physical activities may provide valuable insight into early alterations of the articular cartilage before any declines occur in cartilage structure and health [2]. Researchers demonstrated that changes in the magnitude of knee joint loading affected the ability of the articular cartilage to absorb and redistribute biomechanical forces applied to the knee joint thought physical activities. Abrupt lateral movement, breaking, and accelerating have been theorized to contribute to joint degeneration [3], given that abnormal shear loading could adversely affect the deformational capability of the articular cartilage. In addition, it has been theorized that aberrant shear loading may lead to a shorter fatigue life of cartilage than compressive loading [4]. However, no authors have examined the association between types of mechanical joint loading and cartilage deformation. Understanding the influence of types of joint loading on cartilage deformation may help to develop comprehensive therapeutic strategies to decrease the risk of OA. Therefore, the purpose of this study was compared cartilage deformation in response to cutting and decelerating movement (shear loading), running (compressive loading) and control (no loading) using ultrasonography (US).

METHODS

A randomized order cross-over study was used to examine femoral articular cartilage thickness before and after three loading conditions. Nineteen healthy participants with no previous history of knee joint injury (age: 22.3 ± 2.4years, height:173.3 ± 5.1cm, body mass: 66.5±7.4kg) volunteered for this study. Participants completed three conditions, consisting of 1) 30 min-curing and breaking movement, 2) 30 min-running, and 3) control (30 min-rest in a supine position), during independent data collection sessions separated by at least 1 week at the same time of day. A femoral cartilage US examination was performed before (baseline), immediate after exercise (post0), 30 min (post30) and 60 min (post60) after each condition. For this study, 3 images were recorded of the dominant limb at each time point. Anterior femoral cartilage thickness was quantified and averaged from all 3 of the US images. A percentage change score from baseline to each post-test time point was calculated to represent the amount of acute cartilage deformation for each US measure following each condition. Repeated measures ANOVAs with Bonferroni post hoc analyses were used to compare cartilage deformation between loading conditions. Statistical significance was set at $p<0.05$.

RESULTS

There was a significantly greater intercondylar femoral cartilage deformation following the cutting condition at post0 ($p=0.03$), post30 ($p=0.02$), and post60 ($p=0.02$) compared to the running and control conditions (Figure 1). No differences were observed for other US measures between loading conditions ($p>0.05$).

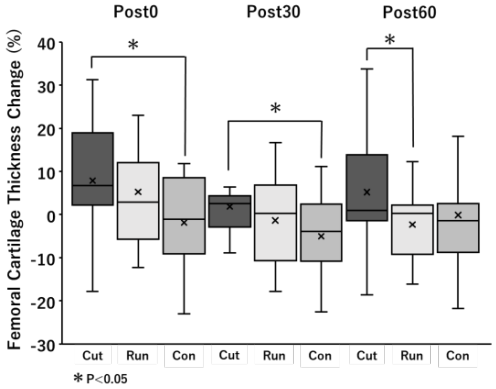

Figure 1. The amount of acute intercondylar femoral cartilage deformation following cutting (cut), running (run), and control (con).

CONCLUSIONS

We observed that cutting movements had a larger magnitude of acute intercondylar femoral cartilage deformation compared to running and control. Results from this study indicate that shear loading may have a larger influence on the magnitude of change in intercondylar femoral cartilage deformation. Future research may consider to use the cutting condition in pathological populations to monitor for early declines in cartilage health.

INTRODUCTION

Cam femoroacetabular impingement (FAI) syndrome is a degenerative hip joint disorder, associated with severe hip pain during locomotion and the development of hip osteoarthritis. FAI syndrome is commonly assessed using the alpha angle on a radiological image plane between the 12:00 and 3:00 clockface positions, regardless of patient sex. Hip joint shape features, evaluated with statistical shape models (SSMs), are an important biomarker for osteoarthritis incidence, progression, and arthroplasty. However, to the best of our knowledge, no studies have investigated 3D SSM cam sex-based differences. This study investigated whether FAI syndrome differ with gender in respect to cam location as measured using focused shape modelling and partial least squares (PLS) regression.

METHODS

Hip MR images from 97 patients with FAI (56 male, 41 female, 16-63 years) were used [1]. CamMorph [2] was used to generate 3D surface models of the femur, and the latent variables (LVs) were derived from PLS regression to capture the sex-specific cam shape features. A two-way analysis of variance (ANOVA) assessed interactions between cam LVs, sex, and cam severity [2]. LVs with a significant sex effect (p<0.05) and a moderate to large Cohen's d effect size were analysed further. Additional exploratory analysis applied scatterplot and Pearson regression line analyses to assess the association of cam volume (generated using CamMorph [2]) and the alpha angle (measured at 1:00 and 3:00 o'clock by N.J.M.) on the LVs.

RESULTS AND DISCUSSION

LV 1 represented cam size and LV 2 characterised cam location (Figure 1). Cam volume significantly correlated with LV 1 (female r=0.83, male r=0.87: both p<0.001) and an alpha angle ratio $\left(\frac{\text{alpha angle at 1:00}}{\text{alpha angle at 3:00}}\right)$ was significantly correlated with LV 2 (r=0.47, p<0.001). The ANOVA indicated no significant interaction between the effects of sex and cam severity on the LVs. Moderate to large effect sizes were observed for sex and LVs 1 and 2 (p≤0.001, D≥0.75). Cam height data showed mean male and female patients presented with a superior- and anterior-focused cam, respectively. Male and female patients with a negligible, mild or moderate cam had a superior and anterior cam, respectively. Both male and female major cams had a global distribution. Although the current study findings are limited by a small cohort size, they suggest female alpha angle measurements should be made circumferentially (beyond 12:00 and 3:00). Additionally, female FAI prevalence data may be inadequate due to false negative FAI diagnoses. Future works are required to confirm current findings.

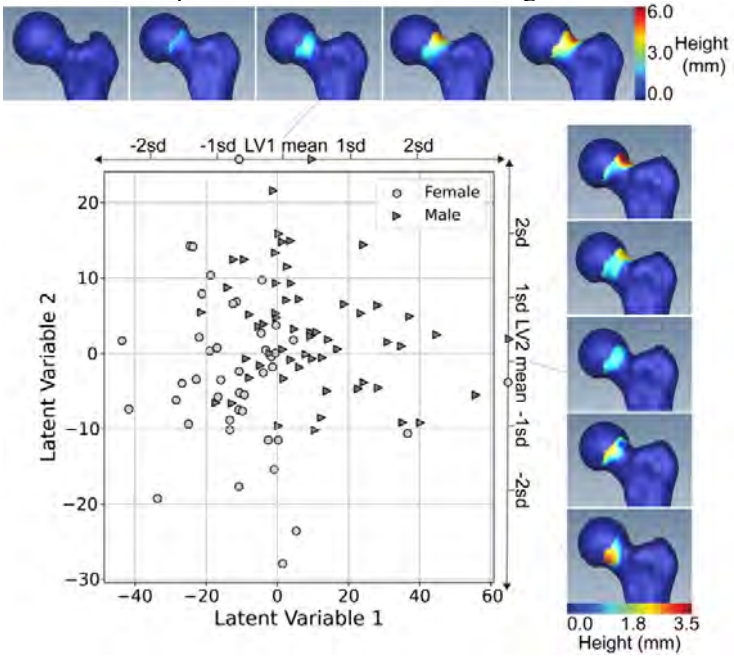

Figure 1 LV 1 and LV 2 scatterplot illustrating female and male cam size and location clustering. Light grey circle and dark grey arrowhead on axes represent the female and male group mean, respectively. LV = latent variable and sd = standard deviation.

CONCLUSIONS

In this study, LVs derived from PLS regression were associated with cam size and location, respectively. Male and female FAI patients with a negligible, mild or moderate cam volume exhibited a superior and anterior cam location, respectively. Major cam volumes occurred in similar locations irrespective of sex.

TIMING AND ACCURACY OF 3D PRINTED PELVIC FRACTURE PLATES

Dale Robinson[1], Peter Lee[1] and Andrew Bucknill[2]
[1] Department of Biomedical Engineering, University of Melbourne, Melbourne, Australia.
[2] Department of Surgery, Royal Melbourne Hospital, Melbourne, Australia.
Email: drobinson@unimelb.edu.au

INTRODUCTION

Pelvic fractures have a relatively rare incidence, representing 1.5% of all fracture cases, yet they are associated with high mortality (7-30%) [1]. These fractures are typically treated with fracture plates comprising a straight or slightly curving design which must be contoured intra-operatively, a process that is timely and imprecise. Plate fixation with screws is also challenging, as screws must stabilize the construct while avoiding injury to surrounding tissue. Patient-specific plates manufactured by 3D printing can potentially solve these issues; plates are created that conform to patient-specific anatomy, while controlling screw trajectories to remain within safe regions of the anatomy. The aim of this study was to evaluate the timing and accuracy involved in using 3D printed pelvic fracture plates, knowledge that will help identify improvements that may be needed to produce 3D printed pelvic fracture plates at scale.

METHODS

Five cadaveric pelvises were sourced from the University of Melbourne body donor program. A fracture was created by impaction of a ball-ended punch into the acetabulum. CT imaging was performed at clinical resolution, then all bony fragments were segmented to obtained their 3D geometry. Fracture reduction was achieved virtually be displacing each bony fragment until the surface of the bone appeared congruent. The outline of the fracture plate was drawn onto the bone, then cut from the bone with a boolean operation and finally extruded to a thickness of 3 mm (Fig. 1). Bicortical locking or non-locking screws (ϕ 3.5 mm) were used, with trajectories chosen to pass through the surgical window while avoiding sensitive anatomy. The plates were 3D printed in Ti6Al4V using a sintered laser melting (SLM) printer with 30 µm layers, followed by a stress relief anneal. Each plate was implanted and a post-op CT scan was obtained to measure print accuracy, implant positioning error and screw angulation error. The duration of each step was recorded.

RESULTS AND DISCUSSION

Each fracture plate was implanted in one hour or less. Apart from specimen 2, which was complicated by a pre-existing fracture plate (Fig. 1B), the design times were less than 10.0 hours, and print times varied from 27.0 to 32.5 hours (Table 1). 3D printing errors ranged from 0.10 to 0.49 mm, plates were mispositioned by 1.7 to 13.0 mm, and mean screw angulation errors ranged from 2.8 to 7.0°.

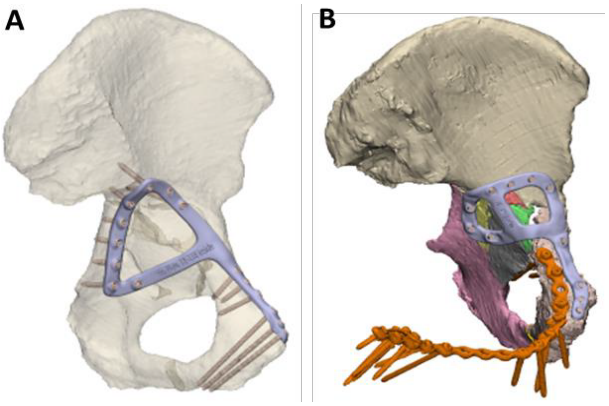

Figure 1 Example plate designs. **A)** Specimen 1. **B)** Specimen 2.

Table 1: Times and errors associated with design and manufacture of fracture plates.

Spec. no.	Design time (hrs)	Print time (hrs)	Print RMSE (mm)	Position error (mm)	Mean screw angle error (°)
1	3.5	32.0	0.37	1.7	6.2
2	17.2	32.0	0.49	5.7	7.0
3	3.0	32.5	0.10	7.5	2.8
4	9.5	32.0	0.13	13.0	6.3
5	7.5	27.0	0.26	5.1	7.3

CONCLUSIONS

A one-hour surgical time was an improvement compared to reported times for standard fracture plates (175-287 min [2]), thus, highlighting the benefit of using 3D printed fracture plates. For four specimens without a pre-existing plate, the total design and print time was less than 48 hours, a duration which would suggest that personalised plates are a clinically viable option. The print errors ranged from acceptable to large, which appeared to be related to the size of the plate. Hence, improved methods to better control the print accuracy of longer plates are needed, particularly regarding the build-up of thermal stresses that is typical of SLM printers. The errors in plate positioning and screw angulation were mostly affected by the limited surgical access available for the pelvic region. In future work, these errors must be reduced using tools such as surgical navigation or fluoroscopy in order for the benefits of subject-specific design to be fully realised.

TROCHLEAR ORIENTATION OF TOTAL KNEE DESIGNS IS OPPOSITE TO THAT OF THE NATURAL FEMUR

Nikhil Gattu[1], Marriah Sutton[1], David B. Doherty[1], Sabir K. Ismaily[1],
David Rodriguez-Quintana[1], and Shuyang Han[1]
[1] Department of Orthopaedic Surgery, McGovern Medical School, UTHealth Houston, Texas, USA.
Email: shuyang.han@uth.tmc.edu

INTRODUCTION

Femoral component designs in total knee arthroplasty (TKA) have evolved to reflect the anatomy of the native knee, particularly the femoral condylar design. However, there is currently still a lack of consensus regarding the trochlear sulcus design, which is a major factor contributing to postoperative patellofemoral complications, such as patellofemoral maltracking, dislocation, and patellar component loosening [1]. The objective of this study was to compare the trochlear sulcus geometry of a broad range of prosthetic knee designs and that of the natural knee, thereby providing references for modification of femoral component designs.

METHODS

Three-dimensional computer models of 14 femoral component designs and 21 non-arthritic human femora (average age: 34.9±13.1) were reconstructed in this study. Each model was aligned in a standard reference coordinate system [2] and coaxial cutting planes were created in 15° increments around the trochlear groove axis (Figure 1). In each plane, the medial and lateral ridges, as well as the deepest point of the trochlear sulcus were marked. The mediolateral position of the sulcus, the sulcus angle (∠ABC), and the trochlear groove orientation θ were then measured (Figure 1). To facilitate comparison, the measurements of each model were normalized to a trochlear radius of 21.0mm.

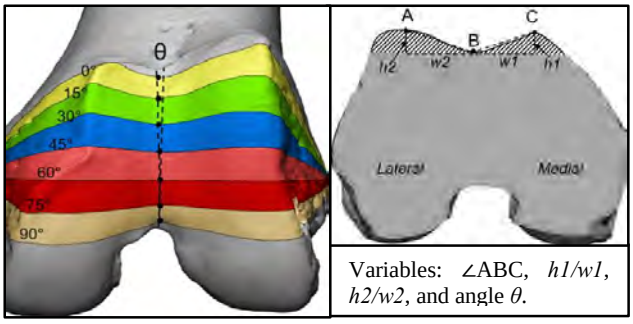

Figure 1. Measurement of the trochlear sulcus geometry

RESULTS AND DISCUSSION

Among the 14 components, nine were contemporary designs. Three (3/14) had a symmetrical geometry (Optetrack, Profix, and Klassic). The sulcus angle (∠ABC) of all components gradually decreased from 0° to 60° (Figure 2A), except AMK, Optetrak, and Profix, which remained fairly constant. All asymmetrical designs (11/14) had a laterally orientated sulcus (θ=7.1°±2.0°, range: 4.3°-10.5°, Figure 2B). Moreover, the height/width ratio of the medial and lateral ridges were nearly identical, and both increased with the planes.

In the natural femur, the sulcus angle (∠ABC) changed in a sine wave pattern from 0° to 120° and was 4°-13° lower than the prosthetic knees in different planes (Figure 2A). Moreover, contrary to the laterally oriented sulcus in prosthetic designs, the sulcus of the native knee was bilinear (0°-60° and 75°-90°) and had a medial orientation (Figure 2B) [3]. In addition, the height/width ratio of the native knee first increased from 0° to 30° and then decreased until 75° and increased slightly afterward, which was also different from the prosthetic designs (Figure 2C, 2D).

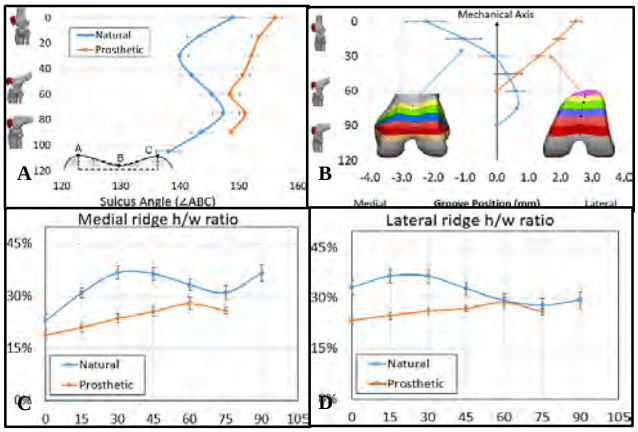

Figure 2. Comparison of the trochlear sulcus geometry of femoral component designs and the natural femur.

CONCLUSIONS

There are large variations in the trochlear sulcus design of contemporary TKA implants. Compared to the natural femur, the femoral components generally have a larger sulcus angle and lower height/weight ratio of the ridges, which could cause an increase in the risk of postoperative complications. Most importantly, although femoral components with a lateral sulcus orientation are often called 'anatomical', our finding demonstrated that the sulcus orientation of the natural femur was the opposite, i.e., a medial orientation. Therefore, it is worthwhile to revisit the rationale behind the lateral sulcus design of contemporary femoral components in TKA.

Accelerometer based assessment of upper extremity movement in patients with obstetric plexus palsy

Catherine Disselhorst-Klug[1], Ligia C S Fonseca[1], Jörg Bahm[2]
[1] Department of Rehabilitation and Prevention Engineering, Institute of Applied Medical Engineering, RWTH Aachen University, Aachen Germany.

INTRODUCTION

Obstetric Brachial Plexus Palsy (OBPP) occurs in approximately 0.5 to 0.77 out of 1000 newborns. In the case of OBPP the upper brachial plexus nerves are damaged and arm function is severely limited. Since the location and extend of the lesion of the Plexus Brachialis nerve are different in each child, the coping strategies of the patients are highly individual. OBPP patients' arm function has to be regularly examined in order to agree about new therapeutic goals. However, up to now this is done mainly through visual observations by physicians or therapists. In order to achieve at least some objectivity and to document functional changes the Mallet Scale (MS) is used. The MS distinguishes 5 different categories of severity. These categories are graded on a scale from I to V, with I being not testable and IV reaching the same endpoint as healthy subjects. MS V is reserved for health subjects only. However, since reaching a certain endpoint determines the membership to a particular category, coping strategies are not taken into consideration. The objective of this work is to present a new approach based on accelerometers in combination with a classification procedure, which allows the quantitative assessment of upper extremity movement performance of patients with OBPP.

METHODS

Experienced physiotherapists have evaluated the movement performance of 10 healthy children and 41 children suffering from OBPP. Each subject has been assigned to one of 5 categories of the MS. Three triaxial-accelerometers were placed at chest, upper arm and wrist of the subject. Acceleration signals have been recorded during repetitive "hand to mouth" tasks.

34 features were extracted from the acceleration signals. For each feature a linear correlation test between the feature value and the MS classification of the subjects was made. A feature was accepted as suitable if the correlation coefficient was higher than 0.5. In this way, a number of F relevant features was identified. Secondly, 6 weighting factors w_i = 0.5, 1, 1.5, 2, 3 or 4 were introduced and assigned to each relevant feature. Assignment was done with respect to the strength of the correlation between the MS score and the feature value.

To calculate a score quantifying the movement performance of each subject, 4 thresholds were identified for each of the F relevant features. The target for optimization of the thresholds was the best discrimination between the 5 MS categories. With respect to the thresholds, each feature value was assigned to a discrete number (N_i) with N_i = 0 representing a feature value within the feature specific thresholds of MS V (healthy subjects), N_i = 1 of MS IV, N_i = 2 of MS III, N_i = 3 of MS II and N_i = 4 of MS I.

An overall score (SC) quantifying the subjects' individual movement performance was calculated by adding the weighted discrete numbers of all relevant features according to:

$$SC = \sum_{i=1}^{F} w_i \cdot N_i$$

with F = number of relevant features, w_i = weighting factor and N_i = discrete number of each feature.

RESULTS AND DISCUSSION

F=13 features out of 34 features showed a correlation higher than 0.5 between the feature value and the MS category assigned to each subject. Figure 1 showed the resulting SC score as a function of the MS category. With the exception of MS I, there is a significant difference in SC score between all MS categories.

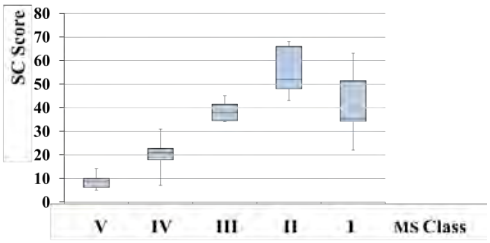

Figure 1 SC scores related to the categories of the MS.

The introduced procedure is designed to evaluate movement performance and to quantify the severity of compensational movement parts. Since MS I is just defined by not reaching a certain end-point, movement performance is more heterogenic in this category compared to the other MS categories.

CONCLUSIONS

The introduced approach demonstrated its ability to assess upper extremity movement performance in patients with OBPP quantitatively. Based on the SC score, direct feedback about the quality of movement performance can be given to patients, physicians and therapists. The quantitative and objective assessment of relevant movements for daily activities will enable an evidence-based, individualised treatment for OBPP patients.

DIFFERENCES IN TROCHLEAR SULCUS GEOMETRY OF TOTAL KNEE DESIGNS

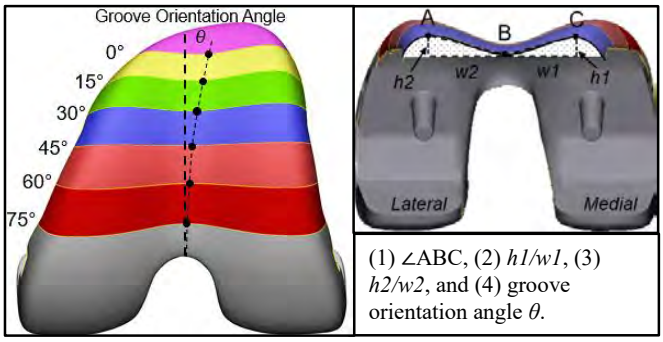
Shuyang Han[1], Marriah Sutton[1], David B. Doherty[1], David Rodriguez-Quintana[1], and Philip C. Noble[1]
[1] Department of Orthopaedic Surgery, McGovern Medical School, UTHealth Houston, Texas, USA.
Email: shuyang.han@uth.tmc.edu

INTRODUCTION

The trochlear sulcus of the femoral component is a major factor contributing to maltracking of the patella following total knee arthroplasty (TKA). Although the femoral condylar design has evolved to reflect normal anatomy, consensus on the geometry of the trochlear sulcus has been lacking [1,2]. With newer data, more surgeons now frequently elect to leave the patella unsurfaced, heightening the importance to the limits of variations in trochlear morphology associated with satisfactory outcomes after TKA. The objective of the present study was to analyze the variation in the geometry of the trochlear sulcus of a broad range of contemporary TKA designs and compare with earlier generations of femoral components.

METHODS

Fourteen femoral components (9 contemporary, 5 legacy) from nine manufactures (Depuy, Exactech, Howmedica, Osteonics, Smith&Nephew, Stryker, Zimmer, Biomet, TJO) were obtained from a large retrieval collection. High resolution laser scans were performed for each component and 3D computer models were created and analysed using Geomagic Design X. Specifically, radial section planes were created in 15° increments for each component. In each section, the variables shown in Figure 1 were measured.



(1) ∠ABC, (2) *h1/w1*, (3) *h2/w2*, and (4) groove orientation angle *θ*.

Figure 1. Measurements of the trochlear sulcus geometry

RESULTS AND DISCUSSION

The sulcus angle (∠ABC) of all components gradually decreased from 156.2°±3.9° in the 0° plane to 148.5°±6.4° in the 60° plane, except for AMK (Depuy), Optetrack (Exatech), and Profix (S&N), which remained fairly constant. Excluding the three symmetrical designs (Optetrack, Profix, and Klassic), the deepest point of the sulcus gradually shifted medially towards the mechanical axis by 3.0±0.9mm (range: 1.9-4.8mm) from 0° to 60°, resulting in a groove orientation angle *θ* of 7.1°±2.0°. PFC Sigma had the largest groove orientation (10.5°), while ScorpioNRG had the lowest (4.3°). The lateral groove orientation was seen in each component and this was contrary to the anatomy of the natural knees [1]. However, the true deviation could be decreased as a result of femoral component positioning during TKA [2]. In addition, Optetrack (Exactech) and AMK (Depuy) demonstrated a high lateral ridge in the middle (30°-60°) of the component compared to other designs.

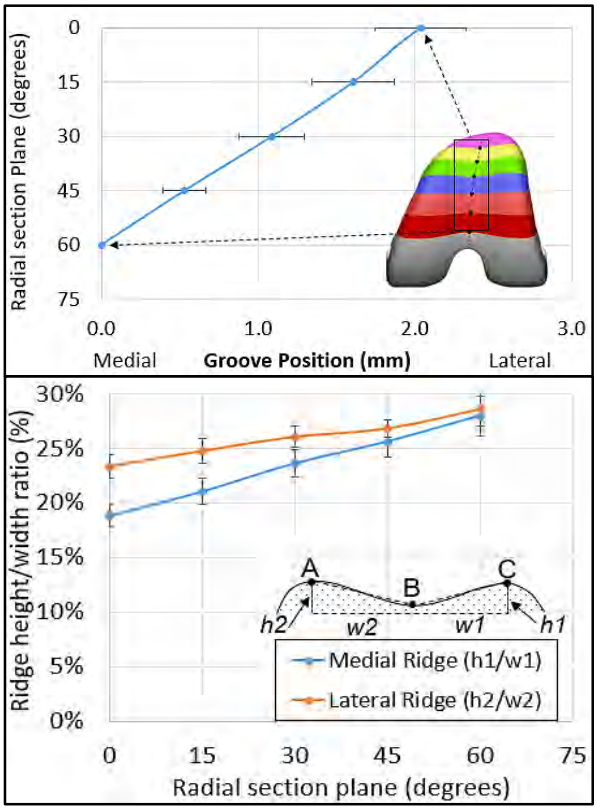


Figure 2. Average groove position of the 14 designs and the variation of the height/width ratio of the medial and lateral ridges.

CONCLUSIONS

The trochlear design of TKA implants does not always have clear anatomic parameters, a major factor in patellofemoral complications after TKA. Our study shows large variations in the geometry of the trochlear sulcus between different prosthetic designs. In the next step, we will compare these parameters to the trochlear geometry of the natural knee in an attempt to provide references for optimizing trochlear sulcus design of TKA implants.

DESIGN AND EVALUATION OF A NOVEL PATIENT-SPECIFIC, UNLOADING KNEE BRACE

Jonas Steensgaard Stoltze[1], Anderson Oliveira[1], John Rasmussen[1], Michael Skipper Andersen[1,2]
[1]Department of Materials and Production, Aalborg University, Denmark.
[2] Center for Mathematical Modeling of Knee Osteoarthritis (MathKOA), Aalborg, Denmark.
Email: msa@mp.aau.dk

INTRODUCTION

Knee Osteoarthritis (KOA) is a degenerative joint disease and, combined with hip osteoarthritis, it is the most frequent cause of walking disability among elderly [1]. Multiple risk factors for the development of KOA, hereunder increased knee joint compressive forces (KJCF), have been identified. For this reason, unloading braces have been investigated, but their effect has not been clearly documented. Many brace designs have focused on reducing the Knee Adduction Moment (KAM) although it does not accurately predict the KJCF. The purpose of this study was, therefore, to develop a novel patient-specific knee brace concept to reduce the KJCF and evaluate its effect in a pilot patient study.

METHODS

The study was divided into three phases: 1) Unloading concept investigation. 2) Prototype development and 3) Evaluation of the brace concept.

Unloading concept investigation

To identify potential mechanisms to unload the knee joint, inverse dynamics-based musculoskeletal models (MSM) were created for ten healthy subjects during gait at self-selected pace in the AnyBody Modeling System (AnyBody Technology, Denmark). On these models, we applied idealized, support moments at the hip, knee and ankle and investigated how these alone and in combination affected the KJCF. The full details of the study can be found in in Stoltze et al. [2] and we found, among other measures, that a knee extension moment applied during early stance can reduce the first peak of the KJCF, whereas an applied ankle plantarflexion moment can reduce the second peak of the KJCF. Based on this, we decided to develop a knee brace prototype to unload the first peak as other studies have already developed a suitable ankle brace for the second peak [3].

Prototype development

Using a combination of strings, springs and a four-bar mechanism, a quasi-passive knee brace was designed to apply a knee extension moment during early stance (Figure 1, left). To apply the knee extension moment only during the early stance, a release mechanism was developed to control whether or not the strings were slack. For brace design details, see Stoltze et al. [4].

Evaluation of the brace concept

Gait data were collected for six KOA patients using motion capture and force plates without the brace.

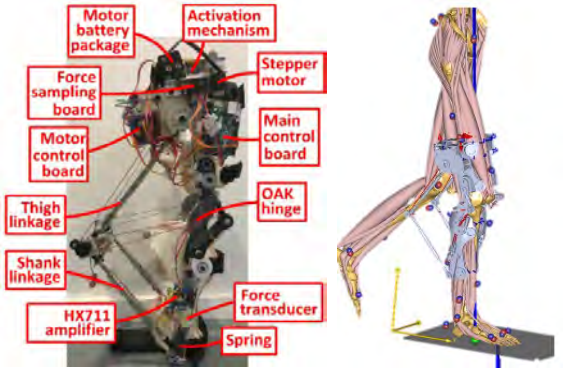

Figure 1 Left: Knee brace prototype. Right: MSM with brace.

For each patient, MSM were created, and an ideal brace model was implemented. Using the model, subject-specific brace parameters (spring stiffness, brace activation etc.) were determined to reduce the KJCF. Subsequently, the prototype brace was manufactured for one patient and the gait mechanics with and without the brace was measured using surface electromyography, marker-based motion capture and force plates. Lastly, the effect from the prototype brace was evaluated with MSM (Figure 1, right).

RESULTS AND DISCUSSION

The simulations with the ideal brace showed a varying reduction of the first peak KJCF between 3.5% to 34% across the six patients. The experiments with the prototype brace reduced the peak vastii muscle activation by 8% and the musculoskeletal models estimated an associated KJCF reduction of 26%. However, the impulse of the KJCF increased by 17%.

CONCLUSIONS

The results with the prototype brace shows promising results in terms of reducing the KJCF through the application of external moments to unload the muscles. However, further studies on large patient cohorts are required to determine the long-term effects on both pain, function and disease progression.

INTRODUCTION

The gold standard for knee implant wear simulation, experiments according to ISO 14243, is too expensive and time consuming for large scale studies. Finite element simulation offers an alternative, but models need to be validated carefully. Moreover, the recent "Stan" dataset [1], containing representative in vivo joint level loads and kinematics based on data from load-sensing implants and video-fluoroscopy [2], presents an alternative set of boundary conditions for both force-controlled (FC) and displacement-controlled (DC) setups. In this study, we compared wear for the ISO and Stan conditions in both FC and DC configuration using simulation and laboratory testing, simultaneously validating a state-of-the-art finite element wear model.

METHODS

Here, we investigated the same knee implant Stan's data was obtained from (*Innex FIXUC*, Zimmer Biomet, Switzerland. To validate the wear model, two groups of three were tested on a six-station knee simulator for 5 million cycles (Mc). One group was subjected to the ISO FC boundary conditions and the other to Stan's kinematics in DC mode. The effective loads and kinematics of the implants were also recorded. Before and after the test, the specimens' 3D geometry was measured using a 3D scanner (Pro S3, HP Inc., USA) and surface deviation caused by wear and creep was visualized by comparison.

Finite-element models of these ISO FC and Stan DC implant wear tests were developed in Abaqus (Dassault Systemes, USA). However, differences in effective loads and kinematics in the joint models and test were expected. To control for this when evaluating wear, two additional models where the mean kinematics measured in each test group were applied in DC mode were run. For the four models in total, polyethylene inlay wear and creep was predicted for 5 Mc using a cross-shear and contact-pressure dependent wear model for the polyethylene inlay material [3] and a compressive creep model using custom software.

RESULTS AND DISCUSSION

Experimentally, wear of the DC Stan condition was 2.7 times higher than for the FC ISO condition (Figure 1, right). For the corresponding simulations (Figure 1, left), the DC CAMS model matched the experiment closely, while the FC ISO model drastically overpredicted wear. Rather than poor modelling of wear, this mismatch was due to a difference of several mm/degree of the predicted joint kinematics between the ISO FC model and bench test. Consequently, there was good agreement for the ISO model with measured kinematics (Fig. 1, middle) and for the Stan condition, which was always in DC mode.

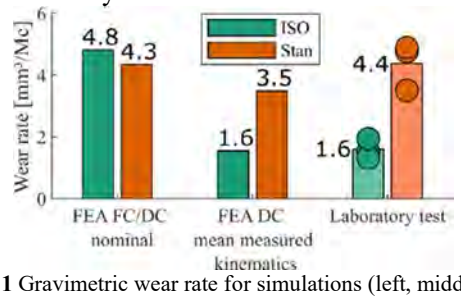

Figure 1 Gravimetric wear rate for simulations (left, middle) and laboratory wear test (right, circles represent each specimen).

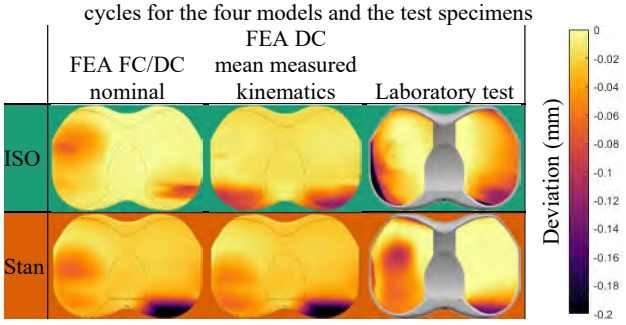
The ISO FC model's surface damage (Table 1, top left) was significantly more anterior and covered a larger area than for the ISO model with effective kinematics applied in DC mode (Table 1, top middle), explaining the different wear volumes. For the Stan condition, both models agreed with the experiment (Table 1, bottom).

Table 1: Surface deviation caused by wear and creep after 5 million cycles for the four models and the test specimens



CONCLUSIONS

Overall, the comparison between the lab tests and the simulations using DC control served to validate our wear prediction algorithm. However, it appears sensitive to variations in contact mechanics. Still, our models are suitable for future investigations into wear and creep damage caused by different boundary conditions (e.g. Stan) or implants.

ACKNOWLEDGEMENTS

We thank Zimmer Biomet for access to data and performing the laboratory wear test.

INTRODUCTION

One of the main risk factors for ulcer formation and eventual lower limb amputation in people with diabetes is sustained high plantar pressure (PP). There is a need for off-loading footwear that actively adapts to the user's changing PP needs. To address this need, our team is developing intelligent footwear (IF) with an auto-contouring insole which will read PPs and automatically adapt the shape of the insole [1]. This pilot study tests the IF's mechanical ability to redistribute high PPs during gait by altering placement of fixed height modules (either full or deformed height).

METHODS

Four healthy participants walked 20m overground donning the PEDAR® system (Novel GmbH, Munich, Germany) in the IF (size EU43) with two comfort insole conditions: thin (TI) and medium-thickness (MI) insoles (Figure 1A). For each insole (TI or MI), baseline measures were collected followed by two to four adjustment conditions. The goal of these adjustments was to redistribute and reduce high PP via specific module replacement. To perform the adjustments, the researchers determined the location of the highest PP in the rearfoot and forefoot across both feet according to the PEDAR®. Then, under the area(s) of high PP, one to four of the 3D-printed full-height module replicas (30mm, Figure 1A-white modules) were replaced with a deformed-height module replica (27.5mm, Figure 1A-blue modules). The peak PPs for each of 99 PEDAR® cells per foot across two walking trials per condition were analysed. The peak PPs within a region (forefoot or rearfoot), around the module(s), and directly over a module were compared between the baseline and adjustment conditions for each insole.

RESULTS AND DISCUSSION

The average (SD) and range of baseline PPs were 392(102) and 273-603kPa, respectively. Across the 29 adjustment conditions, there was an average reduction within the region, around the module(s), and over the module(s) of 29(56), 34(54), and 60(39) kPa, respectively (Figure 1B). If the regional baseline PP was greater than 400 kPa, the adjustment reduced the pressure in that region by 55(66) or 129(19) kPa (11% or 21%) for the TI or MI. The baseline and adjustment PPs for the MI condition were lower than the TI.

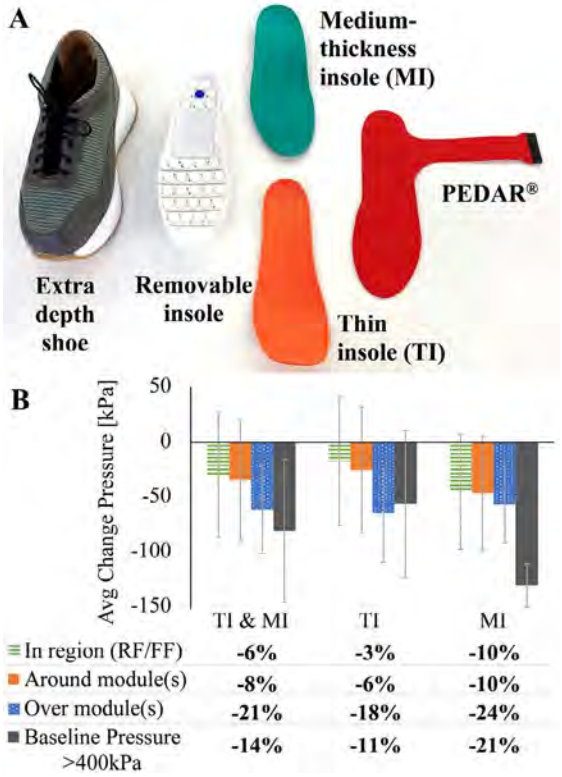

Figure 1 A) Footwear pieces used. B) Average PP reduction with the respective values of % change in pressure below.

CONCLUSIONS

Overall, the PPs in the adjusted conditions were lower than in the baseline condition and were most reduced when the starting baseline PP was above 400kPa. The largest PP reductions were close to the common clinical reduction goal of 25% [2]. This work shows that this novel footwear has promising potential to reduce high PPs and thus, reduce the risk of ulceration and amputation in people with diabetes. Future tests will use the electronic modules [1] and parts to assess the IF's redistribution algorithm, autonomy, human factors design, and thus, real-world application.

INTRODUCTION

Spasticity is abnormal muscle tone which often shows in patients with upper motor neuron syndrome. The Modified Ashworth Scale (MAS) is commonly used to classify abnormal muscle tone in clinical assessments. However, using the MAS to determine abnormal muscle tone heavily relies on experiences and judgments made by clinicians without using other objective tools or data. Robotic measurements can obtain more accurate muscle tone data. Only a few studies have described the muscle tone across multi-joints of upper limbs using robotic measurements. Therefore, this study aims to investigate the muscle tone patterns of stroke patients via a custom Arm Circumference Motor Evaluation System (ACMES) [1], which is a novel device using an indirect measure method to quantify human upper limbs endpoint impedance across multi-joints.

METHODS

The ACMES guides upper limbs in a circular motion via a rotation disk and handle and then measures the impedance of upper limbs during the rotation motion. Nine stroke patients (6 males, 3 females, mean age = 53.6 years) with different MAS scores were included in this study. Each participant was asked to sit in front of an adjustable chair and select an appropriate disc radius depending on the arm length. Next, each participant was asked to grasp the handle and place the forearm on the handrest with the hand stabilized on the handle using a bandage. Both the less-affected side and affected side were measured. The test conditions included three speeds (low/medium/high) and two rotation directions (ABD/ADD). The disk angle was defined using the shoulder horizontal adduction direction. The test was divided into two phases, the flexor stretched phase (FSP) and the extensor stretched phase (ESP). Two phases were divided by the elbow joint motion, as shown in Figure 1.

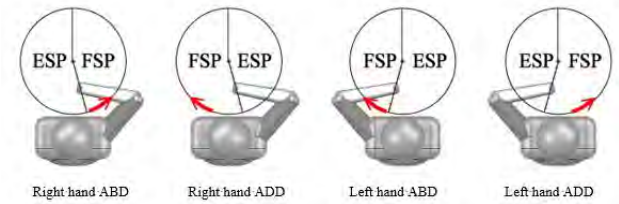

Figure 1 The definition of two rotation directions and two phases during the test.

The paired t-test was used to test the difference of the impedance between the less-affected side and affected side. All the data analysis and statistical analysis were performed using MATLAB R2020a.

RESULTS AND DISCUSSION

The result shows significant differences in all conditions except for the median speed and fast in ADD-ESP.

CONCLUSIONS

The result of this study shows the ACMES can indicate differences in spastic features between affected and less-affected sides of stroke patients. However, it will be necessary to recruit more participants with different demographic characteristics to collect more performance data to understand whether these physical or ergonomic issues would be potential significant factors influencing the impedance in the ACMES examinations.

INTRODUCTION

Anterior cruciate ligament (ACL) rupture is a debilitating and costly knee injury that is common among young, active athletes and military personnel [1,2]. Both generalized joint hypermobility (GJH) and excessive laxity in one or multiple anatomic planes is related to increased risk of ACL injury [5]. However, the physical exams used to assess knee laxity, which include uniplanar tests of anterior-posterior (AP), varus-valgus (VV), and internal-external rotation (IER) laxities and the pivot shift exam, are subjective and are examiner dependent. Moreover, the relationship between GJH and knee laxity is not well understood. To address the lack of measurement instruments available to quantify uniplanar and multiplanar tests of knee laxity, we developed a novel arthrometer. This study had three goals: 1) to assess our device's safety; 2) to quantify its reliability and left-right symmetry in both uniplanar and multiplanar assessments; and 3) to relate GJH to uniplanar and multiplanar laxity exams.

METHODS

With IRB approval, 15 healthy, uninjured volunteers (8 males, 7 females; mean age: 28 ± 6 years) with no prior knee injuries were enrolled. The custom-designed knee arthrometer integrated an instrumented linkage with five degrees of freedom and measured translations and rotations in response to applied forces and moments (Fig. 1). The applied loads were measured using a six axis load cell (Mini58, ATI, Inc), which was fixed to the arthrometer. To conduct a test, the subject sat reclined in a chair, their leg was aligned and oriented at 20° of flexion, the femur was affixed to the chair, and the tibia was secured to the arthrometer. After 3 preconditioning cycles, the examiner manually applied AP forces (-50 N posterior to 135 N anterior), VV moments (±4 Nm), and IER moments (±2.5 Nm) to the tibia and the corresponding translations and rotations were recorded. The examiner performed a simulated pivot shift exam, consisting of the following loads applied in series: 2 Nm external rotation moment, 6 Nm valgus moment, 2 Nm internal rotation moment, and, finally, 50 N anterior force. Anterior tibial translation (ATT) was measured in response to these multiplanar loads. Two examiners conducted two independent tests on both left and right knees. Pain was assessed on a visual analog scale from 0 (no pain) to 10 (excruciating pain). Reliability within a single test and within (intra) and across (inter) examiners was characterized via intra-class correlation coefficients (ICC) and 95% confidence intervals (CI). Left and right leg symmetry was quantified via mean left-right difference in laxity. GJH was measured using the clinical Beighton score. The relationship between GJH and knee laxity was quanitified using linear regression ($\alpha = 0.05$).

RESULTS AND DISCUSSION

All volunteers completed the protocol. Pain across all tests was minimal (mean: 0.2 ± 0.1). Intra-trial reliability was excellent for all tests (≥0.92) while intra-examiner reliabilities ranged from good (0.66 in AP) to excellent (0.92 in VV). For all tests, inter-examiner reliabilities were good (all ICC's ≥ 0.62). Regarding left-right symmetry, in the AP, IER, and VV directions, and the simulated pivot shift, the mean difference was 0.4 ± 3.0 mm, 0.1 ± 4.1°, and 0.0 ± 0.5°, and 2.2 ± 2.0 mm, respectively. The mean Beighton score was 3.7 ± 1.2 ranging from 0 to 9. Regarding uniplanar laxities, the Beighton score was only associated with AP laxity ($R^2 = 0.43$, $p = 0.008$). In AP, a mean left-right difference of 2.6 mm will enable us to relate knee laxity and ACL injury risk [5]. In IER, a mean left-right difference of 3.1° will enable us to detect increased rotatory laxity and to indicate use of lateral augmentation surgery. For the simulated pivot shift, a mean left-right difference of 2.2 mm will enable more precise detection of ACL graft failure.

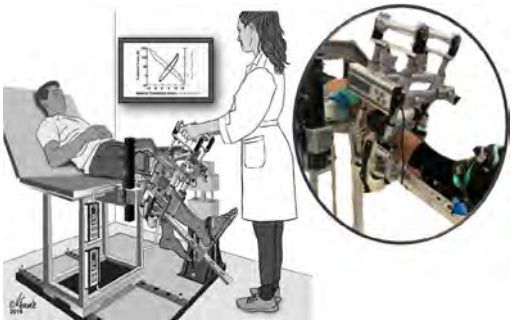

Figure 1: Knee Arthrometer

CONCLUSIONS

Our novel device was safe and showed promising reliability. The uncertainties in left-right symmetry were small enough to identify distinct, clinically relevant subgroups to stratify risk, diagnose injury, and indicate surgery. The Beighton score of GJH was not a surrogate for knee laxity in all anatomic planes.

HUMAN LOWER LEG MUSCLES GROW ASYNCHRONOUSLY

INTRODUCTION

Most studies of muscle growth in childhood have investigated only one or a few muscles. Consequently, little is known about the relative rates of growth in leg muscles. In this study, we sought to determine if leg muscles grow at proportionately different rates, or grow synchronously. The study is part of a large-scale longitudinal study on childhood muscle growth [1].

METHODS

Participants were 208 typically developing children (200 children 5-15 years and 8 infants <3 months; 121 boys and 87 girls; height: 54-180cm; weight: 4-82kg; tibia length: 9-43cm). Anatomical MRI images (mDixon or T1) of one leg from each child were obtained with a 3T MRI scanner. Each image was semi-automatically segmented [2] into ten 3D muscle surface models (Fig. 1A). Each model represented a muscle or a group of small muscles. Relative volume was calculated by dividing muscle volume by the child's total lower leg muscle volume. A small-sample test for isometry was used to test the hypothesis of synchronous muscle growth [3].

RESULTS AND DISCUSSION

If growth was synchronous, the volume of each muscle, expressed as a proportion of leg muscle volume, would be constant with age or leg length [i.e., lines in Figures 1B-C would be horizontal]. The lines were clearly not horizontal, so growth is asynchronous ($p < 0.001$). Before the age of 5, the two largest muscles of the triceps surae group (SOL and MG) grow disproportionately faster than other muscles. This may assist, or be caused by, the onset of weight bearing or ambulation. In contrast, the TA, EEP, TP and FHL muscles grow disproportionately slower than other muscles. Even in children > 5 years, growth is asynchronous ($p < 0.001$).

CONCLUSIONS

A large MRI dataset from a detailed investigation into human muscle growth was used to examine the synchronicity of muscle growth. Muscles in the lower extremity do not grow synchronously.

INTRODUCTION

Residual force depression (rFD) and enhancement (rFE) describe the increase or decrease in force following active shortening or lengthening, respectively, relative to a reference steady-state isometric force [1]. rFD has been proposed to linearly increase with the amount of positive mechanical work [2], which means that limiting shortening under matched activation levels should theoretically reduce rFD. To test this hypothesis, the effective series elasticity of the tibialis anterior (TA) muscle-tendon unit (MTU) was reduced during ramp-and-hold contractions to reduce positive TA muscle work. Further, the amount of MTU lengthening (LEN) and shortening (SHO) to the same final MTU length was varied to alter the magnitude of TA net muscle work.

METHODS

Sixteen participants (23-33 yr, eight women) sat in a reclined posture (90° knee flexion, 110° hip flexion) with the plantar aspect of their right foot secured to the footplate attachment of a motorised dynamometer (IsoMed2000, Ferstl GmbH, DE) that measured net ankle joint torque (2000 Hz). After determining the ankle angle where maximum active dorsiflexion torque was produced (ANG_{Max}), participants matched the bipolar surface EMG signal recorded over TA (2000 Hz, NL905, Digitimer Ltd, UK) to within 30±5% of the maximum EMG amplitude recorded at ANG_{Max} for at least 21 contractions in seven conditions. Each condition consisted of two identical dynamic contractions and one fixed-end reference contraction (REF). The first two conditions involved TA MTU LEN from rest over a small (11-14°) and large amplitude (16-23°) during a 2-s ramp, which was followed by a 6-s hold phase at ANG_{Max}. The third condition involved a fixed-end preload phase during a 2-s ramp before MTU LEN over the large amplitude. The last four randomised conditions involved MTU SHO over similar small and large amplitudes without and with a preload.

TA's muscle fascicles were visualised with ultrasound at ~34 fps (ArtUs, TELEMED, LT). Fascicle lengths (doi.org/10.5281/zenodo.7411280) and fascicle forces were estimated post-processing [3]. Fascicle work from TA's superficial compartment was calculated as the area under the fascicle force-displacement curve. rFD or rFE were estimated as the mean difference in steady-state torque between the valid (≤10% difference in muscle activity level) dynamic and reference contractions.

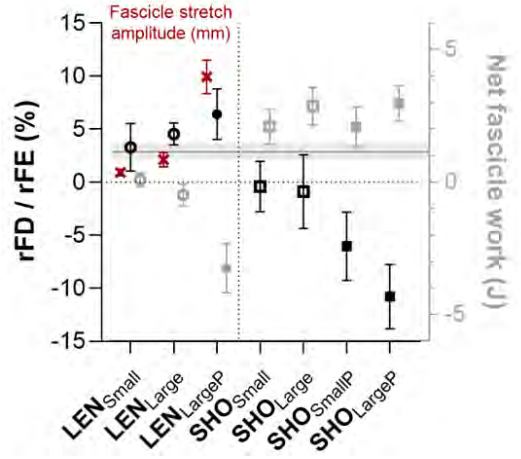

Figure 1. Mean (±95% confidence intervals, CIs) rFD and rFE magnitudes (black symbols), and TA net fascicle work magnitudes (grey symbols; REF: grey line and shaded area) during MTU LEN (circles) and SHO (squares) over small and large amplitudes without and with a preload (P: solid symbols). Red crosses (±95% CIs) indicate TA muscle fascicle stretch amplitudes during LEN.

RESULTS AND DISCUSSION

Reduced rFD and rFE was observed ($p \leq 0.024$) in the LEN conditions without and with a preload, respectively, but magnitudes were similar (3-6%, $p \geq 0.157$) despite different TA fascicle stretch amplitudes (0.9-9.9 mm, $p \leq 0.001$; Figure 1). No significant linear relation ($r_{11} = 0.33$, $p = 0.276$) was found between the reduction in TA positive fascicle work and rFD reduction in LEN conditions without a preload. rFD was similar (0-1%, $p \geq 0.935$) and increased (6-11%, $p \leq 0.007$) in SHO conditions without and with a preload, respectively. As work magnitudes were similar for SHO conditions without versus with a preload (Figure 1), rFD was not significantly related ($r_{41} = -0.24$, $p = 0.115$) to the positive muscle work during voluntary contractions.

CONCLUSIONS

rFD is only linearly related to the preceding positive muscle work for preloaded voluntary contractions.

Post-activation potentiation does not contribute to *in vivo* residual force enhancement

Daniel Hahn[1,2], Lukas John[1], Brent J. Raiteri[1,2]

INTRODUCTION

Residual force enhancement (rFE) refers to the phenomenon of increased muscle force output during an isometric contraction following active muscle stretch compared with an isometric contraction without prior stretch [1]. Although the exact mechanisms behind rFE remain unclear, it is thought that the enhanced force originates from increased cross bridge forces and passive contributions from the elastic element, titin.
Another physiological mechanism that is known to increase muscle force output is post-activation potentiation (PAP) [2]. PAP refers to the phenomenon of increased muscle twitch force following a conditioning contraction. Further, PAP increases with the force output of the conditioning contraction. Accordingly, PAP might contribute to rFE since the enhanced force output in the rFE state occurs following increased forces during active muscle stretch. Therefore, the aim of this research was to examine whether PAP contributes to rFE.

METHODS

Nineteen participants (4 females; mean age, height, and body mass: 25.7 years, 179.8 cm, and 78.3 kg, respectively) were lying prone on the bench of a motorised dynamometer (IsoMed2000, Ferstl GmbH, DE) that measured net ankle joint torque and crank arm angle. Supramaximal single pulse (200 µs) electrical stimulation (DS7AH, Digitimer, UK) of the tibial nerve was delivered to elicit plantar flexor muscle twitches and M-waves. M-waves and voluntary muscle activity of soleus (SOL), lateral (LG) and medial (MG) gastrocnemius were recorded by bipolar surface EMG (NL905, Digitimer Ltd., UK). All data were recorded at 2 kHz (16-bit Power-3 1401, CED, UK).
Participants performed four different conditioning contractions. 3 s before and after each contraction, participants received an electrical stimulation at 20° dorsiflexion to elicit unpotentiated and potentiated muscle twitches. The conditioning contractions included a SOL EMG-controlled fixed-end contraction (ISO_{50}) at 20° dorsiflexion (DF) and a stretch-hold contraction (ECC_{50}) from 0-20° DF at 40°/s with EMG control during the hold phases. Both contractions were performed at 50% of the maximal EMG amplitude recorded during maximal voluntary contractions at 20° DF. Before stretch, participants also needed to match a 50% EMG level determined for 0° DF. Participants also performed two torque-controlled fixed-end contractions at 20° DF; one condition required participants to match the torque level achieved following stretch of the stretch-hold contraction (ISO_{rFE}), and the other condition required participants to match the peak torque achieved during stretch of the stretch-hold contraction (ISO_{Peak}). All conditioning contractions lasted 6 s and visual feedback for control was provided on a screen in front of the participants. At least 3 min rest were provided between contractions. The sizes of M-waves and muscle twitches were determined as peak-to-peak amplitudes. rFE was determined as the normalised difference between the time-matched isometric torque 2.5-3s following stretch of the EMG-controlled stretch-hold contraction and fixed-end contraction.

RESULTS AND DISCUSSION

rFE following stretch was 8.5±2.8% (mean ± 95% confidence interval, CI). PAP following the conditioning contractions was 20.1±4.3%, 20.4±3.8%, 21.4±4.2%, and 33.7±5.7% for ISO_{50}, ECC_{50}, ISO_{rFE}, and ISO_{Peak}, respectively. PAP following ISO_{Peak} was significantly larger compared with PAP following all other conditioning contractions (Fig. 1). M-waves showed no significant differences.

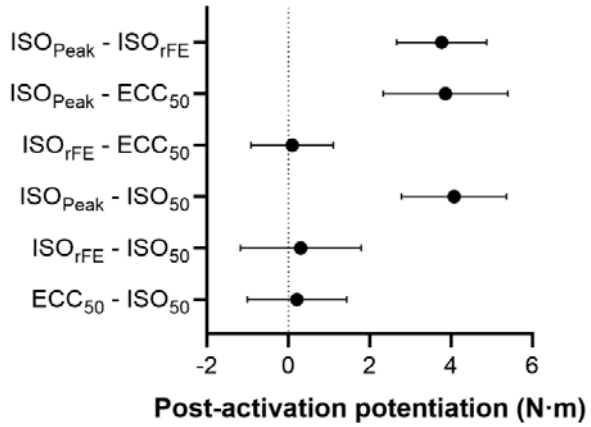

Figure 1 Mean differences±95% confidence intervals between PAP following the four conditioning contractions

CONCLUSIONS

As PAP following ECC_{50} was similar to PAP following ISO_{rFE} and ISO_{50}, PAP likely did not contribute to rFE. The larger PAP following ISO_{Peak} compared with ECC_{50} indicates that impulse rather than peak force output likely determines the potentiating effect.

INTRODUCTION

The force-generating capacity of skeletal muscles deteriorates with advancing age and in vivo monitoring of the mechanical adaptation of muscles would be invaluable for eliminating premature weakness. Ultrasound shear wave elastography (SWE) quantifies muscle mechanical properties by measuring the propagation velocity of the shear waves traveling within the tissue [e.g. 1,2]. Hence, SWE has the potential for early detection of muscle weakness. The objective of this study was to assess the mechanics of the biceps brachii muscle (BB) with the hypotheses that shear elastic modulus reflects (i) the increase in passive muscle stiffness imposed by length change, (ii) the activation-dependent mechanical changes in BB for older adults, and (iii) the differences between the mechanics of muscles of older and young adults.

METHODS

14 young (7 males, age: 28.07 ± 5.06 years) and 14 older (6 males, age: 68.71 ± 5.08 years) healthy volunteers participated. Elbow torque, BB SWE, and surface electromyography (sEMG) were measured at five elbow angles (60°-180°) from flexion to extension at rest, and during maximum voluntary contractions (MVC), and submaximal ramp contractions up to 25%, 50%, and 75% of MVC torque of elbow flexion. BB muscle length was also measured using ultrasound imaging.

RESULTS AND DISCUSSION

Even though the body height and weight of older adults were not significantly different compared to the younger group, their muscle length was 10.5% ± 2.0% shorter and the passive shear elastic modulus of BB was maximally 52.6% higher at 90º elbow angle for older adults (Fig. 1) ($p < 0.001$ for both). This indicates that muscle as a passive material becomes shorter and stiffer with age. The MVC torque was 23.67% less for older adults and it decreased from flexion to extension ($p < 0.0001$ for both). During MVC, the total shear elastic modulus of BB was found to be higher for older adults (by 11.21%, $p = 0.006$) with no significant effects of elbow angle. This could be due to increased passive stiffness even though force production capacity dropped with aging. However, the active shear elastic modulus did not show the effects of age during MVC either. On the other hand, the active shear elastic modulus changed with age ($p = 0.037$) at 25% MVC and elbow angle ($p < 0.001$ for all submaximal contractions) (Fig. 1). 16.18% lower active shear elastic modulus found for older adults at 25% of MVC aligns with the reduced force production in older ages.

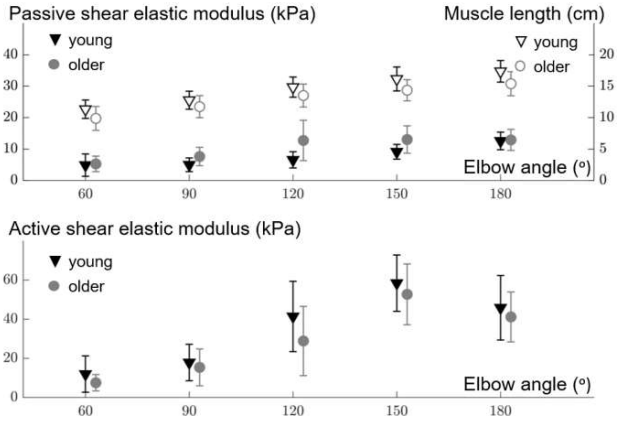

Fig. 1 Upper panel Muscle length, passive shear elastic modulus, and **Lower panel** Active shear elastic modulus during 25% of MVC with respect to elbow angle for young and older volunteers

CONCLUSIONS

The hypotheses were confirmed that shear elastic modulus reflected the changes led by muscle length, activations, and age. Present findings indicate that shear elastic modulus as a measure of muscle stiffness can be used to detect muscular alterations in passive state and during low-level activities (but not at MVCs). We conclude that SWE can be implemented as a muscle stiffness monitoring tool to be used in early muscle loss prevention, rehabilitation, and physiotherapy.

INTRODUCTION

Changes in muscle stress and stiffness are important for development of force during contraction, but the distribution throughout a muscle is likely also important in terms of potential for muscle adaptation and injury. Surprisingly, little is known about the distribution of stress/stiffness in different regions of human muscles during contraction (in vivo). Because human muscles have complex structural and functional arrangements and are innervated by an intricate arrangement of motor neurons, it is difficult to predict/estimate the distribution of tissue stress/stiffness within muscle. Shear modulus (SM) estimated with supersonic shear imaging (SSI), has been demonstrated to be a reliable indicator of muscle stress and/or stiffness within a muscle [1]. The aim of this study was to quantify the distribution of SM in different regions of the human tibialis anterior (TA) muscle during contraction. We hypothesised that distinct regions of the muscle will present different SM values because of differences in architecture and microstructure (e.g., sarcomere length) across the muscle.

METHODS

Ten healthy participants performed voluntary, isometric contractions at 10, 20 and 30% of their maximum voluntary contraction (MVC), while SM was estimated using SSI (Aixplorer V9, transducer SL10-2 MHz, SuperSonic Imagine, France). SSI elastography maps were recorded at 0.7–1.3 Hz (resolution: 1x1mm) at 4 different locations within the TA muscle: proximal, mid medial, mid lateral, distal. From the same regions, fascicle lengths and pennation angles were estimated at the different force levels. A two-way ANOVA was used to evaluate the effect of factors "force" (MVC levels plus resting muscle) and "region" on SM, fascicle length and pennation angle ($p < 0.05$). Tukey's test was used for multiple comparisons between the different muscle regions.

RESULTS AND DISCUSSION

We found a main effect of "force" in all variables, and a main effect of "region" in SM and pennation angle. The multiple comparisons revealed differences in SM and pennation angle between the different muscle regions as denoted by "*" in Figure 1. These results suggest an heterogenous distribution of stress/stiffness within the TA, particularly, a smaller SM within the distal portion of the muscle. The smaller SM in the distal region is unlikely explained by the TA's smaller pennation angle in that region because we would have expected a decrease in SM with increased pennation angles (i.e., force levels).

Studies using passive movements [1] suggest that anatomical (e.g. smaller cross sectional area), mechanical (e.g. force-length relationship properties) or neural (e.g. intramuscular nerve/activation distribution) factors are likely candidates to explain heterogeneous distributions in SM. Animal models [2] suggest that contracting muscle may show differences in stress due to physiological factors such as sarcomere length, density of myofilaments, myofibrillar bundle diameter and/or intrinsic actin/myosin mechanical (cross-bridge) properties. Further studies are needed to elucidate how areas of higher relative stiffness within contracting muscle affect fascicle strain when external forces are applied to rapidly stretch the muscle.

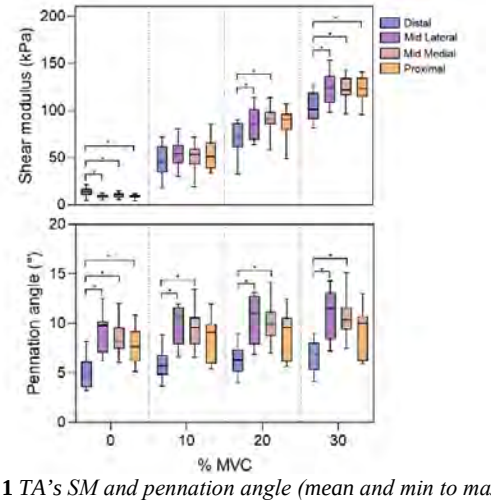

Figure 1 *TA's SM and pennation angle (mean and min to max) at different contraction levels.*

CONCLUSIONS

Distinct regions of the TA present different SM during contraction at different force levels. This may be because of a heterogenous distribution of anatomical, mechanical, neural and/or physiological factors.

INTRODUCTION

Hamstring muscle strain injury is the one of most prevalent injuries in sports. It occurs most often in the Biceps Femoris long head (BFlh). Due to lack of *in vivo* measurements of muscle fascicle length changes during springing, there are debates in the literature regarding the injury mechanisms. Yu et al.[1] proposed that excessive muscle strain is the direct, if not exclusive, cause of muscle strain injury during the late swing in sprinting when a lengthening of the hamstring muscles tendon unit (MTU) occurs. However, muscle fascicle may shorten or contract isometrically when muscle force increases[2]. The purpose of this study is to examine the muscle fascicle behavior of BFlh *in vivo* during sprinting using ultrasonography. The results of this study may bring insight to mechanisms of hamstring strain injury in sprinting.

METHODS

Seven male elite sprinters who had no lower extremity injuries within the past 12 months volunteered to participate in this study. 3D kinematics (200Hz; Vicon Motion Analysis, Oxford, United Kingdom) and ground reaction forces (1000Hz, Bertec Corporation, Columbus, OH) during steady-state at five discrete running speeds: 2m/s, 3m/s, 4m/s, 5m/s, and 6m/s on an instrumented treadmill were recorded simultaneously. Visual 3D (C-Motion, German- town, MD, USA) and OpenSim were used to compute MTU length. BFlh muscle fascicle length changes were recorded using a 128-element linear ultrasound transducer in B-mode, and Ultra-track software was used to track the muscle fascicle behavior.

RESULTS AND DISCUSSION

Regardless of running speed, BFlh fascicles lengthened <1cm during sprinting (Figure 1), which is consistent with fascicle length change magnitude during Nordic hamstring exercise [3]. The decoupling between MTU and muscle fascicle length change demonstrated that tendons are the main role in stretch. Since the amount of strain needed to cause a muscle strain injury is reduced when a muscle is maximally activated [4], excessive muscle strain could not be the direct cause of muscle strain injury during sprinting.

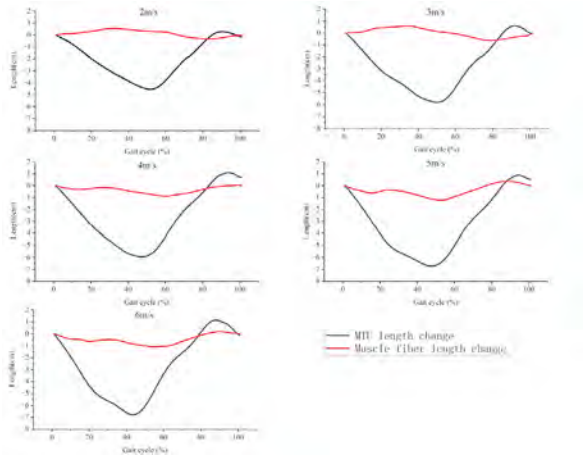

Figure 1 The length changes of BFlh fascicle and MTU

CONCLUSIONS

BFlh presents a nearly isometric fascicle behavior during late swing before foot strike, which suggests tendons are the main role in stretch and excessive muscle strain could not be the direct cause of muscle strain injury.

HOW DOES THE MEDIAL GASTROCNEMIUS AND ACHILLES TENDON INTERPLAY CONTRIBUTE TO THE MUSCLE-TENDON UNIT DURING GAIT IN CEREBRAL PALSY?

INTRODUCTION

3D gait analysis can be enhanced by using portable ultrasound imaging (3DGAUS), thus allowing to assess muscle and tendon lengths during gait [1]. By focusing at the ankle joint, the interplay between medial gastrocnemius muscle (MG) and Achilles tendon (AT) is crucial for optimizing stability and propulsion during each gait cycle. In spastic cerebral palsy (CP), this interplay is altered with consequences to the overall function [2]. Despite the attempts of using musculoskeletal modelling, this interplay is still poorly understood in pathological conditions such as CP due to a lack of experimental data during gait. The goal of this study is to quantify the contribution of MG and AT length changes to the entire muscle-tendon unit (MTU) during gait in participants with CP and typically developed (TD) peers.

METHODS

3DGAUS data was acquired from 5 participants with CP (18.2±5.1 years, GMFCS I/III: 2/3) and 5 TD (18.4±4.7 years) during overground walking at preferred walking speed (average CP: 0.9 m/s, TD: 1.4 m/s). A 12-camera motion analysis system (Vicon Motion Systems Ltd.) operating at 200 Hz was used and synchronized with a portable ultrasound device (Telemed SmartUS), at 50 Hz. Lower-limb Plug-in-Gait model along with additional markers to define the local shank reference frame, were used. The ultrasound probe, within a probe holder instrumented with four reflective markers, was attached to the random (TD) or most-affected (CP) leg. Images were acquired first from the distal MG muscle-tendon junction (MTJ), and secondly from MG fascicles. The ultrasound image locations were mapped into the shank reference frame, allowing both whole muscle and tendon lengths to be estimated [1], and MTU length being their sum. Fascicle, MTU, whole muscle and tendon length patterns were averaged over at least 5 time-normalised gait cycles. Relative values are the length changes from the corresponding values at initial foot contact. Semi-automated software was used to track the MTJ [3] and fascicles [4]. Due to the small and heterogeneous sample, results are presented in a descriptive manner.

RESULTS AND DISCUSSION

Overall, relative length changes are more heterogeneous in CP than TD. On average, participants with CP showed reduced length changes for the MG muscle (2.5 mm in CP and 5.8 mm in TD), for the AT (7.3 and 15.1 mm) as well as for the MTU (9.3 and 15.6 mm), whilst fascicle changes were similar (9.0 and 10.2 mm) during the gait cycle (Figure 1A-B). An efficient behaviour for TD during the stance phase was observed, with the AT lengthening more than MG, whilst for CP, muscle and tendon contributed almost equally to the MTU lengthening at the stance phase (Figure 1C-D). At the final push-off, the contribution of MG to the MTU in TD and CP was 69.3% and 54.8%, and for AT 30.7% and 45.2%, respectively.

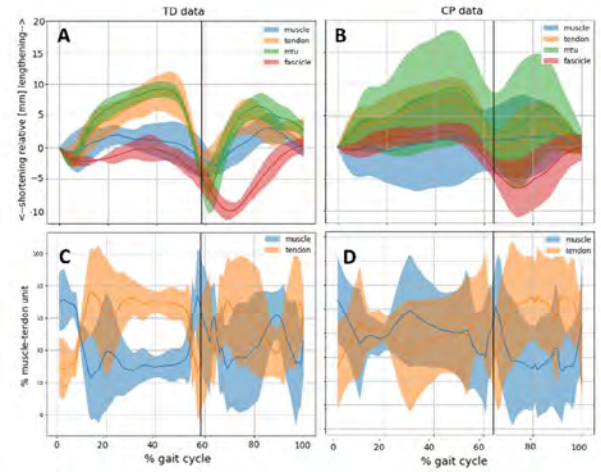

Figure 1. A-B: Relative length changes of muscle, tendon, MTU, and fascicle (mm); C-D: Contribution of the muscle and tendon (%) to the MTU for TD (left) and CP (right) participants. Vertical lines separate stance to swing phases.

CONCLUSIONS

Understanding the differential contributions of muscle and tendon to the overall MTU length in CP compared to TD is clinically relevant. In TD, MTU length changes at 10-50% of gait cycle were mostly due to the AT, whilst at the push-off phase the AT recoiled quicker than MG. This interplay seems impaired in CP, showing that the AT elastic mechanism is not properly exploited. This may be due to a more compliant AT as well as the inability of the MG to sustain an isometric contraction and contribute to the final push-off. These findings need to be confirmed once larger samples are processed.

INTRODUCTION

Resistance training is effective to enhance muscular strength and size, but has been empirically believed to increase passive muscle stiffness. The increase in the stiffness may negatively influence athletic performance and increase the risk of musculoskeletal injury through a limitation of joint range of motion [1]. Meanwhile, our recent study [2] showed that the passive stiffness of the semimembranosus (SM) acutely decreased after a session of resistance exercise with eccentric-only stiff-leg deadlift at long muscle lengths with a long duration. The acute change in muscle stiffness induced by stretching was suggested to correspond to its chronic change [3,4]. Thus, it is possible that resistance training at long muscle lengths with a long duration also chronically decreases muscle stiffness. However, this possibility has not been investigated yet. The present study aimed to investigate the chronic effects of resistance training at long muscle lengths with a long duration on passive stiffness of the individual hamstring muscles.

METHODS

Twenty-four healthy young males were randomly assigned into training (n = 12) and control (n = 12) groups. The participants in the training group performed three sets of 10 repetitions of eccentric-only stiff-leg deadlift at long muscle lengths ([50–100% of maximal exercise range of motion [0% = upright position]) with a long duration (5 s per repetition) for 10 weeks (two sessions per week). The training loads were 60%, 65%, and 70% of body mass at weeks 1–4, 5–7, and 8–10, respectively. Before and after the intervention period, the shear moduli of the individual hamstring muscles (the biceps femoris long head [BFlh], semitendinosus [ST], and SM), were measured using shear wave elastography. Additionally, maximal voluntary isometric torque of knee flexion and muscle volumes of the hamstring muscles (BFlh, the biceps femoris short head [BFsh], ST, and SM) were also measured. The changes in the measured variables during the intervention period were analysed by using the Wilcoxon signed-rank test.

RESULTS AND DISCUSSION

There were no significant changes in the shear moduli of BFlh, ST, or SM (p = 0.375 to 0.922) during the intervention period in both groups. Meanwhile, the maximal voluntary isometric torque (p = 0.004) and muscle volumes of BFlh, ST, and SM (p = 0.004–0.012) significantly increased after training intervention in the training group. The present results are consistent with the previous studies [5,6] that observed no changes in passive muscle stiffness after a period of resistance training. Thus, it may not be easy to change the passive muscle stiffness by resistance training. The lack of changes in the stiffness after resistance training may be related to low training frequency per week.

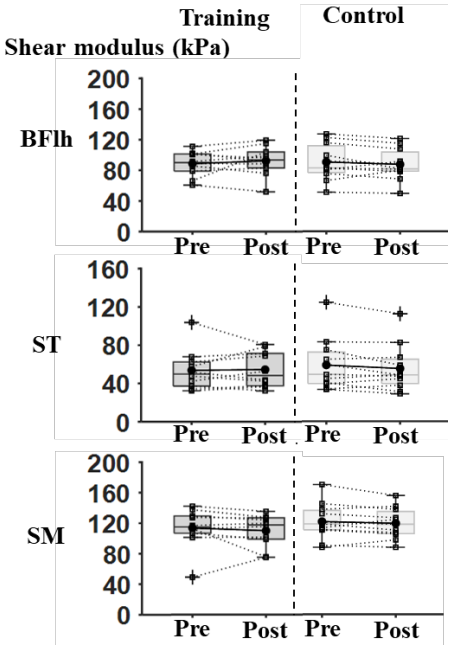

Figure 1 Changes in shear moduli of the individual hamstring muscles before and after intervention period.

CONCLUSIONS

Passive stiffness of the individual hamstring muscles does not change even after eccentric-only resistance training at long muscle lengths with a long duration.

Constant force muscle stretching induces greater acute deformations and changes in passive mechanical properties compared to constant length stretching.

INTRODUCTION

Stretching is applied to lengthen shortened muscles in pathological conditions such as joint contractures. Different types of stretching, e.g. constant length (CL) and constant force (CF) stretching, can be used. It has, to our knowledge, not been investigated if the muscle-tendon unit's deformations and passive mechanics are affected differently by these stretch types. Impulse [1] and maximal strain [2] have been proposed to be determinants of the potential differences in the effect of stretching. We investigated (i) the acute effects of CL and CF stretching, on acute deformations and changes in passive mechanical properties of medial gastrocnemius muscle (MG) of the rat and (ii) the relationship between these effects and the impulse/maximal strain of stretching.

METHODS

Forty-eight hindlimbs from 13 male and 12 female Wistar rats (13 weeks old, respectively 424.6 ± 35.5 and 261.8 ± 15.6 grams) were divided into six groups (n=8 each). Three stretching intensities were applied for each stretch type; the MG was stretched to a length at which the force was 75%, 95%, or 115% of the force found at maximal dorsiflexion and held at either CF or CL for 30 min. Before and after stretching the passive muscle was lengthened to the length corresponding to maximal ankle dorsiflexion to assess MG peak force and peak stiffness. Also, muscle belly and tendon length were measured from displacement data and video. Linear mixed models were performed to assess the effects of stretch type/intensity on acute deformations and mechanical changes and to assess the relation of these outcomes with impulse/ maximal strain.

RESULTS AND DISCUSSION

CF stretching affected peak stiffness and muscle belly length more than CL stretching at similar stretch intensities ($p<0.01$) (Figure 1). This was also found for peak force and tendon length (data not shown). This is in line with previous findings in human subjects [3, 4]. Impulse was associated only with the decrease in peak force, while maximal strain was associated with the decrease in peak force, peak stiffness, and the increase in muscle belly length.

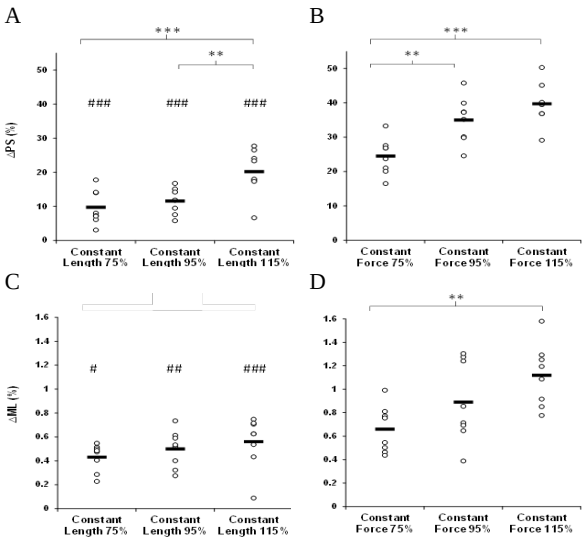

Figure 1 Individual (○) and mean (▬) values of changes in peak stiffness (ΔPS) [A,B] and muscle length (ΔML) [C,D] after 30 minutes of CL stretching [A,C] or CF stretching [B,D]. Significant differences between intensities ** $p<0.01$ and between stretch types # $p<0.05$, ## $p<0.01$, ### $p<0.001$.

CONCLUSIONS

We conclude that CF stretching results in greater acute deformations and changes in mechanical properties than CL stretching, which appears to be dependent predominantly on the differences in imposed maximal strain. Low-intensity CF stretching is equally effective as high-intensity CL stretching, while the latter is likely more painful.

INTRODUCTION

Hamstring strains are the most common lower limb muscle injuries at all athletic levels. Previous studies have showed that athletes with hamstring injuries demonstrated activation deficits in either temporal characteristics or amplitudes during dynamic tasks [1]. However, it is not clear how the injured hamstrings respond to a jump-landing task which is an important activity central to hamstring injury rehabilitation. Also, no evidence of the function of the hamstrings by using time-frequency analysis during jumping which represents the stretch-shortening cycle (SSC) of the muscle has been explored. Thus, the study aims to investigate hamstring recruitment during vertical jumps in athletes with hamstring strains using wavelet analysis. Findings can be used to propose innovative rehabilitation methods regarding jumping training into the program for injured athletes.

METHODS

9 chronically injured athletes (22.3±1.9 years old with 7.6 months since injured) and 9 matched controls (21.3±1.9 years old) were recruited. Two surface EMG electrodes (Delsys Inc., USA) were attached to the middle belly of the lateral hamstring (LH) and medial hamstring (MH) on the injured leg and the matched leg. Three squat jumps (SJ) and countermovement jumps (CMJ) with maximum performance were performed on the force platforms. A 1D continuous wavelet transforms with the modulated Gaussian wavelet (Morlet) was used to analyse the EMG of the LH and MH during take-off (TO), Flight (FL), and landing (LD). Peak vertical ground reaction force during take-off and landing and loading rate (LR) were reported. Data were analysed in self-written code in MATLAB. A 2x2 repeated measures ANOVA was used to compare the differences between groups and jumps using the SPSS version 26 with the alpha level at 0.05.

RESULTS AND DISCUSSION

The injured group presented a lower mean frequency of both LH and MH in the TO ($p < 0.001$ and 0.049) and in the LD phases ($p < 0.001$ and 0.036; Table 1). In addition, the MH elicited greater activation in the CMJ than the SJ in the TO phase ($p = 0.015$). The statistical analysis of the kinetic outcomes demonstrated lower LD force ($p = 0.013$) and LR ($p = 0.018$) of the control group compared to the injured. While the CMJ could produce better TO force ($p < 0.001$) than the SJ (Figure 1).

In the discussion, a jump-landing activity requires a series of SSC components. Chronic hamstring strains contributed to a significant reduction in hamstring activation during the SSC movement. This deficit might be attributed to the deterioration of the stretch intensity and magnitude of the injured muscle leading to impairing the ability to store and utilization of elastic energy [2]. Also, decreased activation in the injured group may be associated with impaired stretch and tendon reflex of the prior hamstring injuries [3] leading to poor jumping and landing performance.

Table 1 Mean frequency of wavelet analysis of the LH and MH

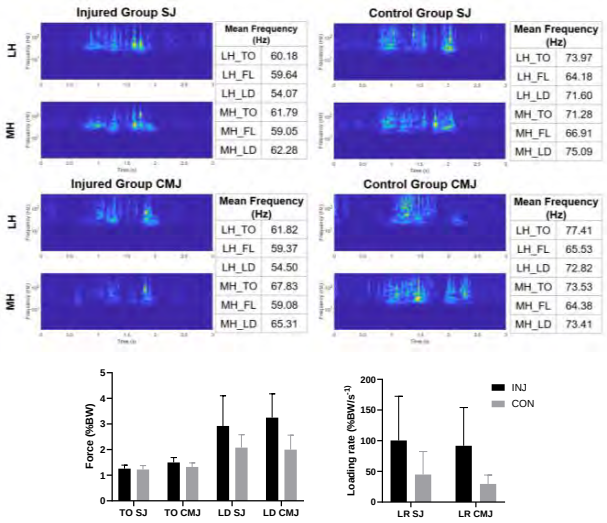

Figure 1 Kinetic outcomes of the SJ and CMJ

CONCLUSIONS

Athletes with prior hamstring strains displayed deficits in hamstring recruitment during the SJ and CMJ. The activation deficits influence the LD force and LR with no effects on the TO force. The findings could have a clinical implication that chronically injured athletes may need to resolve activation deficits in the SSC movement and the CMJ may be a useful tool to improve activation levels of the hamstrings.

THE RELATIONSHIP BETWEEN CENTER OF PRESSURE POSITION AND KNEE EXTENSOR MOMENT DURING DOUBLE-LEG SQUATTING

Tomoya Ishida[1], Ryo Ueno[1,2], Yu Kitamura[1], Yoshiki Yamakawa[1], Mina Samukawa[1] and Harukazu Tohyama[1]

INTRODUCTION

Although the double-leg squat is a common rehabilitation exercise for strengthening lower limb muscles, coordination of the knee extensor moment is required to avoid exacerbation of symptoms such as patellofemoral pain. Recently, real-time feedback of the center of pressure (COP) position has been reported to be useful in modifying the knee extensor moment during double-leg squatting [1]. However, the evidence is limited to a 6% change in knee extensor moment for a 10% difference in foot length of the COP position [1]. The purpose of this study was to compare the knee extensor moment among the anterior, mid, and posterior COP positions.

METHODS

Sixteen male participants (22.9 ± 0.4 years, 173.6 ± 5.0 cm, 63.0 ± 6.6 kg) performed double-leg squatting under the following four conditions: anterior COP, middle COP, posterior COP, and natural conditions. The COP position target was set at the ball of the foot for the anterior condition, at the 1st tarsometatarsal joint for the middle condition, and at the navicular tuberosity for the posterior condition. Real-time feedback on the COP position during squatting was provided with the box indicating the range of target COP ± 10% foot length except for natural condition [1]. Double-leg squat was recorded using an optical three-dimensional motion analysis system (Cortex 5.0.1, Motion Analysis, USA) with seven cameras and two force plates (Type 9286, Kistler AG, Switzerland). Internal lower limb joint moment was calculated by inverse dynamics (Visual3D 6, C-motion, USA) and normalized to body mass. In addition to the peak moment, the mean COP position and moment were calculated for the phase in which the knee was flexed more than 60° [2]. Repeated measures ANOVA was used to compare the variables among conditions ($\alpha < 0.05$).

RESULTS AND DISCUSSION

The mean COP position was significantly different between the conditions except for between the natural and posterior COP conditions (Table 1). The peak knee extension moment in the anterior COP condition was 15% smaller than in the natural and posterior COP conditions and 11% smaller than in the middle condition (all $p < 0.001$). Peak hip and ankle extension moments were greater in the anterior COP condition than in the other conditions (Figure 1). The mean moment results showed a similar trend of difference in the peak moment analysis (Table 1).

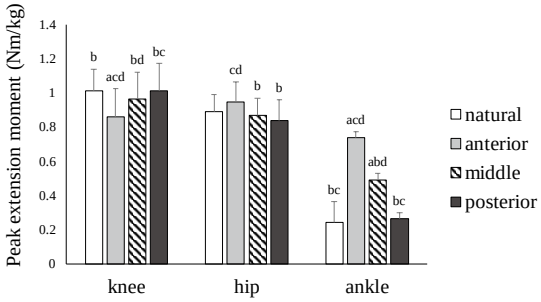

Figure 1. Comparisons of the peak extension moment aomong the four squatting conditions. Indexes indicate significant difference from natural (a), anterior (b), middle (c), and posterior conditions (d).

CONCLUSIONS

Real-time feedback of the COP position is useful for modifying the knee extensor moment, which can be increased or decreased by up to 15% of peak moment. To avoid an excessive patellofemoral loading, it may be useful to guide the COP anteriorly during double-leg squatting.

INTRODUCTION

Criteria-based rehabilitation and return-to-sport (RTS) decision-making critically depends on a therapist's ability to assess movement quality of challenging activities [1]. Several approaches have been developing in recent years, no least the AI-driven markerless motion capturing solutions. The reliability and validity of these systems has been assessed in gait [2], but not in dynamic tasks such as hops, jumps or side stepping. Hence, the aim of this study was to assess reliability of markerless lower extremity joint kinematics and kinetics of dynamic RTS evaluation tasks.

METHODS

A single-group repeated-measures study of 4 healthy subjects (26±5 years) was conducted, with 2 sessions separated by 5±2 days. Five trials of six commonly used RTS evaluation tasks (see listed in Table 1) were recorded using 7 video cameras (Miqus, Qualisys, SE) and two 90x60cm force plates (9287C, Kistler, CH) at 180Hz and 2700Hz, respectively. Theia3D (v2022.1.0.2309, Theia Markerless Inc., CA) was used to compute inverse kinematic 3D pose estimations during all tasks. Analog signals were low-pass filtered at 18Hz, and joint angles and internal moments computed, using Visual3D (v2022.10.2, C-motion Inc., US). For this study we focused on sagittal and frontal plane outcome variables. Pointwise Interclass Correlation Coefficient (ICC) and Standard Error of Measurement (SEM) were calculated in R, and integrated for the observed duration of the task [3]. Integrated ICC values of ≥0.75, 0.50-0.74, and <0.50 were classified as 'good', 'moderate', and 'poor' reliability, respectively. SEM% were calculated from integrated SEM relative to the observed range of motion (joint angles) or highest joint moment value (positive or negative).

RESULTS AND DISCUSSION

Three out of six dynamic tasks had all integrated ICCs ≥0.50, when not accounting for frontal ankle moments (Table 1). ICCs in the other three tasks showed relatively poor inter-session reliability. Joint angular displacements were generally more reliable than joint moments, and had more stable pointwise ICC profiles throughout the movement (example shown in Figure 1). Overall, SEM did not vary much across planes or joints, yet SEM% was lowest in the sagittal plane.

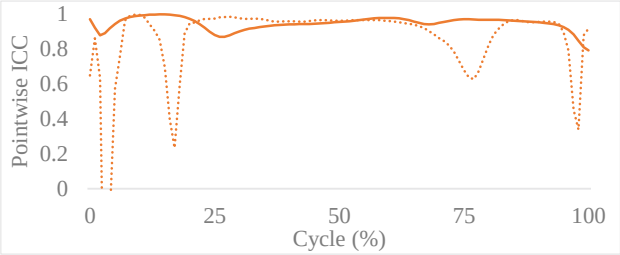

Figure 1 Pointwise ICC of sagittal knee angle (solid) and moment (dotted) in a crossover hop cycle (%) from initial contact to take-off.

CONCLUSIONS

Overall, joint kinematics were more reliable compared to joint kinetics, and the crossover hop and drop vertical jumps were more reliable than other tasks. The use of markerless motion capture for RTS evaluations shows considerable promise, yet further investigations, sample size expansions and/or developments are needed to overcome some joint or plane specific weaknesses.

INTRODUCTION

Knee osteoarthritis (OA) is a leading cause of disability worldwide. Because walking is recommended to manage symptoms, there is a critical need to develop treatment strategies that minimize the deleterious gait mechanics in adults with knee OA. Increasing cadence (i.e., number of steps taken per minute) may be a promising gait modification strategy because lower cadence is associated with higher knee joint loading [1] and risk of cartilage worsening [2]. In runners, increasing cadence reduces peak vertical ground reaction forces (vGRFs) [3]. However, it is unknown if cadence modifications during walking affect vGRFs in those with knee OA. The purpose of this study was to determine the effect of increasing walking cadence on impact loading in individuals with knee OA. It was hypothesized that the vertical impact peak and vertical load rates would be reduced with increasing cadence.

METHODS

22 participants with clinically defined knee OA were included (age = 61.8 ± 7.3; 81.8% female; BMI = 28.8 ± 6.6 kg/m^2). Baseline cadence was measured during a 5-minute walk at self-selected speed on an instrumented, split-belt treadmill. After the baseline condition, five experimental cadence conditions were completed in a random order. For each condition, participants were instructed to walk at 2%, 4%, 6%, 8%, or 10% over their baseline cadence for 2 minutes. A custom-written LabVIEW code was used to monitor and provide real-time visual feedback on cadence using GRF signals. Visual cues were supplemented with auditory cues from a metronome set to the target cadence. Participants were instructed to walk to the beat of the metronome, and to keep their cadence within ±1 step/minute of the target. GRFs were sampled (1200 Hz) for the duration of each condition. Measures of impact loading, i.e., vGRF impact peak (VIP), vertical average loading rate (VALR), and vertical instantaneous loading rate (VILR), were calculated for each step once the target cadence was met. Data were reduced by averaging the vGRF variables across 10 steps for each condition. A repeated measures analysis of covariance evaluated the effect of cadence on each vGRF variable while adjusting for gait speed.

RESULTS AND DISCUSSION

Preferred gait speed and baseline cadence ranged from 0.60 to 1.20 (mean ± SD = 0.87 ± 0.17) m/s and 83.6 to 124.0 (mean ± SD = 99.9 ± 11.8) steps/min, respectively. After adjusting for gait speed, there were no significant main effects of cadence on VIP (F=1.41, p=0.22), VALR (F=1.01, p=0.42), or VILR (F=1.61, p=0.16). Measures of impact loading did not reduce with increasing cadence as hypothesized; while insignificant, there was a gradual increase in these variables as cadence increased (Table). These increases may be partially attributed to the lack of time provided to learn a new motor pattern. Moreover, biofeedback via audible metronome may inadvertently stimulate participants to walk with punctuated steps, thereby increasing impact loading, though this was discouraged.

CONCLUSIONS

In adults with knee OA, increasing walking cadence by 2-10% at a constant speed has no immediate effect on impact loading when adjusting for gait speed. Future work may consider the effects of cadence modifications on more knee-specific measures of loading.

RELATIONSHIP BETWEEN COUNTERMOVEMENT JUMP AND FASTBALL VELOCITY IN ADOLESCENT BASEBALL PITCHERS

Hui-Wen Hsiao, Heng-Ju Lee
Department of Physical Education and Sport Sciences, National Taiwan Normal University, Taipei, Taiwan
Email: hjlee@ntnu.edu.tw

INTRODUCTION

Pitching performance in baseball requires transferring momentum from the lower extremity to the throwing arm. A significant and positive correlation was found between the lower extremity force output during the pitching cycle and pitching velocity, demonstrating the importance of lower limb strength in pitching [1]. Countermovement jump (CMJ) is one of the most common tests for assessing lower-limb strength. Previous studies have shown that lower-limb power performance during jump tests can predict pitching ball spinning velocity of professional baseball players [2]. However, most studies were focused on adult players, and more research needs to be conducted on the relationships between jump performance and baseball pitching performance among adolescent baseball pitchers. Therefore, this study aimed to determine the relationship between CMJ lower extremity power performance and fastball velocity and investigate the predictors of pitching velocity in adolescent baseball pitchers.

METHODS

A total of 18 teenage male baseball pitchers (age 14.1 ± 0.5 years; height 172.7 ± 6 cm; weight 67.5 ± 14.4 kg) from junior high school baseball teams participated in this study. They were asked to perform three CMJ and throw five fastballs on a custom-made pitching mound used for the indoor laboratory experiment after warm-up. CMJ tests were collected by a Kistler force plate (type 9260AA6, Kistler, Winterthur, Switzerland) with a sampling rate set at 2500 Hz. Ball velocity was measured with a pocket radar gun (Pocket Radar Ball Coach, PR1000-BC, Republic of South Korea). GRF data were smoothed using a Butterworth low-pass filter (4th Order Zero Lag) with a cut-off frequency of 12 Hz. CMJ's variables were collected and calculated from GRF data. Those data included braking force (BF), peak force (PF), braking rate of force development (RFD), braking impulse (BI), propulsive impulse (PI), peak power (PP), rate of power development (RPD), leg stiffness (LS), peak velocity, take off velocity, and jump height. We used the trial of CMJ data with the highest jump height and the average of the top three fastball velocities for the follow-up analysis. For Statistical analyses, the Pearson correlation coefficient examined the variable's relations with ball speed. Last, a stepwise multiple regression model determined the contribution of the overall CMJ variables that could predict fastball velocity in adolescent baseball pitchers.

RESULTS AND DISCUSSION

The 18 pitchers in the study had a mean fastball velocity of 111.85 ± 6.09 km/h. All variables normalized with weight show no significant associations. There are eight absolute forces-relate CMJ parameters with significant positive correlations between speed, including BF (r=.753, p<.001), PF (r=.638, p=.004), BI (r=.655, p=.003), PI (r=.62, p=.006), RFD (r=693, p=001), PP (r=548, p=.019), RPD (r=.672, p=.002), and LS (r=.689, p=.002)). We also discovered additional correlations between body height (r=.58, p=.012) and weight (r=.636, p=.005) with velocity. For the stepwise multiple regression analysis models, absolute BF (N) and body height (cm) combined to explain 62.5% of the variance in velocity (r=.818, p<.001). If only considered CMJ variables, absolute BF (N) can explain 54.1% of the variance (r=.753, p<.001). Researchers established a link between CMJ test performance and elbow injury risk in professional baseball pitchers, demonstrating the importance of the kinetic chain in pitching [3]. Pitchers with better CMJ power could likely transfer enough energy from the kinetic chain to improve their pitching performance and reduce injury risk. Other research using normalized CMJ variables found no significant relationships with ball velocity in professional players [2]. In contrast, our study showed that absolute strength might be more important than relative strength for adolescents, making body mass necessary in CMJ and pitching assessments.

CONCLUSIONS

Our study found that the CMJ's GRF variables and physical stature significantly correlate to pitchers' performance and would influence ball velocity among adolescent players. A pitcher with higher absolute braking force during CMJ and higher body height will have a greater chance to increase their fastball velocity. These characters can be a selection strategy for pitchers. Last, we recommend that pitchers in adolescence do lower limb strength training and gain lean body mass to enhance their potential fastball velocity.

INTRODUCTION

Wheelchair badminton is a recent sport that became a Paralympic discipline with the 2021 Tokyo games [1]. The peculiarity of this sport lies in the movements of the athletes which perform only successive forward and backward propulsion. Only four studies have investigated the differences between these two types of propulsion outside a sport setting [2-5]. However, backward propulsion modifies the kinematics of the propulsion of the athletes, which could thus act as a protective factor for the risk of injury [2][4]. However, these results relate to non-athletes and the results could differ in experienced athletes. Therefore, the objective of our study is to compare kinematics of forward and backward propulsion in experienced badminton athletes.

METHODS

18 French wheelchair badminton players (41.4±9.3 years; 64.9±11.1kg; 169.7±13.7cm) were recruited during the 2021 French Championships in Nueuil-les-Aubiers. The athletes did not have any injuries or pain affecting the propulsion of the wheelchair. They performed a consecutive forward and backward propulsion test for 1 min on a 3m straight line on a badminton court with a badminton racket. This test was created to reproduce the conditions encountered during the matches. The athletes used their own wheelchairs equipped with inertial measurement units (IMU) on the wheels. These tools allowed us to collect the following kinematic data: maximum first push velocity, maximum overall velocity, mean acceleration during the first push and mean deceleration from the last push. Fig. 1 illustrates the assessed variables.

RESULTS

Table 1: Comparison between backward and forward propulsion
*With * : $p < 0.01$, **: $p < 0.001$*

	Forward propulsion	Backward propulsion
	Mean (±sd)	**Mean (±sd)**
Maximum first push velocity (m/s)	4.57 (±0.69)	4.08 (±0.65)**
Maximum overall velocity (m/s)	3.47 (±0.71)	2.93 (±0.67)*
Mean acceleration (m/s^2)	6.08 (±1.60)	6.41 (±1.43)
Mean deceleration (m/s^2)	-10.19 (±4.26)	-9.52 (±3.45)

Significant differences between forward and backward propulsion were noted for all measured parameters.

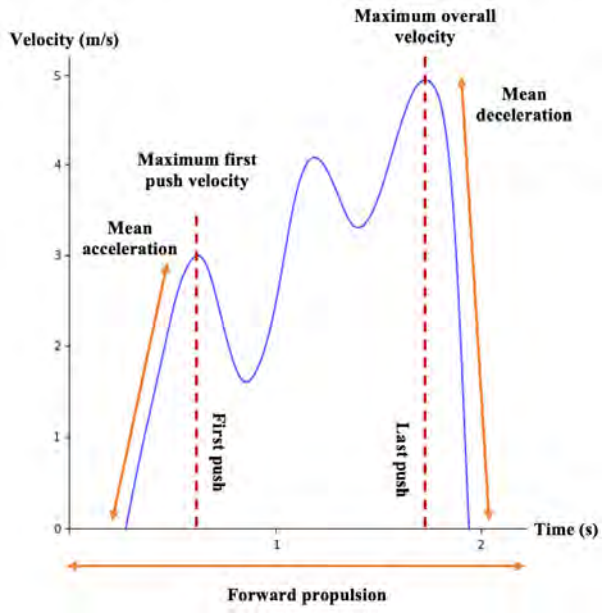

Fig 1: Propulsion velocity during forward propulsion

Maximum first push velocity, maximum overall velocity and mean deceleration were higher in forward propulsion than in backward propulsion, while **mean** acceleration was higher in backward propulsion *vs* forward propulsion.

CONCLUSION

The results are in the direction of a more efficient forward propulsion than backward. However, the mean acceleration is greater in backward propulsion without having a greater maximum first push and overall velocity. This may indicate that athletes have different propulsion kinematics depending on the chosen propulsion mode. These results are interesting for athletes and trainers who should promote training phases in backward propulsion and the transition from forward to backward propulsion to improve the performance of athletes.

INTRODUCTION

Mechanical power is an important performance determining factor in wheelchair sports. Recently, a method was proposed to estimate mean external power during hand rim wheelchair propulsion with data from inertial measurement units (IMUs) on the wheelchair [1]. With this method, mechanical power during wheelchair field sports can be estimated on court from power losses, i.e., rolling resistance (including internal resistance) and changes in kinetic energy. Although results show low errors when limited trunk motion was observed, power was significantly underestimated when considerable (within pushing cycle) variation in trunk inclination is involved during wheelchair propulsion. This under-estimation is due to a larger underestimation of rolling resistance caused by the trunk inclination-induced change in mass distribution between the front (castor) and rear wheels. Therefore, quantifying the dynamic relation between trunk inclination and mass distribution during wheelchair propulsion may improve power estimates. To that end, this study aims to estimate the mass distribution between the wheelchair's castor and rear wheels during hand rim wheelchair propulsion from IMU data with machine learning.

METHODS

In an experimental laboratory setup, 25 participants propelled a manual wheelchair on a large treadmill, with IMUs attached to their trunk (sternum), right wheel axle and wheelchair frame. Simultaneously, custom-made load pins in the castor wheel axes measured the instantaneous load on the castor wheels which was used as the gold standard. Subsequently, machine learning was applied to estimate the instantaneous load on the castor wheels from IMU data only, for which the best predictive set of IMU-based features and the best machine learning model were determined. The final model was evaluated by comparing the predicted with the observed load on the castor wheels. To ensure model robustness to different wheelchair and participant characteristics, the model was trained and tested on datasets with 0 kg, 5 kg and 15 kg of mass added at the seat or datasets in which the tire pressure of the rear tires was adapted to, respectively, 1.75, 3.5 and 5.25 bar. In addition, participants propelled the wheelchair using two different techniques: 1) while keeping the trunk static and 2) with full trunk motion. Of all data, the +5 kg data set of all participants, the 1.75 bar dataset of all participants and all six datasets of four participants were excluded in model training and were used to determine the accuracy of the final model. These 'excluded' data were referred to as test set.

RESULTS AND DISCUSSION

Results revealed that the best predictive feature set consisted of the linear velocity of the wheelchair, the linear acceleration of the wheelchair and the acceleration perpendicular to the sternum. Of the five machine learning models that were tested, a 'long short-term memory' (LSTM) model showed the most accurate predictions (see Figure 1). The mean absolute errors (MAE) for the wheelchair with no additional mass in the test set was 4.3±2.1%, with a root mean square error (RMSE) of 4.9±2.0% of the total mass, for the +5kg condition in the test set MAE was 3.0±1.4% and RMSE was 3.7±1.5% and for the 1.75 bar dataset in de test set MAE was 2.8±1.0% and RMSE was 3.7±1.4%. Similar results were found for the parts of the test set in which subjects were instructed to keep their trunk static compared with parts with full trunk motion.

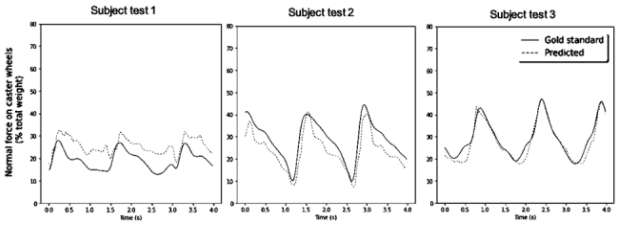

Figure 1 Results of LSTM model on test set with 0kg and 5.25 bar.

CONCLUSIONS

To conclude, instantaneous mass distribution between castor and rear wheels during hand rim wheelchair propulsion can be predicted relatively accurate from wheelchair and trunk-based IMU data. The machine learning model seems robust to different propulsion techniques, wheelchair and participant characteristics. When the predicted instantaneous castor load was used to calculate rolling resistance and, subsequently, power loss, a significantly better power estimation was found when compared with the power estimation based on 'non-varying' castor load. With the obtained model and input from IMUs on the wheelchair and trunk, mechanical power during wheelchair field sports can be estimated more accurately on the court.

INTRODUCTION

The number of panels on the surface of a regular soccer ball has decreased from canonical 32 (Telstar and Fevernova, 1970 World Cup in Mexico to the 2002 World Cup in Korea and Japan) to 14 panels (Teamgeist, 2006 World Cup in Germany) to eight panels (Jabulani, 2010), and lastly, to six panels (Brazuca and Telstar18, 2014 and 2018). Moreover, during the UEFA Euro 2008, the Europass ball that was introduced had a prestressed concrete (PSC) creeps surface design; this ball was evidently rough due to the presence of various protrusions, such as squares, triangles, and hexagons [1]. As such, previous studies have reported on the effects of these changes in the ball's aerodynamic properties and flight trajectory [2]. studies have been conducted to evaluate and assess the changes on aerodynamic characteristics and flight properties due to the changes in the panel orientation that are attributed to the reduced number of panels. In this study, we created soccer balls (32-panels) with various surface shapes (differing dimple structures) using the same material (polyamide-12) using a 3D printer. After fabricating four types of soccer balls with different surface dimple shapes, we compared their aerodynamic characteristics in wind tunnel experiments along with an analysis of their flight trajectories. Further, we analyzed the effects of ball shapes on aerodynamics under constant conditions.

METHODS

In this experiment, we have fabricated soccer balls (with a diameter of 220 mm, 32 panels) from the same material (polyamide-12) on a 3D printer (HP Jet Fusion 3D 4200, HP), and the surfaces of the balls were coated with graphite. The weight of each soccer ball was set at approximately 450 g, which is similar to that of a regular soccer ball. The depth and width of the seams on the ball surface were manufactured at 2 and 1 mm, respectively. Furthermore, we have created the designs of the fabricated soccer balls using 3D CAD software (Autodesk Inventor Professional 2020, Autodesk Inc.). The wind tunnel experiment was conducted on the manufactured soccer balls. In this experiment, the wind speed (U) was set from 7 to 30 m/s, taking two measurements at 1 m/s intervals.

RESULTS AND DISCUSSION

The graphs below show the effects of various dimple shapes on aerodynamic properties of balls and show the correlation between four balls: smooth type, conical type, hemispherical type, and cylindrical type. These four soccer balls have the same seam structure, but each type has a different dimple structure. First, Figure 1A shows the correlation between the supercritical Reynolds number (Re_{crit}) and the proportion of dimples on the surface of the balls (ΣAd/Ab), and an extremely high correlation (R^2=0.91). Figure 2B shows the correlation between the supercritical Reynolds number of each of the four soccer balls and the proportion of the area of dimples and seams on the surfaces of the balls (ΣAd+ As/Ab), with an even higher correlation (R^2=0.92). These results suggest that the shape of the soccer ball surface, particularly the proportion of the dimple surface area, has a significant effect on soccer ball drag, including the ball's supercritical Reynolds number.

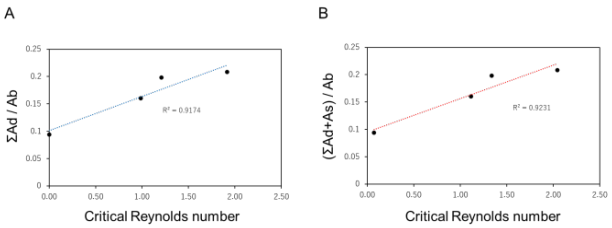

Figure 1 Correlation between the supercritical Reynolds number and dimple shape on the ball' surface of the soccer balls. A is the correlation between Re_{crit} and the dimple ratio (ΣAd/Ab), while B is the correlation between Re_{crit} and the dimple and seam ratio (ΣAd +As/ Ab).

CONCLUSIONS

In this study, we investigated the effects of the surface shape of soccer balls, which includes the dimple structure, that were fabricated using a 3D printer on their aerodynamic characteristics. The results demonstrate that the dimple structure characteristics on the surface of the soccer ball were strongly related to the aerodynamic forces applied to the soccer ball. Moreover, the shape and number of panels of the ball as well as the shape of the ball's surface are important factors in determining its aerodynamic characteristics.

THE LARGEST SEGMENTAL COMPONENTS OF ENERGY DIRECTLY CONTRIBUTING TO HEIGHT DO NOT EXPLAIN THE VARIANCE OF ITS TOTAL IN THE HIGH JUMP.

INTRODUCTION

The High Jump (HJ) is the most height-specific jumping mode for humans. Jumping higher means increasing the mechanical energy directly contributing to the centre of mass height (E_{vert}, the sum of vertical kinetic and gravitational potential energies) during take-off. E_{vert} in HJ is mainly induced by the stance-leg thigh and shank rotations [1]. The largest components are derived from the energy inflow to the segment due to proximal and distal joint work (thigh only) and from the conversion of horizontal kinetic energy (E_{horiz}) into E_{vert} (in thigh and shank) [2]. The curved approach further facilitates this conversion in HJ by altering the initial posture [1]. Meanwhile, from a performance perspective, jumpers can increase E_{vert} by increasing the components of the small contributors and/or decreasing the inhibition of the negative contributors, too. Thus, not only large but also small E_{vert} contributors can be related to the variance of the overall increase in E_{vert}. Here we show the discrepancy between the segment that generates the most E_{vert} and the segment that alone explains well the variance of the total E_{vert}.

METHODS

We analysed the kinematic and ground reaction force data of 16 male jumpers [22.3 ± 3.1 years, 1.801 ± 0.060 m, 66.60 ± 5.90 kg, personal and season best (PB, SB): 1.90–2.35 m, 1.80–2.30 m] who performed HJ with maximum effort with the bar set at 90% of each SB. We decomposed the change in E_{vert} during take-off into segmental components [2]. We used a simple regression to examine whether the E_{vert} component due to segment rotations explained the inter-individual variance of the total increase in E_{vert}. Prior to regression, we removed an outlier in the total increase in E_{vert} based on three times the median absolute deviation.

RESULTS AND DISCUSSION

The stance-leg thigh (4.20 ± 0.84 J/kg) and shank (3.93 ± 0.88 J/kg) rotations contributed the most to total E_{vert} (11.59 ± 0.81 J/kg); however, their variance alone did not explain the variance of total E_{vert} (Fig. 1B). Meanwhile, the variance of stance-leg foot and thoracic components significantly explained the variance of total E_{vert} (Fig. 1B). This supported our hypothesis. The thoracic and foot components are derived from the work of the thoraco-lumbar lateral flexors and ankle plantar flexors. Despite their relatively small E_{vert} inductions (Fig. 1A), we suggest their importance for performance.

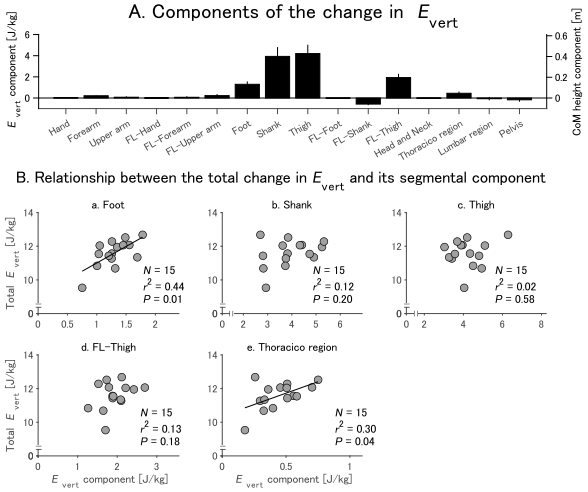

Figure 1 Segmental components of the change in E_{vert} (A) and their relationships to total change in E_{vert} (B) during the take-off.

E_{vert} components due to the stance-leg thigh and shank were negatively correlated (r^2 = 0.60, P < 0.01), and their sum was correlated with the total E_{vert} (r^2 = 0.57, P < 0.01). This suggests the existence of multiple strategies relating to the thigh and shank E_{vert} inductions to jump high in HJ. The shank component is only due to the conversion from E_{horiz} to E_{vert} while the thigh component invovles both the energy conversion and the energy inflow by the hip and knee work [2]. The knee exibits power pattern of absorption followed by generation, implying a strech-shortening action [2]. We suggest that the mechanical properties of knee extensors may be related to individual differences in jumping strategies, rather than the performance *per se*.

CONCLUSIONS

The variance of the largest E_{vert} components due to the thigh and shank does not explain well the inter-individual variance of the total increase in E_{vert}, whereas the variance of the thoracic and foot components each explain it. This suggests that larger components are not necessarily strong determinants of the performance variance. The thigh and shank results further suggest the existence of multiple strategies for jumping higher in HJ.

HAMSTRING MUSCLE KINEMATICS AND ACTIVATION DURING THE ACCELERATION PHASE IN SPRINTING OF SOCCER PLAYERS

Van Thiet Le[1], Yudai Kikuchi[1], Masayoshi Kubo[1]
[1] Department of Physical Therapy, Niigata University of Health and Welfare, Niigata, Japan.
Email: hwd22014@nuhw.ac.jp

INTRODUCTION

Hamstring strain injuries are the most common muscle injury in soccer that directly affects the performance of soccer players and the result of clubs. Sprinting was reported as the most common activity involving hamstring strain injuries. To define hamstring strain injury mechanisms, the hamstring kinematics and activation were investigated to predict the potential injury. However, the hamstring kinematics and activation in the acceleration phase of sprinting have not been clear, although this phase is crucial for sprinting performance. Therefore, the purpose of this study was to characterize the hamstring muscle kinematics and activation during the acceleration phase of sprinting in soccer players to define the potential hamstring strain injury mechanism.

METHODS

Ten male participants with no history of lower limb injuries in one recent year were recruited. The participant gave their written consent to participate. This study conformed to the recommendations of the Declaration of Helsinki and has been approved by the University Ethics Committee at Niigata University of Health and Welfare. Each participant was required to take at least three successful 15 m sprints. Full-body kinematics during the acceleration and the maximum-speed phases in sprinting of each participant was collected. The acceleration phase was defined as the three first steps. A full-body musculoskeletal model was used to make simulations based on the marker data from the experiment in the Opensim. Hamstring muscle kinematics was estimated based on the model's kinematics in simulations. Hamstring muscle activation was recorded using wireless electromyography. The raw EMG data were rectified before filtering to estimate linear envelope EMG data. We just analyzed three biarticular muscles of the hamstring.

RESULTS AND DISCUSSION

In the acceleration phase, the muscle length of all biarticular hamstring muscles was lengthened during the second half of the swing and the first half of the stance of the running gait cycle. The peak strain of biarticular hamstring muscles was reached at around 90 % of the running gait cycle. The biceps femoris long head was undergone significantly greater strain than two other hamstring muscles ($p<0.01$), with the peak strain approximately 10.4 ± 1.73 %, 8.35 ± 1.79 %, and 7.46 ± 1.65 % respectively at the late swing of the running gait cycle (Fig.1). This result contributed to the explanation of the higher rate of occurred injuries in the biceps femoris long head than in the semimembranosus and semitendinosus. The biarticular hamstring muscles were shortened during the stance, the first one-third and the last 10 % of the swing, while the positive elongation velocity occurred at approximately 60 to 90 % of the swing. Furthermore, the muscle activation of the biceps femoris long head and semitendinosus reached the highest point at approximately 90 % and the second peak at the foot-strike of the running gait cycle. In combination, the biarticular hamstring muscles undergo eccentric contraction and a high activation level on the late swing and initial stance.

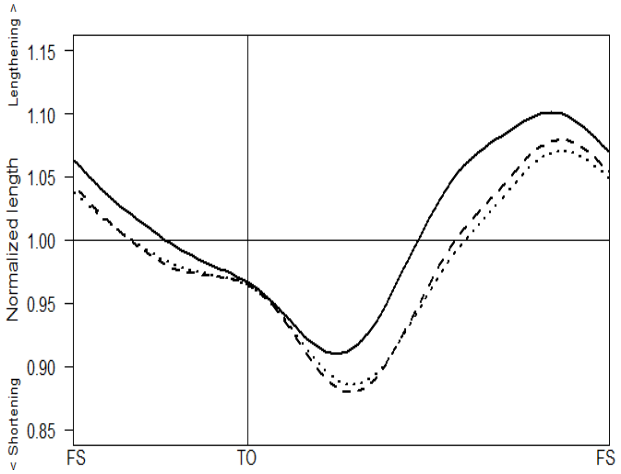

Figure 1 Biarticular hamstring muscle length during the running gait cycle in sprinting acceleration phase. The solid line (Biceps femoris long-head) dashed line (Semitendinosus), dotted line (Semimembranosus), TO (Toe-off), and FS (Foot-strike).

CONCLUSIONS

In conclusion, the mechanisms of potential hamstring injuries occurred at the late swing and foot-strike of the running gait cycle in the sprinting acceleration phase. The biceps femoris long head might be more susceptible to injuries than other hamstring muscles. The acceleration phase in sprinting should be gotten more attention to prevent hamstring strain in soccer players' sprinting.

INTRODUCTION

Knowledge about the interaction of anthropometry and kinematics contributes to success in javelin throwing [1] and is important for sport scientists and coaches to assess performance determinants and adjust training regimes. The purpose of this study was to investigate the relationship of anthropometry and kinematics with javelin performance and to predict throwing distance based of anthropometric and kinematic parameters.

METHODS

Fifty javelin throwers (28 males and 22 females, age: 18-44 years) participated in this cross-sectional correlation study. Anthropometric data were collected via the direct standard anthropometric protocol [2]. During the 20th National Sports Festival, kinematic variables were obtained using two Vicon MX cameras at a sampling frequency of 200 Hz (Peak Performance Technologies, Inc., Oxford, UK) and the 2D kinematic video graphic technique. Paired sample t-test and multiple regression analysis were conducted via SPSS 23 (SPSS Inc. Chicago, IL) at a significance level of $p<0.05$.

RESULTS AND DISCUSSION

Differences in throwing distance (d=1.38, $p<0.001$) as well as in multiple anthropometric (d=0.864–2.252, $p<0.05$) and kinematic characteristics (d=0.704–1.115, $p<0.05$) between sexes suggested sex-specific analyses. Sex-specific correlation results can be found in Table 1. The 'stepwise forward' regression model for females achieved adjusted R^2=0.461, p=0.035 based on angle of trunk and body height. The model for males was based on chest girth and ankle angle (adjusted R^2=0.490, p=0.006). A model across sexes included sex, attitude angle, and arm girth as predictor criteria (adjusted R^2=0.549, p=0.012).

Table 1: Correlation of anthropometric and kinematic parameters with the javelin throwing distance.

Parameters	Male		Female	
	r	*p*	*r*	*p*
Age (years)	0.155	0.432	-0.049	0.829
Weight (kg)	0.344	0.073	**0.497**	**0.019**

INTRODUCTION

In competitive combat sports like boxing, boxer's performance evaluations, including the punch amount and its type, are a valuable source of data for coaching and performance improvement. Studies have shown that the use of machine learning (ML) techniques with IMU sensor data can accurately classify boxer's punch types, such as jab, hook, and uppercut [1]. However, to effectively evaluate the athlete's punch performance, it is crucial to classify the punch range. The ideal position for a boxer to engage in punching is when the weight of the athlete is evenly balanced over both legs, allowing for the body to rotate around a central axis. To achieve this position on engagement the boxer has to move their feet into range or distance, giving them the opportunity to punch. There are 3 main classifications of range, long, mid, and close. Punches will vary at these different ranges. At long range, most punches are straight with full extension of the arm. At mid and short range most punches will have a bend at the elbow and are termed as hooks or uppercuts. Therefore, in this work, we classify boxers' punch type and punch range using various ML techniques fed with IMU sensor data [2].

METHODS

We collected IMU sensor data (accelerometer and gyroscope; 200 Hz) and time-synchronized video recordings from eight elite boxers from the Inspire Institute of Sports (IIS), Karnataka, India. The boxers performed 320 punches for each of the 14 different punches, such as long-range lead jab, mid-range lead jab, long-range rear hook, etc. First, we performed time-frequency analysis of the IMU sensor data for each punch type to obtain Spatio-temporal features such as power spectral density in various frequency bands. Next, we employ several supervised ML techniques such as decision tree (Fine and coarse), random forest, linear discriminant, and quadratic discriminant to classify the punch type and punch range. The ground truth was obtained from the recorded video by visual inspection. Finally, we compared the accuracy obtained across these ML techniques.

RESULTS AND DISCUSSION

Initial results are demonstrated for classifying four different punch types and punch ranges (no punch, long-range rear jab to the head, mid-range rear hook to the head, and mid-range rear uppercut to the head). Fig. 1 shows the accelerometer data for different punch types. The classification result using various ML techniques is reported in Table 1. It can be seen that the random forest is more accurate than the other algorithms (96.5%). The confusion matrix revealed that all four punch types are classified accurately, except for the no punch and rear hook punch, where few instances are misclassified (Fig. 2).

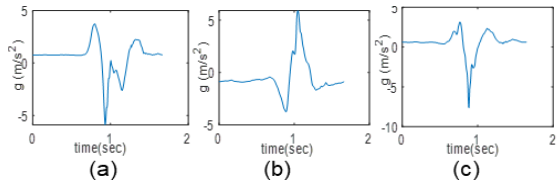

Figure 1. Accelerometer plot; (a) Jab (b) Hook (c) Uppercut

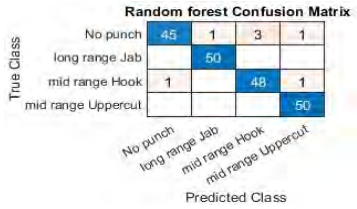

Figure 2. Confusion Matrix

CONCLUSION

The current study uses machine learning techniques to classify boxers' punch type and punch range using IMU sensor data. These classifications are important for improving the boxer's performance in aspects such as offense, defense, and overall control of the match. The results showed that the random forest algorithm performed better than other classification methods. Our future work aims to expand the algorithm to cover all 14 types of punches, their ranges, and to incorporate punch force in the classification. The ultimate goal is to create an IoT (internet of things) platform to aid coaches in evaluating athletes' performance remotely.

A SYSTEMATIC REVIEW AND EVALUATION OF OPEN-SOURCE TRANSTIBIAL AMPUTEE MUSCULOSKELETAL MODELS FOR USE ON FEMALE POPULATIONS

Misha Hasan[1], Tess M.R. Carswell[1], and Joshua W. Giles[1]
[1] Department of Mechanical Engineering, University of Victoria, Victoria, B.C., Canada.
Email: tmrc@uvic.ca

INTRODUCTION

Transtibial amputees (TTAs) have become a population of interest in the computational musculoskeletal (MSk) modeling community [1]. Most studies use a generic MSk model linearly scaled to match the subject's anthropometrics [2]. Despite their prevalence, generic models can neglect innate variations between distinct groups. For example, while sex differences exist in MSk geometry and musculotendon parameters [3], most generic models were developed using predominantly male data [4,5], affecting their validity to study female populations. Therefore, when choosing a model, it is important researchers are aware of the data used to develop and validate it. This work presents a systematic review of existing open-source TTA models, aiming to help guide researchers when choosing an MSk model. Existing models were also evaluated to determine the model most representative and capable of reproducing female TTA biomechanics. This model will be used in future work studying sex differences in amputees.

METHODS

A systematic search of 10 key terms was performed on three online databases (PubMed, Scopus, Web of Science). Eligible studies were retained for review if they presented an open-source, 3D, human MSk model representing a TTA with a generic non-osseointegrated (OI) prosthetic. A database was created based on data detailing the development and validation of the eligible models. The database was then used to evaluate the models on their capability of representing female TTAs based on predefined weighted criteria (Table 1) with scoring scales. Criterion 1 assesses how representative the model development data are of female TTAs. Criterion 2 determines how comprehensive the model's validation was as defined by the MSk Modelling Grand Challenge [6]. Criteria 3 and 5 assess the functionality and motions the model and its prosthesis can accommodate. Criterion 4 evaluates how transparent the model development process was in each study.

RESULTS AND DISCUSSION

The systematic search yielded 352 results. Upon consideration against eligibility criteria, three studies remained: LaPrè et al., Willson et al., and Miller & Esposito [1,7,8]. The database created compiles data for the three models, providing a detailed account of how and with what data each was developed and validated. However, through further investigation of the Miller & Esposito model, it was found to represent an OI prosthetic, making it ineligible for further analyses. Upon evaluation of the two remaining models, the Willson model scored higher against all criteria except Criterion 5. For this criterion, the LaPrè model was able to accommodate more motions than that of the Willson.

CONCLUSIONS

This work presents a systematic review and evaluation of existing open-source TTA models. Data on three models was compiled into a database resource for researchers in future modeling studies. Upon evaluating eligible models, the Willson model was determined the most representative and capable of reproducing female TTA biomechanics. This model will be used in future work studying sex differences in amputees.

COMPLETE 3D KINEMATICS PARAMETERS OF THE TEMPORO-MANDIBULAR JOINTS USING IN VIVO DATA FUSION

Gaël Bescond[1], R. Glineur [1,2], V. Sholukha [1], S. Van Sint Jan [1].
[1] Laboratory of Anatomy, Biomechanics and Organogenesis (LABO), Université Libre de Bruxelles, Belgium.

INTRODUCTION

The temporo-mandibular joint (TMJ) has implications in vital functions and its disorder prevalence is between 5% and 12% [1]. Quantitative motion analysis tools are of interest to better understand normal and abnormal TMJ behavior. The mandible shows morphologic and kinematic particularities: its motions rely on two joints where mandibular condyles are generally asymmetric and highly individual [2], they rotate during jaw opening and closing and translate vertically and anteroposteriorly [3]. Thus, we describe the detailed kinematic behavior of the TMJs through a 3D model, gathering the kinematic parameters contributing to the global movements of the mandible compared to the skull, as well as the local movements of the 2 condyles compared to their sockets and instantaneous helical axis analysis.

METHODS

Five healthy subjects fitted with a tailor-made dental cluster and a head cluster performed 10 mouth opening and closing cycles, 10 diductions and chewed for 20 seconds on a cork. An experimenter palpated with the A-Palp [4] 15 anatomical landmarks (ALs) on their skull and their mandible. The trajectory of the markers and ALs was recorded by opto-electronic cameras and stored in C3D files. Magnetic resonance imaging from the 5 subjects was processed through a segmentation procedure (Amira®) to obtain 3D models, imported into the lhpFusionBox, which is musculo-skeletal data processing software developed at ULB [5]. Virtual palpation was used to locate specific ALs and to build coordinate systems following the ISB recommendations [6]: a Jaw Global Frame (JGF) associated to a Skull Global Frame (SGF); a distal Right or Left Jaw Local Frame (RJLF, LJLF) associated to a Right or Left Skull Local Frame (RSLF, LSLF) (Fig.1). We then fused the ALs coordinates with the C3D motion files and the morphological model.

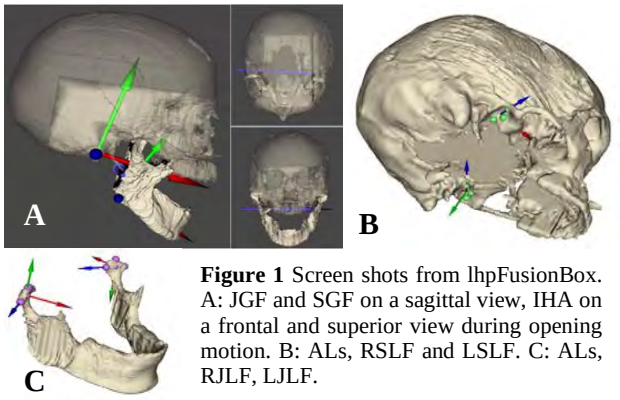

Figure 1 Screen shots from lhpFusionBox. A: JGF and SGF on a sagittal view, IHA on a frontal and superior view during opening motion. B: ALs, RSLF and LSLF. C: ALs, RJLF, LJLF.

RESULTS AND DISCUSSION

Motion cycles were normalized from 1 to 100% of rotations and translations duration in JGF and in the RJLF/LJLF, instantaneous helical axis (IHA) parameters (direction cosines, IHA rotation center coordinates, IHA rotations and translations) were computed for the 3 motions. The fusion residual error (Median RMSE = 8.0 mm) and data (Fig. 2) shows that our model is accurate enough and consistent with previous studies [7].

CONCLUSIONS

By providing complete 3D TMJ kinematics parameters, we hope to contribute to the development of engineers'own model. Also, the calculation of the IHA was made considering further anatomical studies including masticatory muscular lever arms.

MUSCLE CONTRIBUTIONS TO THE BARBELL BACK SQUAT IN TRAINED FEMALES

William Goodman [1], Eric Helms[2], and David Graham [1]
[1] College of Education Health and Human Development, Montana State University, Bozeman, USA.
[2] Sports Performance Research Institute New Zealand, Auckland University of Technology, Auckland, NZ.
Email: wes@likeironstrong.com

INTRODUCTION

The barbell squat is used to enhance athletic performance and rehabilitate the lower body. Several studies describe muscle function during the squat [1,2] but in general most investigations to date ignore the ability of muscle forces to accelerate all joints, limb segments and the whole-body centre of mass (CoM) simultaneously [3]. The purpose of this study was to determine how lower extremity muscles contribute to the vertical acceleration of the CoM and to the flexion and extension accelerations of the ankle, knee and hip when squatting to parallel using 85% 1RM.

METHODS

Thirteen female participants with 6.00 ± 3.65 years of squatting experience completed the study. Participants completed 3 repetitions of the barbell squat at 85% of 1 repetition maximum to a depth where the thighs were parallel to the ground. Trajectories of 65 reflective markers attached to each participant and ground reaction forces under each foot were recorded simultaneously. Data analyses were performed using OpenSim (version 4.0). Muscle forces were estimated using static optimisation and the induced analysis algorithm was used to estimate each muscle's contribution to accelerations of the CoM and lower limb joints. Models were evaluated to ensure possible sources of error were within recommended tolerances [4].

RESULTS AND DISCUSSION

The soleus, vasti, gastrocnemius and gluteus maximus generated the largest upward accelerations of the CoM while the muscles that produced the largest downward acceleration about the CoM were the hamstrings, tibialis anterior, adductors and iliopsoas (Table 1). The muscles responsible for knee and hip extension acceleration were the vasti, adductors, hamstrings, and gluteus maximus while the muscle primarily responsible for knee and hip flexion acceleration was the soleus. The muscles responsible for ankle dorsiflexion acceleration were the vasti, adductors, hamstrings, and gluteus maximus. The main muscle responsible for plantar flexion acceleration was the soleus.

CONCLUSIONS

Overall, our findings indicate that during the squat exercise the muscles of the lower limb perform multiple roles to accelerate the joint they span, joints they do not span, and the CoM simultaneously. In some cases, biarticular muscles accelerated a joint opposite of its moment production. For example, the hamstrings produced a flexion moment at the knee but accelerated the knee into extension. These results corroborate prior findings [5] and demonstrate that considering only the anatomical function of a muscle may result in an incomplete assessment of a muscle's role [3,5]. Most importantly, a muscle's function is task specific, as it depends on both joint position and how an individual interacts with the environment, and this should be considered when prescribing compound exercises such as the barbell squat.

INTRODUCTION

Musculoskeletal modelling (MSKM) represents a powerful tool to assess internal body loads in a non-invasive manner, yet its use in product design and surgical planning is limited, mostly due to a lack of extensive validation. The CAMS-knee dataset [1], comprising kinematic and kinetic data from 6 subjects with instrumented total knee replacements during different activities of daily living (ADLs), represents the gold standard for MSKM validation. The aim of this study was to compare predicted knee contact forces (KCFs) against *in vivo* measurements across different ADLs, including level and downhill walking, stair descent, squatting, sitting, and rising from a chair.

METHODS

Motion capture data from the CAMS-knee dataset were used as input for an inverse dynamics analysis in the AnyBody Modeling System (AnyBody Technology A/S). The generic TLEM 2.1 lower-limb model [2] was scaled to match each subject's anthropometrics. The knee was modelled as a hinge joint and the muscles as Hill-type actuators. A muscle-volume-weighted 3rd-order polynomial criterion was used to solve the muscle recruitment problem [3]. Muscle contributions to the net joint moments and KCFs were computed to identify muscle-related errors, revealing necessary refinements in muscles' geometry [2]. KCFs were computed in an implant-based reference frame, derived from subject-specific implantation data from radiographic imaging, and normalized to body weight (BW). For each subject, five trials per ADL were analysed. Average root mean square error (RMSE) and coefficient of determination R^2 between predicted and measured KCF magnitudes were computed across trials for each subject and ADL.

RESULTS AND DISCUSSION

The gastrocnemii contributed to a large overprediction of KCFs during the push-off phase of downhill walking and stair descent, when the ankle is dorsiflexed and a large net plantar-flexion moment is required. The introduction of an anatomically realistic wrapping of the Achilles tendon around calcaneus and ankle shifted the plantar-flexing demand from the gastrocnemii to the soleus, reducing the error in the predicted KCFs. Following this refinement, the mean predicted KCF magnitudes showed good qualitative agreement with the measured data across all ADLs (Figure 1), although some variability between subjects persisted (Table 1).

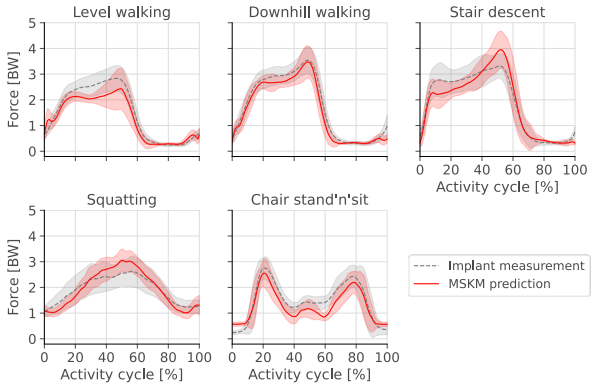

Figure 1 Mean (± SD) predicted (solid red) and measured (dashed grey) KCF magnitude for each ADL across all subjects.

CONCLUSIONS

The current study represents the most extensive MSKM quantitative validation for the prediction of knee loading to date. A strategy to identify errors associated with muscle geometry has been proposed, leading to the refinement of the Achilles tendon wrapping in the TLEM 2.1 model. The analysis of different ADLs enables to test MSK models across larger ranges of joint motion, revealing potential issues which may not be apparent when modelling level walking alone. The established validation framework will serve as a meaningful benchmark for future adaptations and improvements of both generic and personalized models.

INTRODUCTION

Understanding how bone responds to mechanical loading is fundamental for the development of new biomechanical treatments for musculoskeletal diseases [1,2]. Ovariectomy (OVX) is an accepted model for osteoporosis in mice. The *in vivo* tibial loading model is used to investigate the effect of passive mechanical loading on the mouse tibia [1,3]. While a nominal axial load is applied to the tibia through the knee and the ankle joints, the real loading direction in the experimental setup may induce out-of-axis loads on the tibia. These loads may dramatically alter the local strain distributions which affect the bone remodelling [4]. The aim of this study was to evaluate the effect of the loading direction on the predicted local mechanical properties of the tibia in the ovariectomised mouse model.

METHODS

Five female C57BL/6 mice were ovariectomised at week 14 of age. At weeks 18 and 20, the right tibiae were scanned using *in vivo* micro-computed tomography (micro-CT; 10.4µm/voxel). This data was acquired from a previous study [1].

Previously validated micro-CT based finite element models were generated from the segmented images (hexahedral elements; isotropic linear elastic material properties) for the mice at weeks 18 and 20 [5]. Three independent unitary loads cases were applied along the axial, medio-lateral or anterior-posterior direction for each mouse at each timepoint. The principal strains, principal stresses and strain energy density (SED) were recorded at the Gauss points.

A 12N axial load was applied to the finite element models using scaling and the superimposition of the effects to model the typical load applied in the *in vivo* tibial loading model.

The local properties for the different loading directions were calculated as a function of the angle from the inferior-superior axis (θ, 0-30° range, 5° steps), and the angle from the posterior-anterior axis (ϕ, 0°: anterior axis, positive anticlockwise, 0-355° range, 5° steps) (Figure 1).

RESULTS AND DISCUSSION

SED distributions were more sensitive to a change in θ compared to a change in ϕ at both timepoints (Figure 1). More values of lower SED were found for different loading directions at week 20 when compared against week 18, highlighting the importance of considering bone growth in the OVX mouse model. Differences in the variability between week 18 and 20 SED values may be due to the mice responding differently to the OVX.

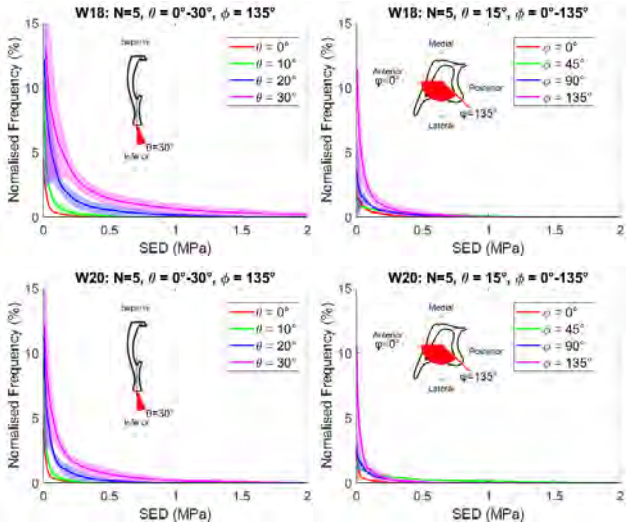

Figure 1 Frequency plots showing the mean and standard deviation for the SED for the group of five mice (N=5) for different loading directions with a 12N axial load, for (left) varying θ and fixed ϕ, (right) varying ϕ and fixed θ, (top) mice at week 18 of age, (bottom) mice at week 20 of age.

CONCLUSIONS

These results suggest that in studies which use the *in vivo* tibial loading model, repositioning of the tibia in the loading device may impact the distribution of local deformation and therefore of bone remodelling [3], and thus should be better controlled during the experiment.

INTRODUCTION

Abnormal knee mechanics is thought to be involved in the causal mechanisms that initiate and progress musculoskeletal (MSK) diseases, such as knee osteoarthritis. Multiscale musculoskeletal finite element (MSK-FE) models show promise in estimating personalized knee mechanics involved in these tissue degradation processes. However, creating such personalized models is cumbersome, with no automated methods existing. We developed and tested a fully automated tool to create personalized MSK-FE knee models with bones, cartilage, menisci, and ligaments.

METHODS

A 3D-nnUNet [1] network was trained using a total of 667 labeled knee MRIs [2,3] to auto-segment femoral, tibial, and patellar cartilages as well as bones, menisci, anterior and posterior cruciate ligaments, and patellar and quadriceps tendons (0.98≥DICE similarity coefficient≥0.82). A personalized MSK model was generated using auto-segmented geometries (Figure 1) and consisted of 12 degrees-of-freedom knee with elastic foundation tibiofemoral and patellofemoral contacts, and ligaments represented as non-linear springs [4]. Last, a modified hexahedral meshing algorithm [5] was used to create and then assemble personalized knee cartilage and menisci meshes. Depth-dependent fibril-reinforced material models with swelling were automatically assigned to cartilages and menisci [6]. Tool robustness (i.e., segmentation, models' assembly, and meshing) was investigated by creating 2,650 left and right knee MSK-FE models from datasets different than the training set. Using subject-specific motion data and MRIs, here we present one gait trial modeled using 1) the automated tool, 2) manual segmentation and meshing, assumed the gold standard, and 3) a previously developed atlas-based method [7].

RESULTS AND DISCUSSION

Creating one MSK-FE model from raw MRI took <6 minutes (single core, <4 GB VRAM). For tibial cartilage's maximum tensile stress during a gait cycle, root-mean-square-error between the manual and automated methods was 1.9 MPa, better than the 4.3 MPa between the manual and atlas-based methods.

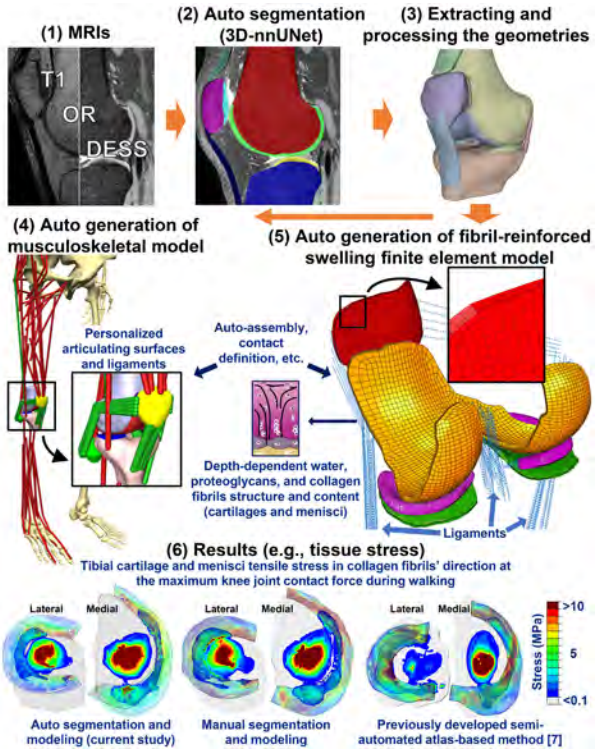

Figure 1. Illustration of the pipeline, created models, and results.

CONCLUSIONS

We presented a fully automated and robust tool for MSK-FE modeling of the knee. The tool provided more accurate modeling compared to the previous atlas-based method and was fast enough to enable the investigation of knee tissue mechanics in large cohorts and different functional activities.

INTRODUCTION

Parkinson's disease (PD) is one of the neurodegenerative diseases, and the cause is still unclear, so it is difficult to diagnose early, subjective diagnosis of severity according to degeneration of motor symptoms and disease progression, and objective and quantitative indicators for disease progression evaluation are insufficient. A classification modeling approach using visual images (Convolutional Neural Network, CNN algorithm) converted from time-series gait data will improve the accuracy of disease severity discrimination according to identifying more symptom-affected body segments in PD patients.

METHODS

The subjects of this study were each 30 PD patients with and without freezing of gait (freezers and non-freezers) and 30 healthy control group (controls) of the same age. PD patients performed the 360° turning tasks in the direction of the more affected side at the preferred speed in an off state of medication. Position and acceleration data of 40 body segments marker trajectories, including the center of mass, were used to analyze the time-series data of the turning phase. These position and acceleration time-series data were converted into new imaging and trained with a CNN algorithm technique (Figure 1). The performance of the three-group classification model was evaluated using accuracy.

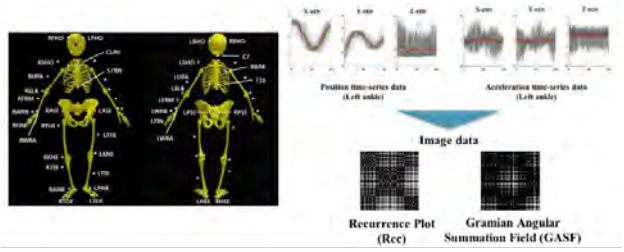

Figure 1 An example shows images converted from time-series data of position and acceleration using the body segments during 360° turning tasks.

RESULTS AND DISCUSSION

As a result, the body segments with the highest performance in classifying freezers, non-freezers, and controls were the left elbow at 61%, right tibia at 60%, and right ankle at 60% in the image-based position time-series data when using the Recurrence Plot (Rec) algorithm, and were the left upper arm at 60% and left knee at 60% when using the Gramian Angular Summation Field (GASF) algorithm. In addition, the left toe at 62% and right toe at 58% were found in the image-based acceleration time-series data when using the Rec algorithm. These results showed that freezers observed uncoordinated gait patterns between the left elbow and knee with more affected body segments and asymmetric steps to complete turning compared to non-freezers and controls [1]. Therefore, freezers may experience difficulty performing automatized movements without attention during turning [2].

CONCLUSIONS

The time-series gait pattern was confirmed using the whole body segments during 360° turning tasks on the affected side at the preferred speed in freezers and non-freezers. In addition, the CNN technique based on time-series gait data imaging may improve the availability as an objective indicator of disease severity in a clinical environment through early diagnosis of motor symptoms such as freezing of gait in PD patients.

INTRODUCTION

Back pain can lead to pathological movement patterns of the spine and vice versa. Therefore, motion analysis is a central component of prevention, diagnosis and therapy, which is, due to a lack of technical alternative, mainly based upon visual observations.
In the current functional model at initial contact the equilateral side of the pelvis is assumed to be maximally forward rotated while the shoulder girdle demonstrates a counter rotation. These opposing movements continue throughout the spine, resulting in a contrary rotation of the upper and the lower spine. T7 is considered to be a point of intersection that mediates between the different directions of movement resulting in no or at least reduced rotary motion. Due to technical progress today Surface Topography (ST) enables non-invasive gait analyses of the vertebral bodies (VB) from C7-L4 and the pelvis. In order to obtain so far lacking ST reference data for a standardized gait cycle (SGC) and to verify the functional model, we have carried out the present study.

METHODS

Three gait cycles of 201 healthy, pain free participants aged 18-70 years (mean 41.3; SD 13.4) have been examined. While walking on a treadmill at 5 km/h, participants were recorded using the DIERS Formetric III 4D. For each of 60 frames per second the rotational position of C7-L4 and the pelvis was calculated resulting in a continuous course of the individual VB and pelvis movement. A treadmill-integrated foot pressure measuring plate allowed for detections of the gait cycles. Using an interpolating spline function the observations were transformed into a SGC, in which the movements are related to 0-100% of SGC, starting with initial contact right foot.

RESULTS AND DISCUSSION

The mean curves of right- and leftside rotation of all investigated VB and the pelvis within the SGC are presented in the Figure. Instead of the expected symmetry, the oscillation is mainly slightly shifted to rightside rotation (negative values), as it is known from standing posture [1]. The averaged maximum of pelvic rotation to the left is 3.3° at 4% SGC and 1.8° at 55% SGC to the right. The amplitudes of rotary motion for pelvis and lumbar spine (LS) are almost identical, but reached their respective maximum shifted in relation to time. The thoracic spine (TS), however, demonstrated different amplitudes of rotary motion (T12-T8 ascending, T7-C7 descending), but all segments reached their maximum values almost contemporaneously. T7 revealed the largest averaged amplitude of rotary motion to the left 6.7° at 48% SGC and T8 to the right 8.2° at 98% SGC. We found large inter-individual differences in the movement in particular of pelvis and LS. There, the individual rotation maxima are time-spread over almost half SGC. This makes it difficult to interpret measurement data related to a pathology in question.

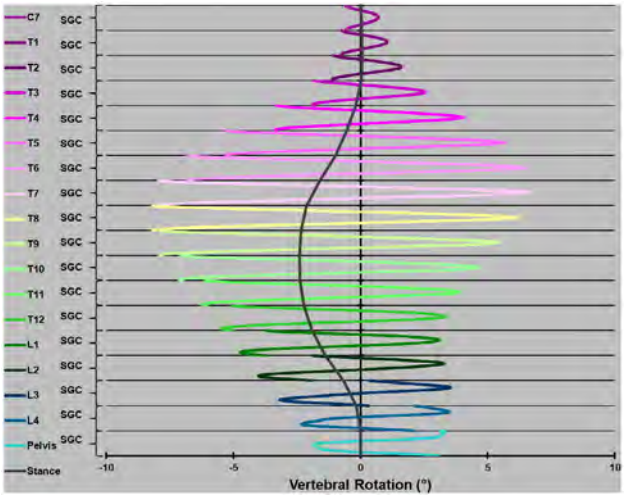

Figure: Mean rotation curves within a single SGC, displayed top down [1]. The beginning of the respective curve at the top indicates the position of VB/pelvis at the beginning of the SGC. A negative value means processus spinous to the left = rotation to the right, a positive value means rotation to the left.

CONCLUSIONS

Pelvis and LS as well as TS acted as a functional unit and demonstrated diametrically opposed, highly individual rotary movement patterns that are co-shaped by the standing posture. The results challenge the current functional model of spinal dynamics in gait.

GAIT AND DYNAMIC POSTURAL STABILITY DURING OBSTACLE CROSSING IN THE INDIVIDUALS WITH EARLY-STAGE PARKINSON'S DISEASE

Nok-Yeung Law*, Jing Xian Li
School of Human Kinetics, University of Ottawa / Ottawa, Canada.
*Correspondence email: nlaw098@uottawa.ca

INTRODUCTION

Obstacle crossing is a challenge task for people with Parkinson's disease (PD) due to a higher propensity for falls. [1-2] Changes in gait and postural stability affect their ability to perform this task safely. [3-4] Limited understanding to dynamic postural stability exists in this population and findings from past studies were of PD participants with big variations in the condition's severity (mild-to-moderate to severe) and small sample size. This study aimed to examine the gait and dynamic postural stability during obstacle crossing in individuals with early-stage PD and compared with that in older healthy adults (HOA). It was hypothesized that the PD and HOA groups will show significant differences in gait speed, crossing length, pre- and post-horizontal distance, toe, and heel clearance distance; center of mass (COM) displacement and velocity, and COM-center of pressure (COP) separation distance; and maximum joint angles and range of motion of the hip, knee, and ankle. Moreover, single-leg stance (SLS) and timed up and go (TUG) test scores would be significantly different.

METHODS

Sixteen individuals diagnosed with idiopathic PD (7 F, 72 ± 7 years, 70 ± 17 kg, 171 ± 11 cm, UPDRS III 21 ± 9, H&Y 1 to 2), and sixteen age- and sex-matched HOA participated. The study was approved by the university's research ethics review board. Data was collected at the Human Movement Biomechanics Laboratory. The participants had no neuromuscular injuries in the last two years and able to stand and walk unassisted; written consent was obtained prior to participation. They were screened over the telephone. Their general cognitive function was assessed using the Montreal Cognitive Assessment (MoCA). The PD participants were tested in the ON-medication state, within 1 to 2.5 hours after their last medication dose.

Three-dimensional motion of obstacle crossing in the participants was captured using a ten-camera VICON system at 200 Hz. Ground reaction forces were recorded using four force plates at 2000 Hz embedded in the middle of the walkway. Thirty-nine reflective markers were attached to the skin or over the participants' clothing following the Plug-in-Gait marker set, as modified from the Helen Hayes marker set. The participants were asked to cross a 20-cm high obstacle that was setup in the middle of an 8-meter walkway at their self-selected comfortable pace. They were allowed to cross the obstacle with their self-select limb as the leading limb and with their comfortable shoes. Five successful trials of obstacle crossing were collected. SLS were collected three times with eyes open and three times with eyes closed; the best time of each condition was reported. A coin toss determined the order of the stance leg to use. TUG was recorded with a stopwatch over a 3-meter distance.

Differences in demographic variables between the two groups were tested using chi-square and independent-sample *t* tests depending on the variable's type after testing for normal distribution. Independent-sample *t* tests were used to examine any difference in the measures between the two groups. A *p*-value of ≤ 0.05 was considered significant. All statistical operations were performed using SPSS software v.20.

RESULTS AND DISCUSSION

The demographic characteristics of the PD and HOA groups were comparable. All participants completed the obstacle crossing trials successfully. The PD group had a shorter SLS time than the HOA group with eyes open (57.4 ± 41.7 s vs. 23.6 ± 20.9 s, $p = .009$) and eyes closed (11.3 ± 8.8 s vs. 3.9 ± 2.5 s, $p = .004$). TUG time was similar between the PD and HOA groups (12.7 ± 3.2 s vs. 11.4 ± 2.0 s, $p = .189$).

No significant difference in gait variables was found between the two groups, toe and heel clearance distance, and pre- and post-horizontal distance of the leading foot and trailing foot. The PD group crossed the obstacle with a slower gait speed and crossing speed, and slightly smaller crossing stride length of the leading foot compared to HOA group (1.35 ± 0.26 vs. 1.41 ± 0.17 cm). The PD group showed a smaller anterior-posterior COM displacement (35 ± 11 vs. 36 ± 8.6 cm) but a bigger medial-lateral COM displacement (9.5 ± 4.0 vs. 8.7 ± 3.9 cm) compared to the HOA group.

CONCLUSIONS

This study showed that individuals with early-stage PD crossed slowly with increased medial-lateral sway, indicating changed dynamic stability. The findings suggest that individuals in the early-stage PD can cross the 20-cm high obstacle but with altered gait and posture.

ACKNOWLEDGEMENTS

The researchers would like to thank the participants and *Parkinson's Canada* for their support of this study.

INTRODUCTION

Dynamic control of the center of mass (COM) and the center of pressure (COP) is crucial for gait performance. The COM in older adults with spinal deformity often shifts anteriorly during gait due to trunk flexion, which likely helps maintain velocity by expanding the anteroposterior COM-COP distance in the terminal stance. However, the trunk cannot flex during gait after spinal fixation. Thus, postoperative rehabilitation is needed to expand the COM–COP distance without trunk flexion. Machine learning can extract the essential characteristics of the gait strategy and may help suggest novel and optimal gait training for each cluster. We aimed to use machine learning to reveal the relationship between COM–COP distance and walking speed, and the gait characteristics related to COM–COP distance.

METHODS

One-hundred-and-five patients (mean age: 73.6 years) with spinal fixation from thoracic vertebrae to pelvis underwent three-dimensional gait analysis at 6 months postoperatively. First, Pearson's correlation coefficient between the COM–COP distance in the terminal stance and walking speed was calculated. Second, machine learning was applied. The gait characteristics related to the COM–COP distance were extracted by Mahalanobis distance [1] and Markov chain Monte Carlo sampling [2] of 116 gait parameters and were used to categorize gait patterns by hierarchical clustering. The feature extractions were repeated in each cluster. Path analysis was used to investigate whether the extracted gait characteristics affected the COM–COP distance and walking speed. All analyses were conducted by Python (3.8.1). The significance level was set at 0.05.

RESULTS AND DISCUSSION

The maximum COM–COP distance in the terminal stance was significantly correlated with walking speed (Figure 1). Gait patterns were categorized into Clusters A, B, and C in order of increasing COM–COP distance. Path analysis showed that knee extension moment in Cluster A, hip flexion angle in Cluster B, and minimum ankle power and hip flexion moment in Cluster C were significantly associated with the COM–COP distance (Table 1). Cluster C comprised the oldest, slowest walking patients with the most trunk flexion.

Our results suggest that the ability to carry the COM more anteriorly by knee extension moment in Cluster A and by larger hip flexion in Cluster B, and to place the COP more posteriorly by eccentric hip and ankle movement in Cluster C play a crucial role in walking.

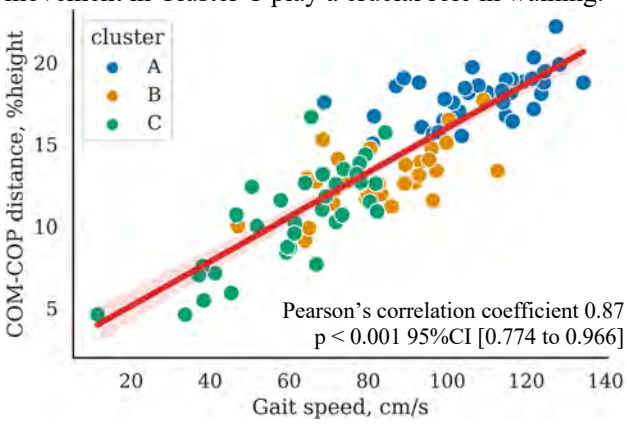

Figure 1: COM–COP distance and gait speed in each cluster.

CONCLUSIONS

More dynamic control of the COM and COP is likely required to improve gait speed in older adults after spinal fixation. Individuals with a small COM–COP distance can walk faster by moving the COP more posteriorly as a first step, then by preparing to move the COM more anteriorly by larger hip flexion, and finally by knee extension moments. The clinical application of machine learning may help offer optimal gait training for each cluster.

INTRODUCTION

During ageing, falls and mobility disorders are one of the main factors leading to loss of autonomy. Clinical functional assessments, such as the 3-m Timed Up and GO (TUG), are usually considered as fall predictors. On the other hand, gait impairment has been shown also to be an important fall predictor in older adults (OA). Among various factors, the loss of strength and muscle quality represent major independent variables which contribute to decrease gait performance, as it may underlie the motor control and balance impairments that lead to falls and adverse outcomes [1-3]. Improving muscle-related predictors of gait and functional performance [i.e. lean and fat masses, muscle strength (MS), quality (MQ) and power (MP)] seems to be a very important strategy to preserve the quality of life of OA. Exercise, especially power training (PT), is considered one of the best intervention to improve fall predictors such as gait parameters, kinematic measures of mobility or muscle function (MP, MS, MQ) [4-5]. Therefore, we aimed to assess whether improvement in muscle function after 12 weeks of mixed PT (MPT) would have an impact on both functional fall predictors and gait fall predictors in healthy older men.

METHODS

Participants: Twenty-one older (age:67±6years; BMI:25±3 kg/m^2; walking speed:1.45±0.23m/s) inactive community-dwelling men were recruited to participate in a 12-week MPT. *Intervention:* 12-week MPT (3sessions/wk.) Each session (1h) included 4 resistance (tempo: 1-0-2-0; 80% 1RM; set 8 to 12 repetitions) and 6 functional exercises. *Measures:* Spatio-temporal gait parameters (speed, stride length and width, stride rate, gait phases duration , GVI, walk ratio) were measured during a 6-min walk test using a Zeno® mat [6]. Fat-free mass (FFM; DXA©), muscle function [absolute and relative MS & MQ, estimated MP (Takaï [7])] and functional capacity [4-m walking speed, 3-m TUG, unipodal balance and stair test)] were also assessed. All measures were performed pre- and post-intervention. *Groups:* Participants were divided into 2 groups for selected fall/mobility predictors as responders (delta change Δ%>10%) *vs.* non-responders (Δ%<10%) Predictor parameters (TUG, MS, MQ & MP) were selected if: 1) correlated significantly with the gait parameters at baseline and; 2) changed significantly after the MPT intervention.

RESULTS AND DISCUSSION

Following the intervention, total FFM, MS (absolute and relative), MQ and MP (absolute and relative) increased ($p<0.05$). For functional parameters, only the stair test ($p=0.019$) and the 3-m TUG ($p=0.001$) improved. Finally, stride length, cadence, speed, duration of support and walk ratio changed significantly. First, there was no difference in Δ% gait parameters between TUG responders and non-responders. Regarding relative MS or MQ, a difference between responders & non-responders was observed for speed and stride length. Furthermore, when divided into absolute MP responders, only the walk ratio Δ% differed between the 2 groups. Finally, a difference was observed for single and double support duration between relative MS responders vs. non-responders.

CONCLUSIONS

A 12-week MPT improves muscle function as well as functional status and gait parameters. However, the adaptation of gait parameters appears unrelated to clinical improvement of fall/mobility predictors in healthy community-dwelling OA. Therefore, further studies investigating the effect of age or functional status are needed to better understand the interplay between muscle function and gait parameters.

GAIT PROPULSION IN PATIENTS WITH UNILATERAL CEREBRAL PALSY WHEN WALKING WITH AND WITHOUT AN ANKLE FOOT ORTHOSIS

Jacqueline Romkes, Katrin Bracht-Schweizer, Elke Viehweger, and Morgan Sangeux
Neuro-Orthopaedic department, University of Basel Children's Hospital, Basel, Switzerland
Email: j.romkes@unibas.ch

INTRODUCTION

Gait propulsive force can be defined as the anterior component of the ground reaction force (aGRF) during gait. The ankle plantarflexion moment and the angle of the trailing limb (TLA) with the vertical during push-off are major contributors to increase the propulsive force generation [1]. Patients with unilateral cerebral palsy (uniCP) have an affected and non-affected body side. Therefore, a lower contribution of the affected side to propulsion can be expected, similar to post-stroke patients. One marked gait deviation in uniCP is an equinus gait pattern. An ankle foot orthosis (AFO) for the affected leg can improve the plantarflexed foot position during the swing phase of gait and improve the stability in stance (figure 1). Since little is known on gait propulsion in uniCP, the purpose of this study was to 1) explore the affected side's contribution to propulsion during gait in uniCP, and 2) explore the influence of walking with an AFO and footwear on the gait propulsive force generation.

Figure 1: Typical study patient with an AFO.

METHODS

Gait kinematics and GRFs of 83 uniCP patients (mean age: 11, range 5-47 years) walking barefoot and with an AFO and footwear at self-selected speed were investigated retrospectively. Propulsive impulse was defined as the integral of the aGRF over time during the stance phase of gait, normalised for the individual's body weight (BW) [2]. The contribution of the affected leg to propulsion, is the ratio between the affected side and the sum of both sides' propulsive impulse. Peak propulsive force, TLA (peak angle between vertical and vector from hip to ankle joint centre), peak plantarflexion moment, peak generating ankle power, step length, and walking speed were also calculated (MATLAB software, Mathworks Inc, Natrick (MA), USA). The Wilcoxon Signed Rank Test (α=0.05) and the effect size were used for statistical comparisons.

RESULTS AND DISCUSSION

Table 1 shows the results for the parameters of interest. When wearing an AFO and footwear compared to barefoot gait, the affected leg contributed less to gait propulsion than the non-affected leg. Therefore, gait became less symmetrical for the outcome measures in this study. Peak propulsive force, peak plantarflexion moment and peak generating ankle power during push-off were significantly lower for the affected compared to the non-affected leg. However, propulsive impulse of the two sides combined increased when an AFO was worn on the affected side.

CONCLUSIONS

This study focussed on gait propulsion and the influence of an AFO in patients with uniCP. On average, the contribution to propulsion of the affected leg decreased when walking with an AFO compared to barefoot walking. In addition, ankle power generation decreased and therefore did not modulate peak propulsive force. However, the TLA and plantarflexion moment were positively influenced when walking with an AFO leading to a higher walking speed and bilateral increased propulsive impulse.

INTRODUCTION

Postural balance is essential for daily activities. As aging leads to a decline in the ability to maintain upright stability, retraining postural balance is crucial for the elderly. Virtual reality (VR) training has been extensively used for specific clinical training [1]. To provide a realistic training environment, we designed an innovative virtual reality-based skateboard training system for balance training purposes. The aim of this study was to investigate the effects of this novel training system by comparing the kinematic and kinetic changes between pre- and post-training in the healthy elderly.

METHODS

A total of 19 healthy elderly (age: 62.21±7.23 years old) and 19 young participants (age: 27.21±2.90 years old) were recruited in this study. All participants completed two functional performance assessments: the Timed Up and Go test (TUG) and the Five Times Sit-to-Stand test (5STS). Moreover, participant also completed the single-leg-stance test. Elderly received 6 weeks of virtual reality skateboarding balance training (Figure 1), twice a week. This training system was integrated with the virtual reality environment and split-belt treadmill. The 3D motion-capture system (Vicon ver. 2.5, Oxford Metrics Ltd., OX, UK) and the force platform (AMTI OR6, Advanced Medical Technology Inc., MA, USA) were synchronized to collect the kinematics and kinetic data, respectively.

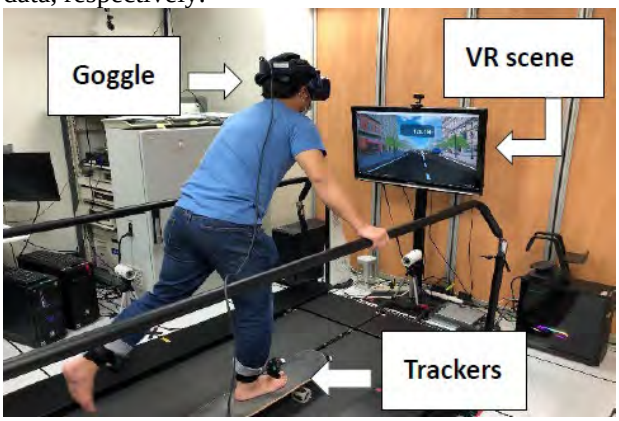

Figure 1 The VR skateboarding balance training system.

All statistical analyses were conducted using SPSS 18.0 software (SPSS, Inc., USA), with the α level of 0.05. The nonparametric Mann-Whitney U test and Wilcoxon signed-rank test were used to compare differences between groups (i.e., elderly and young) and within group (i.e., pre- and post-training), respectively.

RESULTS AND DISCUSSION

For differences between groups, the elderly had significantly decrease in scores on both 5STS and TUG tests, while showing significantly larger values of center of mass (COM) and center of pressure (COP) than young adults ($p < 0.05$). This suggests that decreased extremity power, high risk of fall, and postural instability should be of concern in the elderly population. After the training sessions, there was a significant improvement in functional performance and postural balance within the elderly group (Table 1). The elderly group had an improvement in the TUG test. Furthermore, the COM excursion in the anteroposterior direction and the COP mean distance in the elderly during the single-leg-stance test significantly decreased after training.

Table 1: Comparison of independent variables between pre- and post-training differences in the elderly group.

Independent variables	Pre-training	Post-training	*p*-value
Assessments			
TUG (sec)	9.14 ± 1.47	8.29 ± 1.13	**0.035***
5STS (sec)	7.74 ± 1.79	7.25 ± 1.72	0.446
Center of Mass

ML distance (cm)	0.56±0.16	0.53±0.15	0.277

AP / ML, in the anteroposterior / mediolateral direction; *, $p < 0.05$.

CONCLUSIONS

This study confirmed the positive effectiveness of this virtual reality exergame on upright postural stability in the elderly population, and could reduce the risk of falls. For the implication in rehabilitation, this virtual reality might be a useful intervention in promoting the postural balance of various elderly with balance impairment.

EMG NORMALIZATION APPROACHES SHOW DIFFERING RESULTS IN OLDER ADULTS DURING A STEPPING TASK

Marcel B. Lanza*, Nathan Frakes, Vicki L. Gray
Department of Physical Therapy and Rehabilitation, School of Medicine, University of Maryland, Baltimore, United States. *mlanza@som.umaryland.edu

INTRODUCTION

To avoid a fall, taking a rapid step is a common strategy among older adults. In this sense, rapid activation of the muscles (e.g., rate of activation, RoA) appears to be important for stepping tasks, and surface electromyography (EMG) have been recorded during stepping tasks[1]. EMG normalization is often required during stepping tasks and allows researchers to compare EMG amplitude between different days and/or individuals[2] Yet, there is no consensus about how to normalize EMG amplitude during a voluntary stepping task. The previous research showed that EMG amplitude normalized by different EMG parameters present different values during a knee extension exercise[3]. Since researchers constantly put information from different studies together, understanding the impact of using different EMG parameters allows to decide which parameter should be used for EMG normnalization. Thus, the aim of the present study is to investigate the impact of using different EMG parameters as a reference to normalize the EMG amplitude of the gluteus medius muscle across different trials of a voluntary stepping task and its reliability.

METHODS

Fifteen health older adults (5 males / 10 females; age= 68.7 ± 3.6 years; height= 1.67 ± 0.1 m; mass= 81.8 ± 12.02 kg; BMI= 29.3 ± 4.87) were volunteers in this study. Ten voluntary choice reaction step test (CRST) were performed by standing on two adjacent force platforms. Surface EMG electrodes were placed on the gluteus medius (GM) accordingly to SENIAM guidelines. EMG signals were recorded at a frequency of 1500 Hz and filtered (4th-order Butterworth band-pass filter of 20–500 Hz) before calculating the EMG amplitude as the root mean square (RMS). The RoA was calculated from EMG onset to EMG peak for each CRST trial. Three EMG parameters were used as a reference for EMG normalization: 1) EMG peak during step ($EMG_{TrialMax}$); 2) EMG mean measured during the step ($EMG_{TrialMean}$), and 3) EMG measured at baseline ($EMG_{Baseline}$).

The statistical analysis was performed for the stance leg and stepping leg during the CRST. A repeated-measures one-way ANOVA test was performed followed by a Bonferroni post hoc test when necessary, and intraclass correlation coefficient for inter-trial reliability.

RESULTS AND DISCUSSION

When the right or left side is acting as stance leg or stepping leg, there was a difference in normalized EMG ($P< 0.0001$) with RoA normalized by $EMG_{Baseline}$ showing higher values than the others, and RoA normalized by $EMG_{TrialMean}$ showing higher values than $EMG_{TrialMax}$. Reliability was excellent with all ICC values above 0.839.

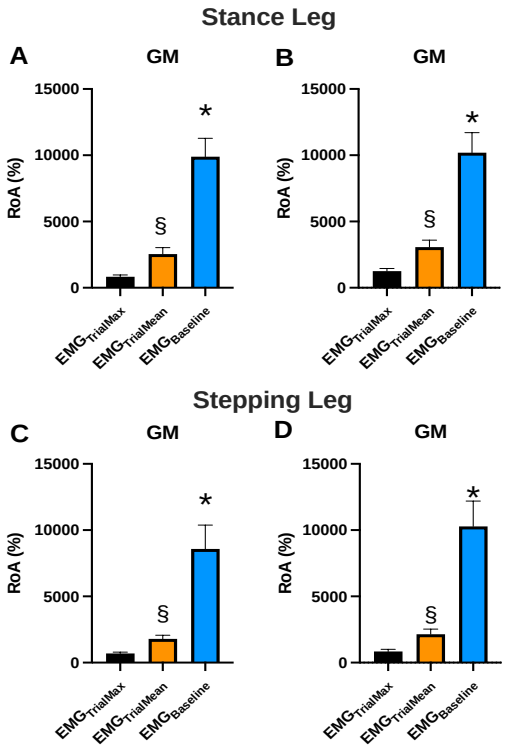

Figure 1 Likelihood of acceptance as a function of writing clarity. A and C are right and B and D are left EMG values.

CONCLUSIONS

The present study showed that the normalized RoA of the GM during a voluntary stepping task will be different depending on the EMG parameter used to normalize the signal, with excellent reliability for all EMG parameters. Therefore, comparisons between studies should be made with care between studies that use different EMG amplitude normalization procedures, even though all three EMG parameters present excellent reliability.

ADAPTATION IN REACTIVE BALANCE CONTROL OVER REPEATED STANDING SLIPS IN BALLET DANCERS

Caroline Simpkins[1] and Feng Yang[1]
[1] Department of Kinesiology and Health, Georgia State University, Atlanta, Georgia, United States of America.
Email: claubacher1@gsu.edu

INTRODUCTION

Ballet is being increasingly used to reduce fall risk in older adults [1]. Our recent work showed that ballet dancers react to a novel standing-slip more effectually than non-dancers through a more effective recovery step and a better trunk movement control [2]. This study aimed to test if the reactive responses to repeated slips would differ between ballet dancers and non-dancers. We hypothesized that dancers would exhibit a larger adaptation in reactive balance control than non-dancers.

METHODS

Twenty young adults were recruited: 10 ballet dancers (age: 24.5 ± 4.9 years) and 10 age/sex-matched non-dancers (22.6 ± 3.4 years). Participants wore a safety harness while undergoing the protocol on the ActiveStep treadmill (Simbex, NH). After three standing trials without a slip, participants were told a slip may or may not occur on any following trial. Then, three more standing trials were completed, followed by five unexpected standing-slips (S1-S5). The standardized slip was created by accelerating the belt forward to 1.2 m/s over 300 ms, and then reducing the belt speed to zero over 300 ms. The belt's slip distance was 36 cm. The S1 and S5 trials were analyzed.

Full-body kinematics were collected from 26 markers attached to the skin through a motion capture system (Vicon, UK). The belt's movement was measured by a marker attached to the belt. Locations of joint centers, heels, and toes were computed from filtered marker positions. Two time instants were obtained: the slip onset (ON) was calculated using the belt's movement and the recovery step liftoff (LO) was determined by the foot kinematics. Since LO occurred after ON, participants' performance at LO characterized the reactive control of balance after a slip. The body's center of mass (COM) kinematics were computed using the joint centers data. The two components of the COM motion state (position and velocity) were calculated relative to the base of support and normalized by foot length and $\sqrt{g \times bh}$, respectively, where g is the gravitational acceleration and bh represents the body height. Dynamic gait stability (a unitless variable) was calculated based on the COM motion state at LO. Step latency (sec) was the time elapsed from ON to LO and slip distance (normalized by bh) was the distance travelled by the belt marker from ON to LO. The primary outcome was the change in dynamic gait stability (as defined by the Feasible Stability Region (FSR) theory [3]) from S1 to S5. Secondary variables were S1-S5 changes in the step latency and slip distance. Independent t-tests (with the effect size of Cohen's d) or Mann-Whitney U tests (effect size: r) compared normally or non-normally distributed outcomes between groups, respectively. Statistical analyses were conducted using SPSS 28.0 (IBM, NY) and an α of 0.05.

RESULTS AND DISCUSSION

The results supported our hypothesis. Dancers showed larger adaptive changes in all outcome measures over the five slips than non-dancers. The dancers' improvement in stability at LO from S1-S5 was significantly greater than non-dancers (p = 0.003, Fig. 1a). This more rapid adaptation could be attributed to the improved reactive balance control involving a shortened step latency (p = 0.004, Fig. 1b) and reduced slip distance (p = 0.004, Fig. 1c).

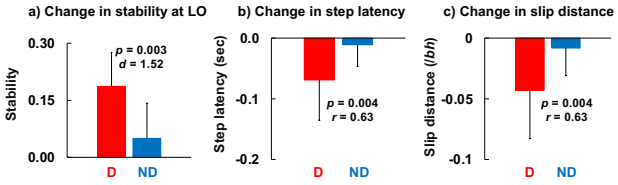

Fig. 1 Comparisons between dancers (D) and non-dancers (ND) of S1-S5 change in a) dynamic gait stability at LO, b) step latency, and c) slip distance. Also shown are p-values and effects sizes (Cohen's d or r).

CONCLUSIONS

Our study suggests that dancers can adapt their reactive balance control more quickly over repeated standing-slips than non-dancers primarily by initiating the recovery step much sooner. These findings could offer preliminary evidence for applying ballet to improve balance loss resilience and fall resistance for high fall risk populations. Studies with older ballet dancers are needed to investigate if they would exhibit similar adaptation as their young counterparts.

CORTICAL INVOLVEMENT FOR POSTURAL CONTROL

INTRODUCTION

The simplest tasks, such as maintaining upright stance, require the involvement of the cerebral cortex [1]. Sensory inputs from the visual, vestibular and somatosensory-proprioceptive systems are integrated by the cortex and are the basis for the development of a postural corrective strategy [2]. Our aim was to study postural maintenance through the lens of corticokinematic coherence (CKC), the coupling between brain activity and movement kinematics, to reveal how center of pressure fluctuations are encoded in the cortex. We also aimed to determine if such coupling reflects generated motor commands or proprioceptive integration at the cortical level for postural control.

METHODS

Thirty-six young healthy participants (age: 25 ± 3.5 years; weight: 71.7 ± 18.9 kg; 21 women) participated in this study. Participants completed a total of 8 recordings, in 4 standing conditions, each repeated 2 times, for a total of 10 minutes of recording per condition. The 4 conditions were bipedal quiet standing on a solid surface with eyes open (SEO) or closed (SEC) or on a foam mat under each foot with eyes open (FEO) or closed (FEC). Cortical activity was recorded during the balance tasks with a 64-channel EEG headcap (EEGO, ANT) and ground reaction forces and moments were recorded during each condition with a force plate (AccuSway, AMTI). Postural sways were quantified with the standard deviation of COP fluctuations (SD_{COP}). Coherence (i.e., CKC) was estimated between each EEG signal and COP fluctuations. For the electrode showing the maximal coherence between 0.5 Hz and 10 Hz, we derived the time delay from the phase slope of the cross-spectral density at frequencies where coherence was significant.

RESULTS AND DISCUSSION

Figure 1 presents COP traces, CKC topography and spectra, and estimated delays. An ANOVA confirmed CKC strength depends on balance condition ($F_{3,140} = 9.7$, $p < 0.0001$). Table 1 presents post-hoc tests. CKC strength was significantly increased in FEC compared to the other conditions. CKC in SEC was not significantly different from that in SEO. Estimated time delays from COP to EEG were significantly positive in FEC, supporting an afferent role to increased oscillations during situation of high postural demand. Finally, the percentage of change in SD_{COP} from a change in surface was correlated with CKC strength ($r = 0.267$, $p = 0.0236$).

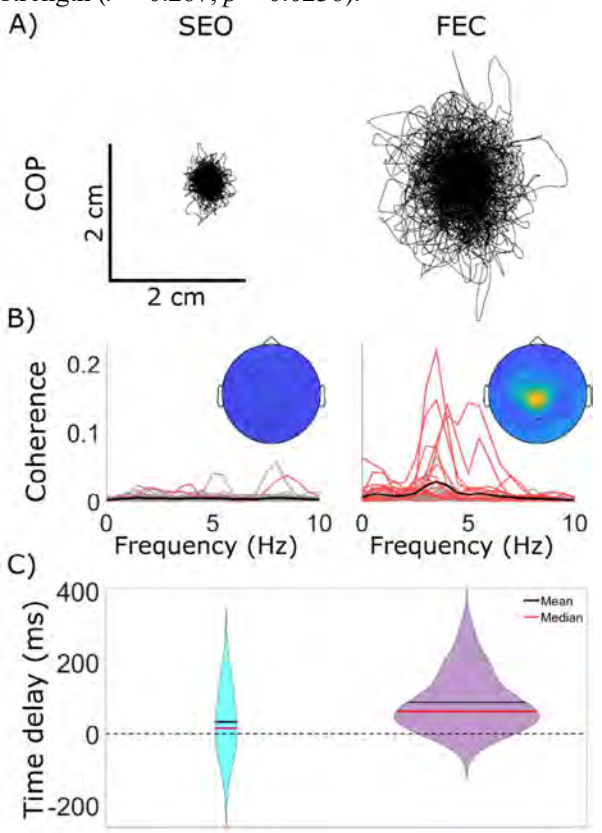

Figure 1 A) COP traces. B) Coherence spectra for each participant and corresponding average topography. Significant coherence is shown in red, and the grand average is shown in black. C) Estimated time delays from COP to EEG signals.

CONCLUSIONS

During challenging balance conditions, increased CKC may be indicative of less efficient balance control and increased need to monitor COP fluctuations. Such findings could help optimize the rehabilitation of patients with impaired balance.

INTRODUCTION

Increasing ankle stability has been a crucial topic to improve sports performance and avert sports injuries. In recent years, the number of athletes who use sports taping has gradually increased. Among many taping products, Dynamic tape® (DT) is believed to provide mechanical tension and boost sports performance [1]. Nonetheless, the effect of DT on lower-limb biomechanics and balance capability is still lacking scientific evidence. Therefore, the aim of this study was to investigate the effect of Dynamic tape® (DT) on the range of motion and balance of the lower limb.

METHODS

Eighteen healthy subjects (nine females; aged 22.6±1.9 years old) volunteered for this study. Static and dynamic balance, as well as ankle range of motion in the sagittal plane, were assessed in each subject under three different conditions in a randomized order: no taping (NT), dynamic taping (DT), and a placebo (PB) using MUELLER MWrap®. The tape was attached from the sole to the calf. In the static balance test, the subject stood by one foot in the center of a force plate (BMS400600, AMTI, USA) for 30 seconds on each leg. The center of pressure (COP) was used as the outcome measure. In the dynamic balance test, we employed the Y-balance test measurement [2] as our assessment tool. The subject stood with one leg on the center of a stance plate and used the other leg to touch three different directions three times each. The Y-balance test score was determined by calculating the average distance between the center of the stance plate and the maximum reach of the leg, normalized by the subject's leg length. We used an optical motion capture system (VantageV5, Vicon, UK) with Plug-in-Gait marker placement to determine the maximum range of motion (ROM) of the ankle joint in the sagittal plane during active movements. To test for significant differences between conditions, we employed the nonparametric Wilcoxon T-test (SPSS 22) and set the level of statistical significance at $p<0.05$.

RESULTS AND DISCUSSION

Table 1 shows the experimental results. The results of the DT condition were found to be lower than those of the NT and PB conditions in all COP parameters, indicating the efficacy of increasing stability. Additionally, the comparison between DT and NT conditions revealed that the COP area and anterioposterior sway were statistically significant ($p<0.05$).

In the Y-balance test, the score of the DT condition increased by 1.11 when compared to the NT condition. In addition, the Y-balance score difference in the DT condition was significantly different from those in the NT and PB conditions. This provides evidence that the use of DT is helpful in enhancing dynamic balance.

The maximum range of motion in the sagittal plane of the ankle joint during active movements was 1.16 degrees lower in the DT condition as compared to the NT condition, indicating that the DT condition still had an impact on the range of motion of the ankle joint.

Table 1. The result of static and dynamic balance test

	DT mean (SD)	NT mean (SD)	PB mean (SD)
COP path length (mm)	887.86 (203.57)	940.54 (248.73)	943.29 (296.09)
COP area (mm^2)	499.01 (138.22)	555.06* (172.15)	536.59 (229.68)
COP AP sway (mm)	36.24 (8.01)	41.69* (9.16)	40.76 (10.76)
COP ML sway (mm)	27.47 (3.91)	29.29 (4.75)	29.38 (5.25)
Y-balance score	90.79 (5.91)	89.68* (5.74)	89.36** (5.90)
ROM (degrees)	63.98 (4.02)	65.14** (3.49)	- -

DT: Dynamic tape; NT: No tape; PB: Placebo; COP path length: total path length of COP; COP area: the area including 95% of the COP data points; COP AP sway: maximum sway range of COP in anterioposterior direction; COP ML sway: maximum sway range of COP in mediolateral direction; Y-balance score: normalized Y-balance test score; ROM: range of motion, *p<.05 compared to DT, **p<.01 compared to DT.

CONCLUSIONS

According to the results of the dynamic test, the Y-balance score was significantly larger under the DT condition compared to both the NT and PB conditions. This suggests that the use of DT may increase balance ability, at least partially due to the restriction of ankle range of motion in the sagittal plane caused by the use of Dynamic tape®.

INTRODUCTION

Falls among older adults result in injuries and even death. The incidence of falls is 33% among older adults aged over 65 and increases to 50% among same age with knee osteoarthritis (KOA)[1]. The impairment of postural control caused by KOA is one of the strongest risk factors and predictors for falls[1]. The Berg balance scale (BBS) is clinically used to assess postural control[2]. Poor proprioception (PPR) and plantar tactile sensation (PTS), pain, weak strength (ST), and limited range of motion (ROM) in the joints were detected in KOA patients[3], each of which alone can affect postural control. However, it is not clear how the combination of these factors affects postural control, the difference between people with and without KOA. Clarifying these issues can provide insight to facilitate the development of accurate KOA rehabilitation programmes. This study explored the relationship between the five factors and postural control in people with and without KOA.

METHODS

A total of 124 adults with KOA (age: 68.8±4.0 years; height: 160.55±7.7 cm; body mass: 69.3±10.1 kg) and 116 without KOA (age: 67.9±3.5 years; height: 162.4±7.7 cm; body mass: 64.5±9.8 kg) were recruited for the KOA and control (CON) groups. Postural control and pain were assessed by Berg Balance Scale (BBS) and Visual Analogue Scale (VAS). PPR, PTS, ROM, and ST were measured by Proprioception devices, Semmes-Weinstein monofilaments, goniometer, and IsoMed 2000 system, respectively. Partial correlations were used to test their relation to BBS, and factor analysis and multivariate regression were used to determine the degrees of correlation.

RESULTS AND DISCUSSION

In the KOA group, BBS was correlated with PPR, PTS, pain, ROM, and ST. In the control group, the BBS was correlated with PPR and ST. Regressions indicated the following equations: $BBS_{KOA}=54.41+(0.668*F_{ST})-(0.579*F_{PTS})-(1.141*F_{PPR})+(1.054*F_{ROM})-(0.339*F_{pain})$; $BBS_{CON}=53.85+(0.441*F_{ST})-(0.677*F_{PPR})$. In the KOA group, adjusted $r^2 = .612$, $p_{F1}=.003$, $p_{F2}=.008$, $p_{F3}<.001$, $p_{F4}<.001$, $p_{F5}=.009$, $\beta_{F1}=.218$, $\beta_{F2}=.189$, $\beta_{F3}=.374$, $\beta_{F4}=.343$, and $\beta_{F5}=.195$. In the CON group, adjusted $r^2=.464$, $p_{F1}=.004$, $p_{F3}<.001$, $\beta_{F1}=.248$, and $\beta_{F3}=.374$. Different factors related to postural control between those with and without KOA. Both proprioception and strength were associated with postural control in both groups since proprioception provides information of body position and strength is necessary to generate corrective torques for maintaining postural control[4]. PTS, ROM, and pain were only shown to be associated with BBS in KOA patients. The difference in correlations between PTS and postural control among people with and without KOA may be explained by sensory reweighting. Alternative sensory inputs can be used to compensate for the impairments of particular sensory inputs[2]. PTS might compensate for the deteriorated proprioception and provide useful information on postural control. Reduction Of pain has been linked to increased ROM in people with KOA[3], which could explain the correlation between pain/ROM and BBS was detected only in people with KOA. We have also observed that proprioception was correlated with postural control and ranked 1st among people with and without KOA. Previous research supports this view, reporting that proprioceptive afferents from the lower extremity was the primary source of information for postural control[5], and the influence of proprioception on postural control among older adults is greater than other sensory systems[6].

CONCLUSIONS

PTS, ROM, and pain are unique fall risk factors for people with KOA. Among older adults with KOA, postural control was correlated with the five factors at a sequence of proprioception, ROM, strength, pain, and PTS. Proprioceptive training should be prioritized in a KOA rehabilitation programme, as proprioception makes the greatest contribution to postural control.

SYNTHETIC SIMULATION OF STEPPING MANEUVER USING REINFORCEMENT LEARNING

Yoshimori Kiriyama[1] and Naoko Tamada [1]
[1] Department of Mechanical Systems Engineering, Kogakuin University, Tokyo, Japan.
Email: kiriyama@cc.kogakuin.ac.jp

INTRODUCTION

To avoid a falling down and to keep the upright posture, the foot is needed to step forward in a quite short duration. For this, the hip, knee, and ankle joints need to cooperate quickly. The cooperation of the joints to step the foot is based on the stepping strategy [1]. The stepping strategy seems to be induced by the neuro-musculoskeletal system of the human, but the principle or mechanism of the stepping strategy is not necessarily elucidated. In this study, to understand the stepping maneuver, the behaviors were searched using a reinforcement learning technique evaluating the relationship among the posture, the joint torque and disturbance loads.

METHODS

In this study, the human model consisted of seven rigid-body links including the upper body, and the bilateral feet, shanks, and thighs. The model was assumed to move in the sagittal plane, and all the joints rotate around the axes perpendicular in the sagittal plane. The physical parameters including weight, length and inertia moment were decided based on the averaged Japanese data [2]. Each joint was rotated by the joint torque $\tau = \alpha T_{joint}$, where α ($|\alpha| \leqq 1$) is a control activity, and T_{joint} is the maximum value of the torque by the muscles around the *joint* (= the hip, knee, and ankle). The positive or negative value of the torque corresponds to the rotatory direction of flexion or extension respectively. The control activity α needs to change itself to step forward. To obtain adequate α for time series, this study used a Deep Deterministic Policy Gradient (DDPG), which is a kind of a reinforcement learning technique. This method allows us to search an adequate policy to maximize a long-term reward, and then the model can keep the posture to step the foot. The reward R in this study was defined as following,

$$\begin{cases} R = \gamma_1 f(Y_U) + \gamma_2 f(\theta_u) + \gamma_3 f(X_A) + \gamma_4 f(Y_A) + \gamma_5 f(\|\boldsymbol{\tau}\|) + \gamma_6 T_{time} \\ f(x) = \frac{1}{x+\varepsilon} \qquad (\varepsilon = 1.0^{-7}) \end{cases} \tag{2},$$

where γ_i (i=1 to 6) is a weight factor, Y_U is the descent height of the upper body, θ_U is an inclination angle of the upper body, X_A and Y_A are the ankle position, $\boldsymbol{\tau}$ is a torque vector including all the torques at the time, and T_{time} is a duration time during which the model keeps upright. The function $f(x)$ was used to evaluate highly small values x. Some combinations of the weight factors were investigated to elucidate which terms of the reward equation were important to step the foot forward. To the model, forward loads (30 or 50 N) as disturbance were applied in duration of 0.4 or 0.01s.

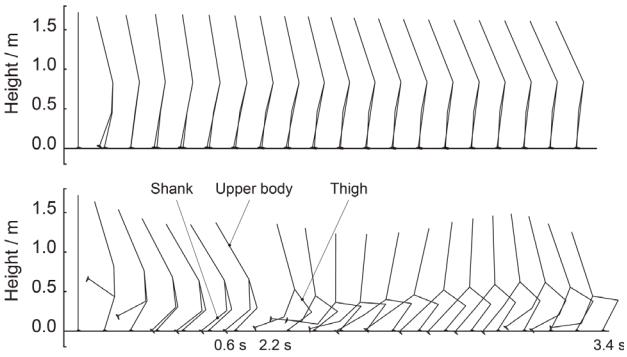

Figure 1 Stick pictures of simulated stepping maneuvers
Top: F = 30 N, t = 0.4 s, $\gamma_{i=1\sim6}$ = (4, 0, 2, 2, 1, 15)
Bottom: F = 30 N, t = 0.4 s, $\gamma_{i=1\sim6}$ = (0, 4, 2, 2, 2, 15)

RESULTS AND DISCUSSION

Figure 1 shows two typical results of the simulated maneuvers. In both simulations, the same value of the impulse of 12 Ns (= 30 N×0.4 s) was applied to the models. However, the different weight factors were used. The top figure does not show that the model steps the foot forward, and the bottom figure shows the stepping maneuver. In the top result, the torque generation could be suppressed (γ_5 = 1), and then the model could maintain the posture without the stepping maneuver. On the other hand, the bottom result shows the large joint motion and then the model steps the foot. The top result should maintain the height of the upper body, while the bottom simulation could show the change of the posture of the upper body due to the weight factors of γ_1 and γ_2. This means that the stepping maneuver should require an ease to generate joint torque and to tolerate the change of the posture. Thus, our method could be useful to understand the mechanism of the stepping maneuver.

CONCLUSIONS

Stepping maneuvers were simulated using Reinforcement learning. The maneuver seemed to require an ease of a generation of the joint torques.

INTRODUCTION

Underwater gait and balance training is common during rehabilitation and is used for simulating reduced gravity environments due to the bodyweight unloading effects of buoyancy. Buoyancy provides vertical forces that oppose gravity in proportion to the degree of underwater immersion [1]. Greater external fluid resistance forces moving underwater compared to moving through air can also be used to strengthen muscles and increase energy expenditure during training [2, 3]. Although human biomechanics and electrical muscle activations have been studied during underwater gait and balance, we understand relatively little about how the human brain and body are interactively influenced by underwtaer bodyweight unloading. Here, we aim to identify changes in electrical brain and muscle activity during underwater standing balance, compared to standing on land, and in response to external balance perturbations. This knowledge can help to design personalized rehabilitation protocols using objective neural measures to assess postural control in conditions that were previously not possible.

METHODS

We instrumented ten healthy subjects with 64-channel wireless electroencephalography (EEG) and 14-channel electromyography (EMG) sensors on the left and right lower limbs during underwater standing balance. Here, we limited our analysis to the EEG data and EMG from the gastrocnemius and soleus muscles. We used customized pipelines and EEGLAB functions to analyse our EEG data [4] and calculated spectral power within frequency bands (θ: 4-8 Hz and α: 8-13 Hz) for each study condition. Study conditions included: (1) standing on land (ST), (2) standing underwater at chest-level (CST, ~50% unloading [2]), (3) standing underwater at waist-level (WST, ~30% unloading [2]), (4) standing underwater at waist-level water with low external fluid forces applied to the front of the body (WST+Low), and (5) standing underwater at waist-level with high external fluid forces applied to the front of the body (WST+High). We randomized condition order made comparisons using a one-way ANOVA with Bonferroni corrections for multiple comparisons ($\alpha = 0.05$).

RESULTS AND DISCUSSION

We identified greater alpha band spectral power from premotor cortex and reduced gastrocnemius and soleus muscle activity while standing underwater compared to standing on land; see **Figure**. In response to postural imbalance caused by high external underwater fluid forces applied to the front of the body, we identified reduced alpha band spectral power compared to standing on land or underwater at chest or waist-level. Taken together, greater premotor alpha band spectral power and reduced ankle plantarflexor muscle activity show that underwater bodyweight support reduced cortical engagement, while external balance perturbations increased electrocortical processing without affecting plantarflexor muscle activity.

CONCLUSIONS

Our findings provide insight into neuromotor changes in postural control during bodyweight unloading, which can provide biomarkers for developing rehabilitation protocols to restore and improve human balance.

MUSCLE POWER AND STRENGTH DEFICIENCIES IN FALLERS WITH LOWER LIMB LOSS

Lin, Isabel, Chang, Meghan, Chang, Kelvin, Lescas, Cali and Chen, Tzurei
Pacific University School of Physical Therapy and Athletic Training / Hillsboro, Oregon
Email: tchen@pacificu.edu

INTRODUCTION

Falls leading to injuries are prevalent in adults with lower limb loss, with a reported occurrence rate of 40-60% [1]. Limited literature examined the differences in power/torque between distinguished non-faller and faller groups in unilateral lower limb amputees compared to a control group [2,3]. Our research aims to investigate the differences in muscle power and torque in hip, knee and ankle joints under two different contraction speeds among three groups: control, non-faller and faller with lower limb loss.

METHODS

Eleven participants with lower limb loss (four transfemoral and seven transtibial; six with fall history in the past six months) and thirteen adults without lower limb loss participated in this study. Bilateral peak torque over bodyweight (Torque/BW) and average power were evaluated in hip extension/flexion, knee extension/flexion, and ankle dorsi/plantarflexion in isokinetic condition (60°/s and 120°/s) with a Biodex™ dynamometer [4]. A repeated measure mixed model ANOVA was used to identify group and speed effects on muscle power and torque. The significance level was set at 0.05.

RESULTS AND DISCUSSION

In measuring torque/BW, non-fallers were similar to control except for the affected limb knee extensors and flexors, and sound limb ankle plantar/dorsiflexors. Fallers' torque/BW were significantly smaller than control for all joint movements. In the control group, the torque/BW is significantly smaller in 120˚/s compared to 60˚/s in all joint movements. Speed affected torque/BW in faller and non-faller groups only for the sound and affected hip flexor, and for sound ankle plantar/dorsiflexors in non-fallers.

Control and non-faller groups were similar in all joint movements for power, except in affected knee extensors and flexors, where non-fallers' power values were significantly smaller than control. Fallers had smaller sound hip extensor muscle power compared to non-fallers. In addition, compared to control, fallers had smaller muscle power values in the following muscle groups: sound hip extensor/flexor, affected hip flexor, and affected knee extensor/flexors. No speed effect was found for fallers except for sound knee extensors, in contrast, significant speed effect was found in majority of the joint movements for control and non-fallers.

CONCLUSIONS

Non-fallers' sound limb performance is similar to control, while fallers' sound hip muscle power is smaller than the faller and control groups. Lack of propulsion strength during push off from the sound limb hip extensors may lead to compensations of hip flexors lifting the affected leg. With reduced hip flexor power in fallers' affected limb, foot clearance may decrease, causing the affected limb to catch during gait.

In addition, fallers are unable to generate larger muscle power during a higher speed contraction. The ability to generate fast and adequate movement to recover from loss of balance is critical for fall recovery. Power training emphasizing movement at higher velocities for the sound limb hip extensors and the affected limb hip flexors may be clinically important in improving physical function and reducing fall risk. Future intervention studies are needed to examine the effectiveness of power training for fall prevention in individuals with lower limb loss.

ACKNOWLEDGEMENTS

We would like to thank all the involved personnel from Pacific University for their assistance in data collection.

Initial Changes in Knee Loading from a Personalized Gait Modification are Associated with Changes in MRI Metrics of Cartilage Health after 1 Year

Kirsten Seagers, Scott D. Uhlrich, Julie A. Kolesar and Scott Delp
Mechanical Engineering, Stanford University, Stanford, CA, USA
Email: kseagers@stanford.edu

INTRODUCTION

Knee osteoarthritis affects 250 million people worldwide and is characterized by joint pain and cartilage degradation, where severe cases are treated with a total joint replacement [1]. Gait retraining is a non-invasive intervention for early-stage medial knee osteoarthritis that aims to reduce joint loads that are thought to contribute to pain and cartilage degradation [2]. Knee contact forces cannot be directly measured in the native knee, so surrogate metrics of knee loading have been used as targets for gait modifications. Yet, these surrogate metrics do not fully explain changes in knee contact forces [3]. It is unknown which joint loading metrics are most associated with cartilage degeneration. Quantitative MRI is sensitive to changes in cartilage composition and microstructure induced by changes in joint mechanics [4]. Here, we explore which changes in knee loading metrics, induced by a gait modification, are associated with changes in MRI-based estimates of cartilage microstructural health after one year.

METHODS

Twenty-five participants with medial knee osteoarthritis were trained to walk with a personalized foot progression angle modification over one year that reduced the peak knee adduction moment [5]. Using motion capture and force plate data from the initial visit, an OpenSim musculoskeletal modeling and simulation pipeline estimated changes, induced by the gait modification, in knee loading: external knee adduction moment, external knee flexion moment, vertical medial knee contact force, and shear medial knee contact force. MRI scans were conducted after the initial visit and after one year to calculate the change in $T_{1\rho}$ and T_2 relaxation times in the medial weight bearing compartment of the knee. Canonical correlation analysis was performed with leave-one-subject-out cross validation to find linear relationships between the knee loading and cartilage microstructure metrics which was evaluated using the Pearson correlation coefficient (α=0.05) [6]. Metrics that were statistically correlated with the identified canonical variates, called the Knee Loading Index and Cartilage Microstructure Index, were used to explore univariate correlations directly between knee loading and cartilage microstructure metrics.

RESULTS AND DISCUSSION

Reductions in the Knee Loading Index (i.e., reduced knee loading) and reductions in the Cartilage Microstructure Index (i.e., reduced $T_{1\rho}$ and T_2; improved cartilage microstructure) from canonical correlation analysis were correlated (r=0.84, p<0.001, Figure 1). Among the variables statistically correlated with the Cartilage Microstructure and Knee Loading Indices, the change in the T_2 relaxation time was positively correlated with the change in the late-stance peak vertical (r = 0.42, p = 0.04) and anteroposterior shear medial knee contact force (0.43, p= 0.03).

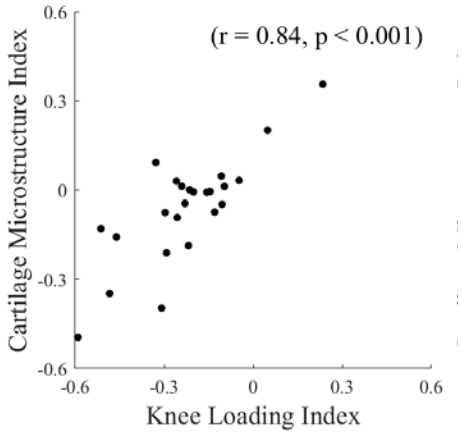

Figure 1. Canonical correlation analysis identified correlated Knee Loading and Cartilage Microstructure Indices.

CONCLUSIONS

Changes in knee loading from a personalized gait modification are associated with changes in the cartilage microstructure after one year. Reductions in late-stance peak anteroposterior shear and vertical medial knee contact force during initial training are associated with improved cartilage microstructural health after one year. Reducing peak medial compartment anteroposterior shear and vertical contact forces in late stance should be explored as targets for gait modifications.

CHARACTERIZING MECHANICAL ADAPTATION OF MUSCLES AFFECTED BY MYASTHENIA GRAVIS USING SHEAR WAVE ELASTOGRAPHY

Manuela Zimmer[1], Benedict Kleiser[2], Justus Marquetand[2] and Filiz Ateş[1,2]

INTRODUCTION

Patients with myasthenia gravis (MG) show a post-synaptic defect of the neuromuscular transmission which often leads to muscle weakness. However, little is known about the mechanical adaptations of the muscles. Using ultrasound shear wave elastography (SWE), mechanical properties of skeletal muscles such as the shear elastic modulus as a measure of stiffness can be assessed assuming transverse isotropic and linear elastic material characteristics. Previously, SWE was shown to represent both passive [1,2] and active muscle mechanics [2,3] in vivo. Characterizing the muscle mechanics of MG patients, we hypothesized that muscle stiffness (i) demonstrates a muscle length-dependent characteristic both in passive and active states and (ii) increases with increasing contraction intensity. (iii) The muscle mechanics are altered compared to the healthy.

METHODS

11 patients (4 males, age: 47.64 ± 15.74 years) diagnosed with MG and 14 healthy volunteers (7 males, age: 28.07 ± 5.06 years) [2] participated in the study. SWE, surface electromyography (sEMG) of the biceps brachii muscle (BB), and elbow torque were measured at five elbow angles (60°-180°) at rest, during maximum voluntary contractions (MVC), and submaximal ramp contractions (up to 25%, 50%, and 75% of MVC torque) of elbow flexion. BB muscle length was determined by ultrasound imaging.

RESULTS AND DISCUSSION

MG Patients: The BB length increased with increasing elbow angle ($p < 0.001$). Normalized to the patients' individual maximum elbow torque, the MVC torque decreased from flexion to extension ($p < 0.001$) whereas the shear elastic modulus measured during MVC increased with increasing elbow angle ($p = 0.004$). Shear elastic modulus during rest also increased with increasing elbow angle ($p = 0.001$). The increase in muscle stiffness during MVC might be due to the increased muscle stiffness imposed by the extended joint positions and the resulting muscle length changes. sEMG amplitude during rest was above 3% in more than half of the trials. It might mean that the low-level muscle activity during rest is a symptom of MG showing the inability of MG patients to fully relax their muscles. Significant effects of elbow angle and contraction intensity ($p < 0.001$ for both) on shear elastic modulus were found during ramp contractions confirming the first two hypotheses posed.

Compared to the healthy group, MVC torque was 26.46% lower ($p < 0.001$). Shear elastic modulus during rest was greater by factor 2.1 ($p < 0.001$, Figure 1) for MG patients. The muscle weakness of the MG patients was quantified by the reduced torque production capability. SWE measurements reflected this at 75% MVC: During ramp contractions, the shear elastic modulus was 8.93% lower at 75% ($p = 0.044$, Figure 1) but not at 25% or 50% MVC ($p > 0.05$). The measured shear elastic modulus during muscle contraction represents the passive and active state combined. We conclude that at lower contraction intensities the increased shear elastic modulus during rest shadows the reduced shear elastic modulus imposed by the reduced torque outcome.

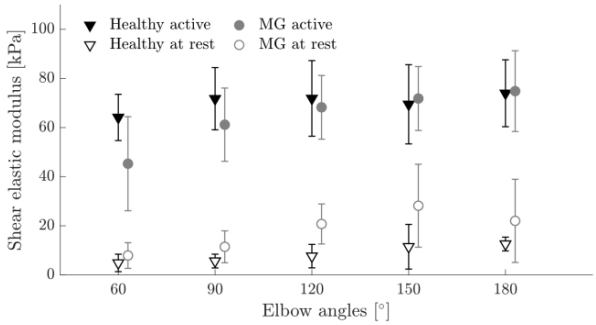

Figure 1 Shear elastic modulus at rest and during active state (submaximal ramp contractions at 75% of MVC torque) for Myasthenia Gravis (MG) patients and healthy volunteers

CONCLUSIONS

Mechanical properties of diseased muscle in MG were comprehensively studied and the hypotheses posed were confirmed. Muscle weakness of MG patients quantified as reduced torque production capability was partially reflected by the shear elastic modulus at submaximal contractions. Muscle stiffness being greater at rest in MG might be a promising diagnostic marker that needs to be further studied.

INTRODUCTION

Increased step width is a gait modification strategy that has been shown to reduce internal knee abduction moment (KAbM) in pateints with knee osteoarthritis (OA) [1]. However, increases in Q-Factor (QF, inter-pedal distance), have been shown to increase KAbM during stationary cycling, [2]. In the previous study [2], we used fixed and relatively large increases of QF. The purpose of the current study was to examine changes in KAbM with smaller and normalized increases in QF. It was hypothesized that KAbM would be greater with each normalized increase in QF.

METHODS

Fifteen healthy participants were included in this study (Age: 22.7±2.5 years, BMI: 23.95±3.21 kg/m2). They cycled in five different QF conditions. Each participant's QFs were achieved using a customized adjustable crank arm assembly (Figure 1). For all subjects, the narrowest QF was 160 mm and each subsequent QF was achieved by increasing from 160 mm by 2% of the participant's trochanteric leg length (L) in five QF conditions: Q1 (160 mm), Q2 (160 + 2%L mm), Q3 (160 + 4%L mm), Q4 (160 + 6%L mm), and Q5 (160 + 8%*L mm). A 13-camera motion capture system (240 Hz, Vicon) and a pair of custom instrumented pedals (1200 Hz, Kistler) were used to collect kinematic and pedal reaction force (PRF) data, respectively.

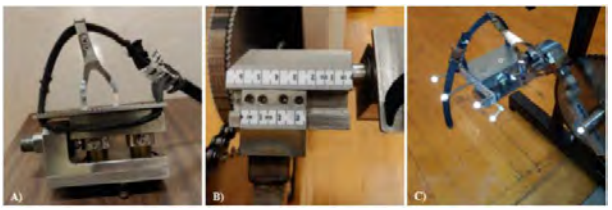

Figure 1. The custom pedal and crank arm assembly.

A mixed model analysis of variance was performed to detect differences between QF conditions ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The peak KAbM was significantly greater in QF5 than QF1, QF2, QF3, and QF4 ($p \leq 0.004$ for all comparisons, Table 1). The KAbM was increased by at least 30% in Q5 from Q1, Q2, Q3, and Q4. The abduction ROM was reduced in QF4 and QF5 compared to QF1. Peak medial PRF was significantly greater (more negative) in QF5 than QF1, QF2, and QF3 ($p < 0.001$ for all comparisons). The peak PRF was increased by at least 20% in Q5 from Q1, Q2, and Q3. There was no significant change seen in knee extension moment.

Our hypothesis about the change of KAbM was partially supported. The mean QF difference (2%L) of 18 mm between conditions across all participants was smaller than the fixed QF change (42 mm) which induced a significant increase in KAbM in previous literature [2]. This study was the first to investigate the effects of small and normalized changes in QF.

CONCLUSIONS

The results of this study show that it is possible to detect a significant increase in KAbM with changes in QF as small as 2% of leg length at a high QF. Our data suggest that it is feasible to modify inter-pedal distance in cycling exercise prescription for the benefits of modulating medial compartment loading for patients with knee OA.

Email: smoh433@aucklanduni.ac.nz

INTRODUCTION

To date, a combination of Inertial Measurement Units (IMUs) and Machine Learning (ML) techniques has been used in many studies to predict some specific joint angles and moments. However, the optimal IMU sensor placement, number of features, and window size for predicting all gait time series (joint kinematics and kinetics) have yet to be determined. This study aimed to investigate how a random forest (RF) model's performance can be affected by different IMU combinations, the number of features it uses, and window sizes.

METHODS

Twenty healthy volunteers (11F, 27 ±5 yrs, 1.70 ±0.70 m, 66 ±10 kg) were asked to walk over-ground for a minimum of 16 trials. Marker trajectories from a 12-camera optical motion capture system (Vicon), 7 IMUs (Vicon IMeasureU), and 3 GR plates (Bertec) were synchronised. Pelvis, hip, knee, and ankle kinematics and kinetics were computed using a MAP-client [2] scaled OpenSim model (gait 2392) using marker trajectories and GRFs. Acceleration and angular velocity from IMUs in different locations (a combination of the pelvis, thigh, shank, and foot IMUs) were used for feature extraction by Tsfresh [3]. For each IMUs combination, we first extracted the top ten relevant features for each target (joint angles and moments); then, an RF model was trained using the most important features. Once the best IMU combination was determined, we changed the number of features from 10 to 50 with intervals of 10 and window sizes from 0.5 to 2s with intervals of 0.25 simultaneously to explore how it can affect the RF model's accuracy. To evaluate the performance of the RF model, a leave-one-out analysis was used in each step. Data analysis consisted of root mean square error (RMSE) calculation.

RESULTS AND DISCUSSION

Average RMSE was calculated between the OpenSim computed and RF-predicted joint angles and moments for each IMU combination (Figure 1). The average RMSEs for all IMU combinations were in the same range. In the case of using only one IMU, the lowest prediction errors were related to feet IMUs for both joints' kinematics and kinetics prediction. Therefore, we investigated the effect of the number of features and window size on the RF model's performance using only the feet IMUs. Regarding the optimal window size, 0.75s length of data provided the lowest prediction errors among all. By increasing the number of features from 10 to 50, we saw that RMSE converged to a constant value after 30 features, which means 30 is the optimal number of features to predict joint kinematics and kinetics.

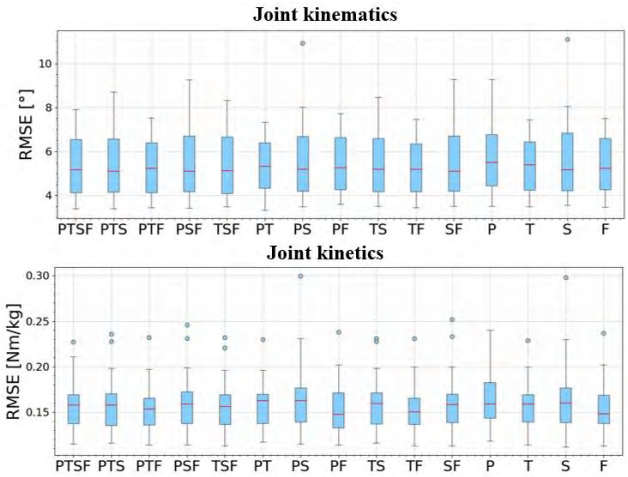

Figure 1 Joint kinematics and kinetics RMSE for different IMU placements. P stands for the pelvis, T for the thigh, S for the shank, and F for the foot.

CONCLUSIONS

This study suggests that using IMUs on each foot combined with an RF model is as accurate as using 7 IMUs with an average RMSE of 5.34 degrees for kinematics and 0.154 Nm/kg for joint moments' prediction. For future studies, it would be beneficial to explore how the IMU combination, number of features, and window size would affect the RF performance for muscle forces prediction. Moreover, determining a general optimal IMU sensor combination applicable to all functional movements would be of help to clinicians.

CAN COMPUTER VISION BE AS GOOD AS MULTI-CAMERA INFRA-RED SYSTEMS FOR MOTION ANALYSIS?

INTRODUCTION

Recent advancements in Computer Vision enables marker-less motion capture to potentially be a convenient and cost-effective alternative to conventional marker-based methods considered as the gold-standard. Marker-based motion capture is usually lab-based using multiple infrared cameras which requires extensive calibration and reflective markers attached on the human body. Marker-less motion capture drastically simplifies the requirements to just one or a few cameras from different angles [1]. Therefore, the purpose of this study was to quantify the accuracy of 2D and 3D marker-less motion capture through video processing from various camera angles and determine its feasibility.

METHODS

Two participants participated in this research, each of them were asked to perform simple fundamental movement skills: throwing a ball, catching a ball with different ball types (i.e., shapes, size, weight). Each participants performed 25 throws and 25 catches. Five cameras were used to video record the performance of those two participants and an infra-red motion capture system was used to collect kinematic data for those same trials (Qualisys, Sweden). Four video cameras were Qualisys cameras and positioned at various angles around the participant to test the optimal angle for kinematic detection: camera 1 in front (0 deg), camera 2 oblique (45 deg), camera 3 side (90 deg) and camera 4 oblique (135 deg). The camera 2 (oblique) camera was doubled with a 4k GoPro camera to test the effect of the camera resolution on the detection accuracy of the algorithm. The whole process was captured by the Qualisys system and video cameras simultaneously. 3D coordinates of the landmarks at a sampling frequency of 200Hz was exported from the Qualisys system. The videos recorded at 25Hz from Qualisys cameras and 59.94Hz from GoPro are processed using MediaPipe (https://google.github.io/mediapipe/) which predicts 3D coordinates of the landmarks frame by frame as demonstrated in Fig. 1.

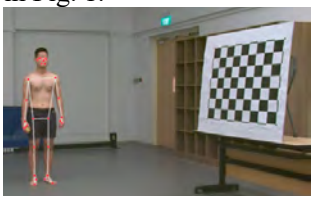

Figure 1 Sample of a camera view containing the calibration chessboard and the automatic detection of joints MediaPipe algorithm.

Accuracy and measurement error was therefore computed and compared between all the different views and camera types. Bland-Altman analysis, mean and standard deviation of absolute error was used to determine the validity of MediaPipe.

RESULTS AND DISCUSSION

Results were in accordance with similar set-up reported [2], while the % of measures outside the limit of agreement remains below 10% for all the conditions (average = 6.21%). While the frontal view showed the best results, the use of a higher resolution camera also shows better accuracy in the detection of the joints and kinematics (Table 1).

Table 1: Example of Bland & Altman results for a throwing movement

Camera View	Mean Bias (deg)	% Outside Limits of Agreement (+/- 1.96 SD)
1	12.44	6.44
2	15.97	5.62
3	15.37	6.71
4	14.42	8.16
2 (GoPro)	13.45	6.53

CONCLUSIONS

Computer vision algorithms seem to be a convenient tool for marker-less motion capture as they only require a single regular camera view to get 2D or 3D joint coordinates. While their accuracy in measuring raw angles is not perfect, they might be useful in detecting joint coordination, the occurrences of certain joint actions such as detecting the stroke frequency in swimming or running, or even to detect patterns of play in sport. Considering the continuous improvement in the algorithms, they represent a huge potential for movement analysis in the coming years.

Introduction

Kinetics plays an important role in biomechanics, especially in sports injuries such as anterior cruciate ligament rupture (ACLR) which occurs during fast sidestepping. One of ACLR's risks is ground reaction forces (GRF) [1], however, it's hard to acquire in the field. Artificial neural network (ANN) is used to estimate GRF from kinematics such as body landmarks [2] which is easily obtained out of the laboratory. The performance of ANN mostly depends on inputs, but the effect of the number of body landmarks as inputs on the performance of ANN is not clear. This study aimed to determine the effect of landmarks setup on the validity of GRF estimated during sidestepping by ANN.

Methods

Four different sidestepping were executed by 71 male college soccer athletes, in total 12 trials per athlete. The motion was synchronously captured by infrared cameras and force plates (FP). The lower body landmarks included bilaterally hip centers, knee centers, ankle centers, heels, and toes, along with the mid-hip. Besides the landmarks above, whole body landmarks contained bilaterally centers of the shoulder, elbow, and wrist, plus the head's center. Whole body landmarks were obtained by transforming from anatomically relevant retroreflective markers. Coordinates of body landmarks and GRF normalized by body weight (BW) from the touch-down to the take-off of the sidestepping were extracted and normalized to 100 points.

The dataset was split subject-wise into training (61 athletes), validation (6 athletes), and test set (4 athletes). Two ANNs with whole (18*3*100) and lower body landmarks (11*3*100) as inputs separately were trained to estimate posterior-anterior (AP), lateral-medial (ML), and vertical (V) GRF (3*100) in the same dataset above. Pearson correlation coefficient (R) and root mean square error (RMSE) was used to evaluate the performance of ANN. Statistical parametric mapping was used to analyze significant differences in GRF curves between ANNs and the FP. The paired t-test determined the difference in the performance of ANNs with whole and lower body landmarks as inputs.

Results and Discussion

No significant difference was found in the performance of ANNs between the two inputs. There were few time points in the results of the whole (AP: 10-12% and 93-95%, V: 5-12%) and lower body landmarks ANN (AP: 10-12% and 96%, V: 5-15%) were significantly different with the FP. Both ANNs showed high correlations (R > 0.94) and low errors (RMSE: AP < 0.8BW, ML < 0.8BW, and V 0.27BW) with FP which proved that ANN could exextract useful information from landmarks to estimate GRF. The results indicated information provided by lower body landmarks was enough for ANN to accurately estimate GRF during sidestepping and the upper body landmarks may be meaningless because the main movement and the acceleration were from the lower body. Just a few time points in the outputs of two ANNs showed significant differences between the FP and the results of other time points were credible and useful.

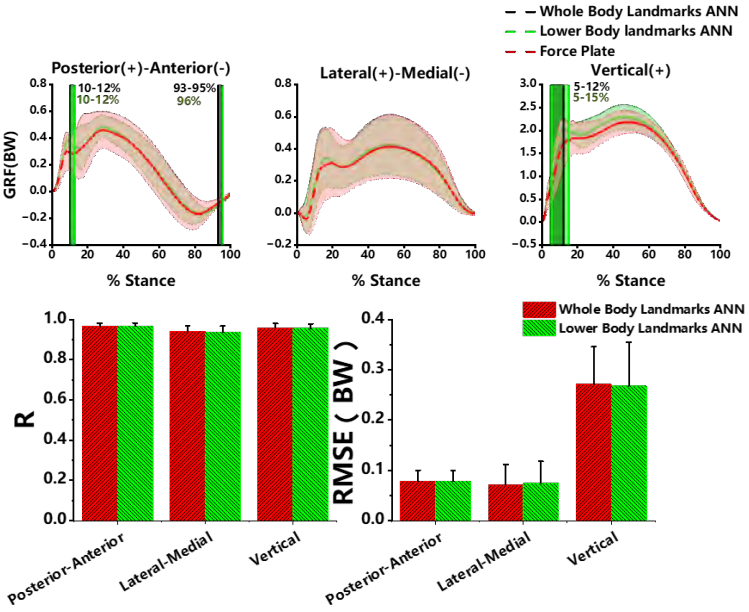

Figure 1: The performance of ANNs

Conclusions

The validity of ground reaction forces estimated by ANN during sidestepping wouldn't degrade with lower body landmarks as inputs compare to whole body landmarks. In practice, lower body landmarks are recommended as they could be used to obtain accurate ground reaction forces during sidestepping.

INTRODUCTION

Employing artificial neural networks (ANNs) to estimate parameters that cannot be directly or easily measured due to instrumentation limitations is a novel and feasible approach in biomechanics. One such application is stair walking; an important and physically demanding activity of daily living that is regularly studied to assess motor function in neurologic and orthopedic patients [1]. Three-dimensional (3D) ground reaction forces (GRF) provide input data for the determination of clinically relevant joint moments but in stair walking this generally relies on custom developed staircases with integrated force plates. A recently published ANN [2], trained to estimate 3D GRFs during stair walking using more than 3500 trials of 172 participants, reported correlations of 0.950-0.996 between ground-truth and predicted GRF signal. The significant size of the dataset, particularly from a biomechanics discipline perspective, suggests the trained ANN may be able to generalise when tested with new data inputs. However, it appears the training data in [2] was collected only by one research group that used a distinct data collection protocol, which may serve to restrict its generalisability to independent data from other laboratories and research groups.

In this study, we aim to investigate if Ma's [2] pre-published ANN can achieve similar GRF estimation accuracy as that achieved by the original source set, when independent test data inputs are used.

METHODS

The dataset provided by Ma [2] contains a trained ANN to estimate GRF for stair ascent and decent using 3D full-body joint angles as input data. The author further provides example data of a single participant. Independent test data collected by Komnik *et al.* [3] comprising 138 trials from 13 participants was used to test the accuracy of the proposed ANN. The stair setup in both studies was similar. Major differences between Ma's and Komnik's data were in the marker sets used which resulted in differences in joint angles [4]. To minimise differences, the accuracy of the model was evaluated using only 3D hip, knee, and ankle joint angles, which were more similar than upper body angles. First, we evaluated the accuracy of the pre-trained ANN, second, we applied transfer learning, and third, we fine-tuned the model using Komnik's data. The correlation coefficient (r) between the estimated and ground-truth GRF was determined for the stance phase of each step.

RESULTS AND DISCUSSION

The estimation accuracy of the base model was very good for Ma's provided sample data (r=0.976). However, the accuracy decreased using Komnik's data that was collected using a different marker set. The estimation of the GRF showed good accuracy for the anterior-posterior (r=0.868) and vertical (r=0.897) components, but not for the medio-lateral (r=0.640) component. The accuracy could be improved by 6.4% when applying transfer learning and another 4.1% when fine-tuning (Table 1) but it was still 9.0% lower than for the provided sample data of [2]. Since stair walking is a constrained movement, the variability in the training data is small. Hence, differences in joint angles due to the marker sets used cannot be covered.

CONCLUSIONS

This study shows that ANNs developed for biomechanics applications cannot be adopted easily to external datasets even when trained on a large dataset. Different experimental protocols, such as the use of different marker sets, can result in unknown patterns and larger variance in the input data. The ANN cannot handle unknown patterns and therefore estimate the desired output with low accuracy.

INTRODUCTION

One in five patients experiences dissatisfaction with their knee replacement surgery not explained by existing outcome assessments used in the clinic, such as patient-reported outcome measures (PROMs) [1]. Biomechanical variables such as joint kinematics and forces can be used as objective measures of outcome assessment and could explain inconsistencies in patient satisfaction when coupled with PROMs. These measurements could be collected using cheap and accessible wearable sensors such as Inertial Measurement Units (IMUs) in-clinic and out-of-clinic. Using IMUs also have the benefit of not just relying on the patient answering a questionnaire. This removes subjectivity and the possibility of misinterpreting the questions. This study aimed to determine the best combination of PROMs and IMU-derived biomechanical measures for predicting postoperative patient satisfaction (EQ-5D-5L VAS).

METHODS

Synced Optical Motion Capture (OMC) and IMU data were collected from four healthy participants (two males, two females, 36 ± 9 years, 160 ± 9 cm, 68 ± 14 kg, during treadmill walking) and 28 patients (13 females and 15 males; 23 TKR and 5 UKR, age: 68.2 ± 6.2; height: 1.67 ± 0.11 m; body mass: 87.5 ± 19.4 kg; BMI: 31.3 ± 5.4 kg/m2, overground walking).

Knee contact forces (KCF) were calculated via biomechanical simulation in OpenSim [2] using the healthy participant's data. Next, regression models were built with the KCF as the target variable and relevant IMU features obtained through the python package tsfresh [3] as the predictor variables. These features are then used to train surrogate models for predicting patient satisfaction.

28 patient datasets (IMU + PROMs) were used to build patient satisfaction models at four time points: during physiotherapy, six weeks, six months, and one year after surgery. In addition, post-operative PROMs (Oxford knee score (OKS), OKS change score (pre- to post-operative OKS), forgotten joint score (FJS), EQ-5D-5L VAS and IMU measurements during physiotherapy sessions were collected from knee replacement patients.

RESULTS AND DISCUSSION

Selected features could accurately ($R^2 > 0.90$) predict the total KCF of seen participants across the stance phase 84% of the time. Using this result, a model to predict the EQ-5D-5L VAS score using OKS and IMU time-series features associated with knee kinematics and KCF during the patients' recovery period was created for the four time points. The most important combinations of variables for each time points were OKS, knee kinematics with OKS, KCF with OKS, and KCF only, respectively. The chosen models were able to predict EQ-5D-5L (VAS) scores within a mean difference of -0.070±4.33, 1.11±2.51, 0.29±1.85, and -0.23±1.58 units of the actual (95% confidence interval) for each time points (Figure 1).

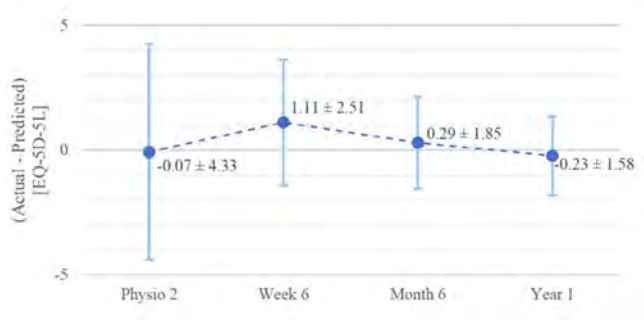

Figure 1 The mean difference and 95% confidence interval between the actual and predicted patient satisfaction across the four time points.

CONCLUSIONS

We have created a powerful predictor of satisfaction corresponding to knee contact force and OKS. In addition, due to the use of the same feature set biomechanics measures, we could estimate the patient's gait parameters if their score suggests that more information is needed to assess their joint function.

USING DEEP LEARNING TO PERSONALIZE STROKE REHABILITATION

Sina David[1], Sonja Georgievska[3], Cunliang Geng[3], Yang Liu[3], Michiel Punt[2,3]
[1] Department of Human Movement Sciences, Vrije Universiteit Amsterdam, Amsterdam, The Netherlands

INTRODUCTION

An impairment of gait due to a stroke results in a decline in quality of life and independence. Setting up efficient gait training requires an objective and wholesome assessment of the patient's movement pattern to target individual gait alterations. Current assessment tools are limited in their ability to capture the complexity of the movement and the amount of data acquired during gait analysis. This study aimed to investigate the ability of variational autoencoders (VAE) to recognize different gait patterns within both, pathologic and healthy gait.

METHODS

The 3D lower-limb joint angles of 29 stroke survivors [1] and 42 healthy participants [2] were used to train a VAE. All participants walked on a treadmill at preferred speed for several minutes. The data was acquired using optical motion capturing (see references for further details) and joint angles were calculated according to the ISB recommendations [3]. The foot contact events were used to segment one measurement of a participant into multiple epochs of four seconds of data (50 Hz) resulting in 5876 periods. These formed the input data for the VAE. The test set consisted of 2300 periods (35%). A 1D convolutional VAE was used as an unsupervised deep learning technique, containing 3 convolutional layers, a flatten and dense layer. The information from the encoder is represented in 3 latent variables which were used as the 3D coordinates to map each of the input files in the 3D space to further analyse the characteristics of a specific location. The decoder was used to reconstruct the input based on the latent space and is symmetrical to the encoder. The root mean squared error (RMSE), normalized RMSE (RMSE normalized to the joint's range of motion) and Pearson correlation coefficient r between the input and reconstructed signal was calculated to evaluate the reconstruction accuracy.

RESULTS AND DISCUSSION

The average RMSE and the nRMSE for the test set were 6.03° ± 2.71 and 23.02 % ± 4.05 respectively.
The correlation between the reconstructed and the raw data showed high (range 0.70 – 0.91) to moderate relationships (range 0.52 – 0.69) depending on the joint and plane.
The regional analysis revealed that the gait periods of one participant are located within the same region, apart from trials of another participant. Thus, supporting that the VAE can detect distinct gait patterns and also explaining the overall location of the stroke survivors versus the healthy participants (Fig. 1). Following the spiral structure of the latent space, an increase in the peak knee flexion angle and in the hip's sagittal plane amplitude was discovered. Also, a change from internally rotated to externally rotated ankle joint angles can be seen with an overall increase of transverse plane amplitude in the ankle while the frontal plane amplitude of ankle joint motion declines. Selected regions can be characterized by a higher asymmetry, reduced knee extension angles during the late swing as well as an altered plantar flexion angle, typically presented by stroke survivors. This opens a new opportunity to assess the gait quality of a patient purely based on the gait pattern. During the rehabilitation progress, the patient can be monitored by presenting the new gait data to the VAE and tracking a change of the patient's location within the latent space over time.

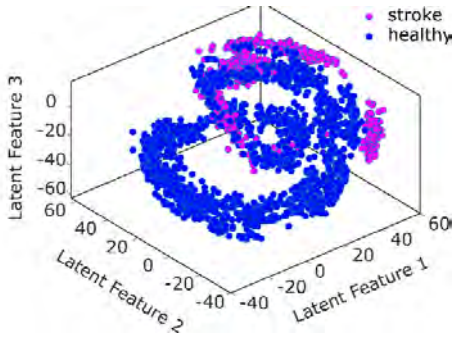

Figure 1 Representation of the test set within the 3D latent space.

CONCLUSIONS

The presented results highlight the promising nature of deep unsupervised learning algorithms to assess the movement pattern of an individual. By being able to recognize the smallest differences in gait patterns, VAEs could be utilized as an objective and data-driven tool to assess the holistic quality of movement in general and the gait alterations of patients more specifically. This is beneficial for the clinician to be efficient without loss of quality, and it is beneficial for the patient as therapy that focuses on individual needs will improve the rehabilitation outcome.

A MACHINE LEARNING APPROACH TO CHARACTERISING RUGBY HEAD IMPACTS FOR LABORATORY RECREATION

INTRODUCTION

The incidence of head impacts in rugby has been a growing concern for player safety. While the use of headgear shows potential to mitigate head impact intensity [1,2], evaluating its on-field effectiveness is challenging. Rugby-specific laboratory testing methods, which involve the use of a steel headform and a steel impact surface [3], diverge from ecological validity. Head impact testing standards relevant to other collision sports (such as NOCSAE) have not been shown to represent unhelmeted rugby head impacts. This study aims to address this limitation by proposing a novel method for characterising head impacts for recreation in a laboratory drop test setting.

METHODS

The laboratory head impact dataset comprised 1,806 individual impacts using a drop test rig and a Hybrid III 50th percentile male headform with and without the accompanying HIII neck [1,2]. Linear and rotational accelerations, and rotational velocities, were measured for each impact and used to derive a feature set consisting of 73 single-value features. Four parameters were required to categorise a laboratory head impact: the impact location, impact surface angle, neck inclusion, and drop height. Assuming different kinematic features would better predict each of the four drop test parameters, separate k-nearest neighbours (KNN) models were developed for each. Data was split into training (70%) and testing (30%) datasets with each KNN model fit to the training data. The permutation feature importance algorithm identified the 10 most important features from which 10-fold cross-validation identified the optimal number of neighbours and subset of kinematic features. Accuracies and f1-scores were subsequently found using the hold out testing dataset.

RESULTS AND DISCUSSION

The KNN models predicting the impact location and impact surface angles achieved accuracies during testing of 97.6 and 93.0% respectively using the normalised peak linear and rotational accelerations in the x and z directions. The KNN model predicting neck involvement displayed an accuracy of 99.6% using only the log of the rotational velocity injury criteria (RVIC, algorithmically identical to the rotational injury, and head injury, criterion [4], but applied to the time-series rotational velocity), followed by the ratio of the PLA to the peak rotational velocity (PRV). This was in line with previous investigations that found the duration of the time-series rotational velocity peak to be most heavily affected by the presence of the HIII neck [1]. Finally, drop height was predicted with an accuracy of 96.0% using only the change in linear velocity during the impact. The f1-score for drop height predictions was lower than all other drop test parameters (Table 1). This resulted from the low precision and recall associated with the least common drop heights (7.5 and 22.5cm) with only 6 and 7 data points each compared to 130 – 133 for all others.

CONCLUSIONS

The present study proposed a method for categorising rugby head impacts for recreation in a laboratory setting. When combined with time series comparison and finite element simulated brain strain, this method may inform the development of improved headgear impact testing practices, providing more realistic assessments of the protective performance of new headgear.

INTRODUCTION

The post-mortem interval (PMI) estimation is a vital tool in forensic pathology focused on investigating the circumstances surrounding death. Routine methods include analyses of the rectal temperature [1], lividity [2], stiffness [3] and the electrical excitability of the facial muscles [4]. PMI is influenced by a number of factors and is reported as a suspected time since death period rather than a determined point in time [5]. Changes in the mechanical properties of biological tissues after death remain unexplored for forensic time since death estimations. Soft tissues, such as brain tissue, are of particular interest for improved PMI estimation due to rather fast decomposition which can occur in a matter of hours [6]. In this work, for the first time, the changes in the mechanical properties of ovine brain tissue were studied over four days post-mortem at different ambient conditions to probe the correlation between the tissue decomposition and PMI.

METHODS

Eight abattoir ovine brain tissue samples from frontal lobe, parietal lobe, anterior and posterior deep brain, superior colliculi, pons, medulla and cerebellum of 30 sheep were stored at an ambient temperature of 20°C ('warm') and further eight samples were refrigerated at 5°C ('cold'). The samples underwent rheological tests (MCR302; Anton Paar, Graz, Austria) on days zero to four after death. A 0.1 N preload was applied to the sample fully submerged in normal saline solution at 20 °C to ensure adhesion to the contact surfaces. The sample was given 100 seconds to recover before a total of 50 cycles of a rotational shear of 3% at 3Hz. The strain magnitude and strain rate were selected to prevent tissue slippage during testing and ascertain the strain rate independant tissue response. The storage modulus, loss modulus, complex shear modulus of the brain tissue were measured on a daily basis for four days.

RESULTS AND DISCUSSION

All brain tissue biomechanical rheological properties decreased for all brain regions investigated between 0 and 4 days as the tissue decomposed. The rate of tissue degradation was higher for the room temperature brain tissue compared to the refrigerated brain tissue. The day 4 moduli measured to be up to 20% and 40% lower than on day 0 for the cold and warm tissues respectively. Day 0 values of the storage modulus, loss modulus, complex shear modulus and torque revealed statistically significant decreases for all measured points in time after death. Additionally, the day 0 values comparison between the sampling brain regions showed no significant differences of the biomechanical properties within the cerebral samples. Some scatter was observed for the pons, medulla and cerebellum samples. The post-mortem tissue biomechanical properties over the subsequent four days revealed differences between the various brain regions. The samples from different regions exhibited varied rates of degradation over time reflected in the differences in the corresponding measured moduli. The storage moduli of the cerebral samples, for instance, were gradually decreasing over the four days of testing. While the medulla oblongata, being a part of the brainstem, storage moduli increased between days 3 and 4.

CONCLUSIONS

The biomechanical properties of brain tissue can discriminate between fresh and at least one-day-old samples with rheometry tests. Similar trends in brain tissue post-mortem mechanical moduli decrease between brain regions were observed but the sample retrieval sites was a major factor alongside with the tissue storage conditions. This evidences the value of biomechanical analyses for forensic time since death estimations.

INTRODUCTION

Cartilage consists of proteoglycans (PGs), collagen fibres, interstitial fluid and ions. The main function of PGs is to provide compressive stiffness to cartilage by osmotic swelling [1]. In joint disease such as osteoarthritis (OA), PGs and/or collagens in cartilage degrade, causing functional deficit and joint pain. The PG degradation is generally construed as a loss of PG abundance [2]. It is unclear if the remaining PGs maintain the quality of generating osmotic pressure for load-bearing function. The purpose of this study was to estimate the osmotic pressure generating ability of PGs in cartilages at different OA stages using a geometrically, structurally and compositionally realistic Finite Element (FE) model. We hypothesised that the PG degradation in OA is related to abundance loss, but not to PG ability in generating osmotic pressure.

METHODS

18 cartilage-bone specimens harvested from tibias of 7 patients aged 68–79 years were measured for the depth-wise composition and structure of the cartilage [3]. PG abundance was measured in terms of optical densities of Safranin-O stained sections, which were converted numerically into fixed charge density (FCD). Collagenous organisation and content were measured by polarised light microscopy (PLM) and infrared spectroscopy, respectively. Based on OARSI scoring of the histological sections, the specimens were divided into healthy (0–1, n=5), early OA (2–3, n=6), and late OA (4–4.5, n=7) groups.

Cartilage was modelled as a multi-phasic material containing solid (collagens & PGs), water, and monovalent counterions (Na^+, Cl^-) [4]. PGs were modelled to contribute to tissue compressive stiffness by osmotic swelling resulting from the FCD and the configurational entropy. Collagenous network was represented by a continuous ellipsoidal distribution based on PLM data, with individual fibres modelled to only sustain tensile loads. Fluid flow is assumed to obey Darcy's law with an isotropic permeability.

The tissues were indented by four steps of 5% nominal tissue strain and stress-relaxed for 15-min at each step. The resulting indentation curves were used for FE modelling-informed numerical optimisation procedure to determine five material parameters, which include the fibre modulus (ξ) for collagens, as well as the attenuation of FCD (α_F), and the attenuation of configurational entropy (β_F) for PGs. A value of 0.0 and 1.0 for α_F or β_F indicates full and no attenuation, respectively.

RESULTS AND DISCUSSION

The optimization procedure produced a good fit to the experimental indentation data, with r^2 ranging from 0.87–0.95. PG abundance loss with OA was observed from densitometry data of unloaded tissues (Fig. 1B). We also found that the weight-bearing quality of PGs were severely degraded compared with healthy tissues (i.e., decrease of α_F and β_F values, Fig 1A), causing reduced osmotic pressure and, thus, decreased tissue compressive stiffness. Consequently, the superficial tissues of OA cartilage (top 10% depth) were deformed more than the healthy cartilage during indentation, leading to ~2x increase of the local FCD (Fig. 1B). Surprisingly, OA progression did not affect the moduli of individual fibres, with mean values ranging from 223 – 377 MPa for healthy, early OA and late OA tissues.

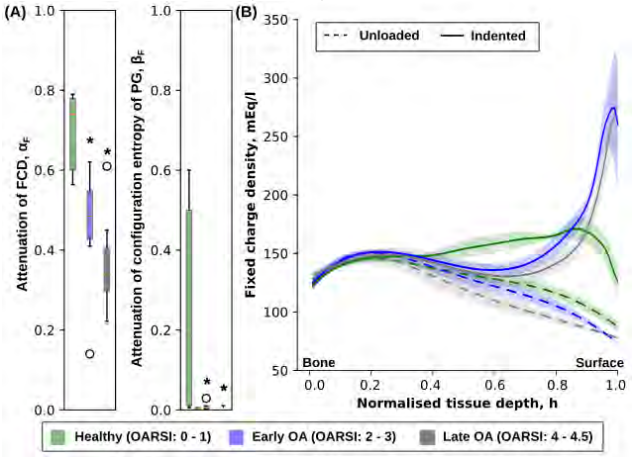

Fig. 1. (A) Fitted material properties of PGs, and (B) FCD distribution as a function of tissue depth for cartilage of different OA severity. * indicates statistical difference from healthy group.

CONCLUSIONS

Degradation of PGs involved a loss of their abundance and quality. This led to a doubling of FCD during physiological loading, which could cause additional metabolic stress to the cells and swelling tension to the embedded collagenous network. These findings highlight the significance of PG quality loss in OA pathogenesis.

INTRODUCTION

Due to its highly hierarchical structure, the mechanical properties of skeletal muscle are anisotropic. However, in the field of muscle biomechanics, most elastography methods assume the skeletal muscle as an isotropic material, which violates the anisotropy of skeletal muscle and cannot bring reliable insights into muscle function [1]. Recently, an increasing number of studies have proposed methods that consider the anisotropy of soft tissue in magnetic resonance elastography (MRE). Still, the use of anisotropic MRE in evaluating mechanical properties of skeletal muscles has been very limited due to the lack of a reliable methodology. This study aims to propose a direct MRE inversion approach with the combination of diffusion tensor imaging (DTI) for *in vivo* quantification of the anisotropic mechanical properties of two major ankle plantarflexors, gastrocnemius (GAS) and soleus (SOL).

METHODS

MRI data of 5 able-bodied subjects (3F/2M, 27.4±3.6 years) were analysed. All subjects gave written informed consent before participation. The study was approved by the Swedish Ethical Review Authority. The MRI scans were performed on a 3.0 Tesla MR scanner (Ingenia CX, Philips, Netherlands). All subjects were scanned in a supine position, with the thigh relaxing on a wedge and the foot fixed on a foot support while the GAS and SOL were assumed remaining relaxed. Anatomical scans, DTI, and multifrequency MRE were performed. The MRE scans were performed at three motion-encoding gradient directions at three frequencies (40, 50 and 60 Hz). The GAS and SOL were manually segmented into six sub-compartments according to the fascicle orientation. Tractography was performed using DSI studio for each muscle sub-compartment to identify the muscle fascicle coordinate system. The skeletal muscle was modelled as an incompressible transverse isotropy material. Laplacian unwrapping was used for phase unwrapping. Direct inversion of three complex-valued viscoelastic constants, shear modulus in the plane of isotropy μ_{12}^*, shear modulus in the plane of symmetry μ_{13}^*, and Young's modulus in the plane of isotropy E_3^*, were solved based on the curl-based wave equation [2]. The storage, loss, and magnitude moduli were calculated for each muscle sub-compartment. The performance of the proposed approach was evaluated as whether the characterization of anisotropy ($\mu_{12}^* \neq 1/3\,E_3^*$ and $\mu_{13}^* \neq 1/3\,E_3^*$) and frequency dispersion (different stiffness responses at various frequencies) can be determined in individual muscle sub-compartment.

RESULTS AND DISCUSSION

Anisotropy was found in all muscle sub-compartments at each frequency. Both $\mu_{12}^* \neq 1/3\,E_3^*$ and $\mu_{13}^* \neq 1/3\,E_3^*$ existed for all the storage, loss, and magnitude moduli, which was in line with previous research [2]. Frequency dispersion was also observed as stiffness increased with higher frequency (Figure 1). The major advantage of our proposed approach was the consideration of the complexity of fascicle orientation within GAS and SOL, as *in silico* experiments revealed that the accuracy of the MRE inversion decreased with an increase in the fascicle orientation complexity [3].

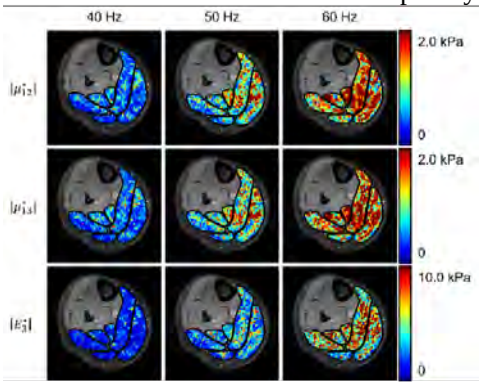

Figure 1 Elastograms of the three magnitude moduli at different MRE frequencies overlapped on the anatomical image.

CONCLUSIONS

We proposed a direct MRE inversion approach with the combination of DTI that can quantify the anisotropic mechanical properties of the skeletal muscle. The proposed approach has the potential to more accurately quantify muscle stiffness *in vivo* in related biomechanical and clinical research.

INTRODUCTION

Reducing head injuries is a priority since they represent one of the most likely cause of hospitalization and death after traumatic events. Skull and brain traumas could be mitigated by protective gear, and research is ongoing to improve its effectiveness. Indeed, evaluation of protective performance is carried out using rigid head forms and simple criteria based on linear and rotational kinematics [1,2], but is well known by numerical modeling that more factors such as strain/stress contribute to brain damage mainly during rotational impacts [3]. To address limitations of rigid head forms, some authors developed more biofidelic surrogates which account for soft tissues and other anatomical features [4,5]. Aim of the study is to improve an existing biofidelic head surrogate to investigate brain stress thanks to novel sensors [5,6], and test it in drop tests.

METHODS

Adult male MRI scans were obtained and simplified in a mesh manipulating software (MeshMixer, Autodesk, USA). Skull was divided into two halves and 3D printed in Polyamide with laser sintering technique. Brain and scalp models were used to create a set of dies to cast the two elements in PlatsilGel OO30 and PlatsilGel 10 silicone rubbers (Polytek, USA), respectively. During the casting of the brain: a tri-axial accelerometer, a tri-axial gyro meter, and a six-axis stress sensor [6] were embedded in its centre of mass. After completing the casting, the brain was covered with a 5 mm thick layer of open-cell foam to simulate the sub-arachnoid space of the meninges. Then, the brain was inserted in the skull which was closed and sealed. After closure, the cavity between skull and brain was filled with water to simulate the cerebral-spinal fluid, and the scalp was fit over the skull. Figure 1a shows the assembled head.
To test the surrogate, an anvil with a 44 kN load cell was prepared and preliminary drop tests from varying heights were performed. In these first trials, a Vega mountaineering helmet (Salewa, Italy) was fit on the head. Data were collected at 5 kHz and the 25 ms from first contact were analysed to compute injury criteria such as HIC [1] and peak Von Mises stress [3].

RESULTS AND DISCUSSION

Preliminary tests showed the response of the head as a function of energy and are reported in Table 1. Example of stress development inside the brain is showed in Figure 1b. Highest forces, acceleration, and stress were observed in the mid energy impact. Conversely, data from the head sensors better follow increases in load cell peak force, indicating a possible error in the test procedure that needs investigation. Nevertheless, tests with higher energy will be performed since injury criteria of HIC and Von Mises stress showed low values compared to hazardous thresholds [1,3].

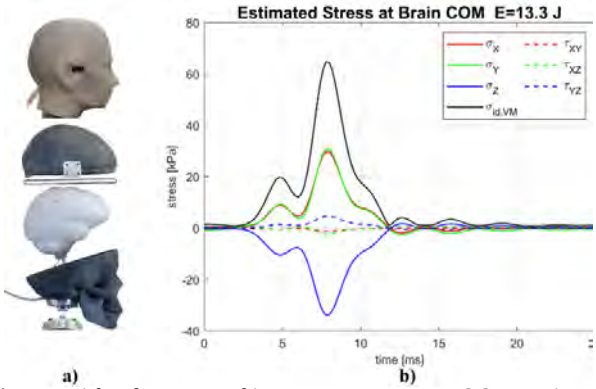

Figure 1 a) head surrogate; b) Von Mises stress in 13.3 J test (Z direction of impact; X, Y transversal directions).

CONCLUSIONS

The presented head surrogate includes several anatomical features which are rarely found in literature. Moreover, its sensors allow the experimental evaluation of injury criteria both based on global kinematics and on brain kinematics and stress/deformation. Further test will aim to increase impact energies and to validate the surrogate against numerical models and/or available cadaveric data under multi-directional impacts.

Email: vaibhav.shah@umontreal.ca

INTRODUCTION

Recent advances using deep learning to predict joint angles from inertial measurement units (IMUs) are promising [1], [2]. Nevertheless, current methods lack the accuracy of marker-based systems. Moreover, none of the prediction strategies have applied knowledge from pre-existing physical methods to guide model architecture. Here, we present a novel model with a "predict-update" block—based on the extended Kalman filter concept. We hypothesize that our approach will accurately predict sagittal plane knee joint kinematics.

METHODS

To demonstrate our approach, we used a database of IMU-based gait data from 30 participants [3]. First, ground truth was obtained by computing knee flexion/extension angles using a Complimentary filter (c.f. [4]). Next, trials were separated into two continuous gait cycles. A sliding window (window size = 60 and stride = 5) of acceleration and gyroscope data of thigh and shank sensors were used to predict knee flexion/extension angles. A subjectwise split with five repetitions (train/test: 80/20: 24/6 subject) validated model performance via the root mean squared error (RMSE). The model consisted of two blocks: the predict block, with three models (T1, T2, T3), and the update block, with two models (T4, T5). Blocks included Convolutional Neural Networks (CNNs), long short-term memory units (LSTMs), or combinations of the two (see Table 1). The predict block used the first 50 frames to predict the subsequent 10 frames, while the update block used the last 10 frames of present and predicted data to optimize results.

RESULTS AND DISCUSSION

The best configuration is a series of CNNs with a final LSTM block in T5 (Table 1). Average RMSE across all folds was 3.80 (mean) and 2.98 (median) (Fig. 1a). An example of predicted knee angles with predict block improving results is shown in Fig. 1b.

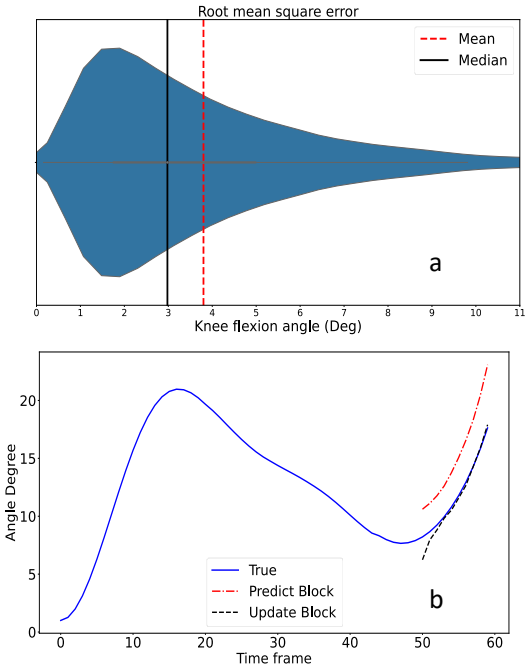

Figure 1 Prediction errors (a) and example predictions (b).

CONCLUSIONS

Results of the study show that a "predict-update" configuration optimizes predictions. Performance was improved compared to past studies where individual gait cycles were used as inputs [5]. Future work will optimize the model with motion capture data and extend to all lower-limb joints and planes. Our approach may facilitate real-time prediction scenarios.

INTRODUCTION

Social insect performances are inspiring robotics because of its remarkable cooperation in collective tasks. Yet, the phenomenon of collective transport among worker ants is often poorly understood, although it exists at least in 40 genera in different subfamilies of Formicidae [1]. Cooperative transport, occurs when a group of individuals work together to move an otherwise unmanageable object. However, analysing ant locomotion is challenging due to its scale. Current works are often reduced to one or few individuals and consider only the main joint locations [2]. To overcome this limitation, this study proposes to perform 2D kinematic analysis of a collective transport model: the long horn crazy ant *Paratrechina longicornis*. Our assumption is that the acceleration of the ant heads ($\vec{a}$) reveals their action forces on the load according to the fundamental physics principle (FPP, $\sum \vec{F} = \overrightarrow{mag}$) and explain the acceleration of the load centre of mass ($\overrightarrow{ag}$). The aim of this study is a first attempt to verify this assumption on the basis of the simplification of the forces to the accelerations measured thanks to the kinematics.

METHODS

In order to get the kinematic of a group of ants that collectively carry a load, we filmed from above a walkway (20 x 2,5 cm) (fig. 1a). Three infrared strobe spots, synchronised with the camera sampled at 300 Hz, were used to illuminate the walkway, allowing us to achieve a better contrast and reveal ant's joints. Then, the X, Y axes corresponding respectively to the antero-posterior and medio-lateral directions of the walkway, were defined by digitising the points of a control object (Lego® brick) of known dimensions. After a calibration, the location of the points on the ant's body and the load were tracked and specified in an external 2D coordinate frame calculated by Vicon Motus (v.10) software. This allows us to build a polyarticulated model comprising the four ant's heads and the load they transport.

RESULTS AND DISCUSSION

A set of 12 points of interest allowed digitizing the ant's necks and mandibles thus the corners of the load carried (fig. 1a). They were then used to define a 2D stick model system. The trajectories of the centre of mass of each ant's head and the one of the load in the XY frame can then be followed (fig. 1b). The acceleration of the load and of the ant's heads (fig1. c, d) calculated from these points have similar shapes during the 3 first seconds of the collective load transport (fig1. c, d). After this period, the shapes of the curves vary, which can sign the time of the beginning of the rotation of the load occurring at the end of the recording. Indeed, the load rotates due to the moment of force applied by the ants.

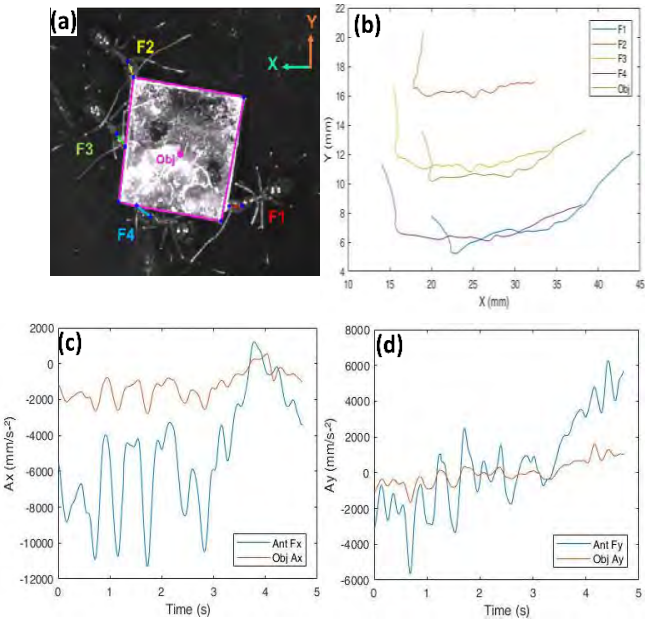

Figure 1: (a) Anatomic points locations: mandibles and ant's neck, and 4 points for the load. The nest was on the left of the image. **(b)** Ant's and load center of gravity trajectories. **(c, d)** Evolution of the acceleration (mm.s-2) of the ant's head (blue) and of the load carried (red) respectively on X and Y axis.

CONCLUSIONS

The purpose of this study was to test a method to estimate the forces applied by four ants on a load they collectively carry. The results demonstrate the accuracy of the method to discern the translations of the object due to the action force of the ants. Furthers investigations will enable us to precise the method to consider both translations and rotations in 3D to finally address the collaboration and the efficiency of the ants.

INTRODUCTION

Different running landing patterns such as rearfoot striking (RFS) and forefoot striking (FFS) may affect kinematic and kinetic parameters associated with the risk of tibial stress fractures (TSF). Risk factors relating to TSF are not clear and it is important to quantify internal loading [1]. Foot strike is known to influence the work done at the ankle [2] which in turn may influence the loading of the tibia through muscular-tendinous forces. Thus, the aim of this study was to evaluate the influence of foot strike on tibial bending moments and stress.

METHODS

Nineteen recreational runners (9 males and 10 females) with a habitual RFS participated in this study. Participants were asked to run with their habitual running foot strike (HFS) pattern overground at 4.0 m/s (±5%). Participants were then asked to modify the landing patterns to a distinct RFS or FFS randomly. Participants were given verbal feedback regarding the landing patterns, defined as follows: a foot strike angle with a positive value represents toes higher than heel at the point of ground contact (HFS: 14.3 ± 6.4°; RFS: 29.0 ± 6.3°; FFS: -4.4 ± 3.9°; mean ± SD). Kinematic and kinetic data were recorded using 3D motion cameras and force plates. Tibial stresses in the sagittal plane were estimated at a cross section area at the distal 1/3rd of the tibia [2] using a customized Matlab script (Mathwork Inc.) [3]. Bending moments due to muscular forces was calculated using static optimization. One-way repeated measures ANOVA SPM analyses (www.spm1d.org) were conducted to compare time series throughout running stance ($p<0.05$). Post-hoc paired t-tests were performed with a Bonferroni correction.

RESULTS AND DISCUSSION

SPM indicated a main effect for the bending moment, anterior and posterior tibial stresses (Figure 1, $p<0.001$). Post hoc SPM paired t-test revealed that the bending due to muscular forces in FFS increased in comparison to both RFS and HFS (3-56% stance; 3-33% stance, respectively). The anterior stresses in FFS increased in comparison to both RFS and HFS (2-50% stance; 3-25% stance, respectively). The posterior stresses in FFS increased in comparison to both RFS and HFS (2-52% stance; 3-28% stance, respectively). There were no differences in anterior and posterior stresses between running with RFS and HFS. The greater bending due to muscular forces observed in FFS compared to other foot strikes may be the main explanation for the greater tibial stresses.

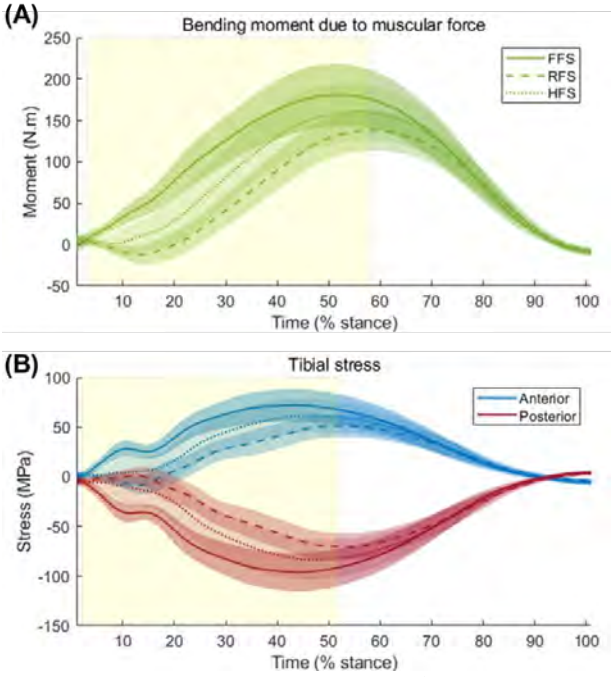

Figure 1 Bending moment due to muscular forces (A), and tibial stresses at the anterior and posterior peripheries (B). Vertical shaded areas indicate a main effect with a significant difference. Solid, dot, and dashed lines represent FFS, HFS and RFS, respectively.

CONCLUSIONS

Running with FFS could increase sagittal bending moments due to muscular forces at the distal 1/3rd of the tibia as a result of greater tibial stresses. This may have implications for the risk of TSF.

MUSCLE SHAPE CHANGES AND GEARING ARE MEDIATED BY INTERNAL MUSCLE PROPERTIES IN THE HUMAN GASTROCNEMII

INTRODUCTION

Skeletal muscles bulge when they contract. These dynamic three-dimensional shape changes coupled with fibre rotation, influence a muscle's mechanical performance by uncoupling fibre velocity from muscle belly velocity in a process known as gearing [1]. Alterations in internal muscle properties, owing to aging [2] or disuse, may mediate the direction and degree to which a muscle bulges and gears during a contraction [3], but this remains unexplored during *in vivo* contractions. The aim of this study was to determine the influence of internal muscle properties on *in vivo* muscle shape change, fibre rotation, and gearing in the human gastrocnemii during isometric plantarflexion contractions.

METHODS

Twenty younger (24±3y) and 13 older (70±4y) adults participated in this study. Multi-modal imaging techniques including shear wave elastography, magnetic resonance imaging, and B-mode ultrasound were used to measure shear modulus (index of stiffness), intramuscular fat, and physiological cross-sectional area (PCSA), respectively. A dual probe ultrasound configuration was used to record synchronous changes in fascicle length, muscle thickness, and pennation angle during submaximal (30% MVC) and maximal isometric plantarflexion contractions in the MG and LG while participants laid prone with their ankle fixed at 90 deg. Gearing was calculated as the ratio of fascicle velocity to belly velocity (calculated with fascicle length multiplied by cosine pennation angle). Linear mixed effects models were used to determine the influence of Shear Modulus, Intramuscular Fat, and Fat-corrected PCSA on the change in pennation angle, muscle thickness and gearing. Significance was set to p=0.05.

RESULTS AND DISCUSSION

The MG had greater shear modulus (p<0.001), intramuscular fat (p=0.019), and fat-corrected PCSA (p<0.001) compared to the LG. The MG had higher gearing, greater fibre rotation, and less bulging in thickness at 100% MVC compared to the LG (all p<0.001). Fat-corrected PCSA was positively associated with fibre rotation, gearing, and changes in muscle thickness during submaximal contractions (all p<0.001), but negatively associated with changes in muscle thickness during maximum contractions (p<0.001). Increased muscle stiffness and intramuscular fat were related to limited muscle bulging in thickness (p=0.008) and reduced fibre rotation (p=0.014), respectively, but only at high forces (Fig. 1).

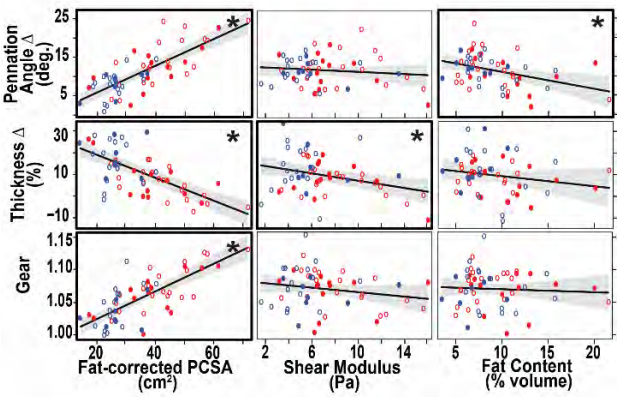

Figure 1 Effect of internal muscle properties on change in pennation angle, thickness, and gearing at 100% MVC. Data is shown for older (filled circle) and younger (open circle), medial gastrocnemius (red) and lateral gastrocnemius (blue). Darker lined boxes with an asterisk (*) indicates a significant relationship.

CONCLUSIONS

Our results highlight that internal muscle properties play an important role in modulating muscle shape change and gearing, particularly during high force contractions. Further, differences in internal properties between synergistic muscles may lead to differing mechanical behaviours. These findings improve our understanding of the factors that influence a muscle's mechanical response to force (i.e., gearing) which has future implications for preventing and treating muscle deficits associated with aging, disease or disuse.

INTRODUCTION

The human ankle joint contributes up to 50% of the total mechanical power for walking and running [1], but it is unclear how the foot helps or hinders the ankle's ability to generate power. The unified deformable (UD) power approach is ideally suited for analyzing foot and ankle power, because it simplifies the foot's complexity by assuming that all structures distal to a proximal rigid body (bone) are massless and deformable [2].

We introduce a novel approach that applies the UD power model to highly accurate bone motion from biplanar videoradiography (BVR) and force plate measurements. This allows us to use the talus as the proximal rigid segment to compute foot power over the traditionally used calcaneus. The talus offers advantages over the calcaneus because it is the apex of the arch and all foot structures are distal to it. Our approach is advantageous because it allows us to characterize foot, ankle-foot, and talocrural (ankle) power.

Here, we seek to understand the kinetics underlying the previously observed coupling of medial longitudinal arch and ankle kinematics [3],[4]. We expect the foot and ankle will simultaneously begin generating power during propulsion.

METHODS

Six participants walked and ran in minimal shoes over split force plates while BVR data was captured. Models from CT scans were used to find the position and orientation of the foot bones over stance. Dorsiflexion of the first metatarsal with respect to the calcaneus defined arch deformation.

A UD segment analysis applied to the talus and tibia quantified the instantaneous power of the foot and ankle-foot complex, respectively. Ankle power was defined as the ankle-foot minus the foot power. The UD foot power was also calculated using the calcaneus to understand differences between using the talus and the calcaneus.

RESULTS AND DISCUSSION

The foot, ankle-foot, and ankle dissipate power in the first part of stance then generate power later in stance (Figure 1). Both the foot and ankle begin to produce power simultaneously (overlapping confidence intervals) at the point where the arch is maximally flattened, and the ankle is maximally dorsiflexed for both walking and running (72% ± 4% stance walking, 50% ± 2% stance running).

The foot power calculated using the calcaneus (not shown) agrees with the talus prior to toe strike. The calcaneus underestimates the positive power generated by the foot during propulsion for both walking and running.

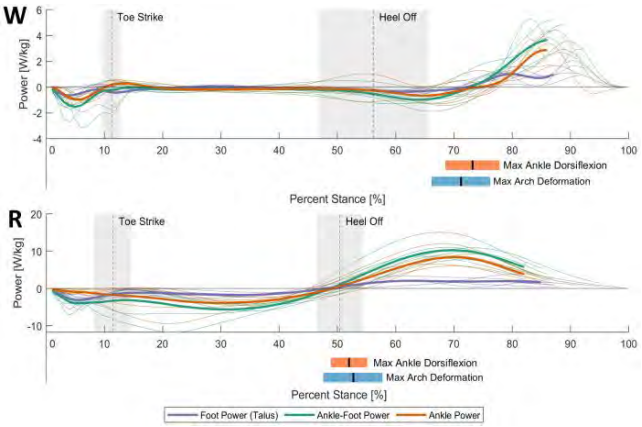

Figure 1. The UD foot, ankle-foot and ankle power plotted over stance for walking (W) and running (R). Thin lines represent each subject with the thick lines representing the mean (mean lines stop when data becomes unavailable for a single subject). Mean ± standard deviation of toe strike and heel off are indicated with dashed lines and gray shading. Orange and blue boxes represent mean ± standard deviation of maximum ankle dorsiflexion and arch deformation.

CONCLUSIONS

We found the ankle and foot simultaneously produce positive power during propulsion for both walking and running. This suggests the timing of arch and ankle mechanics, and their synchronization, is important for propulsion across locomotor modes. This supports the existence of a mechanism linking arch recoil and ankle plantarflexion.

We also found the UD power calculated using the talus was higher during propulsion than when calculated using the calcaneus. This suggests structures in the foot proximal to the calcaneus may be important for generating power during propulsion.

INTRODUCTION

Inertial Measurement Units (IMU) require complex calibration algorithms to convert orientation data expressed in their local reference frame into a clinically meaningful reference system. The algorithms require the wearer to perform a series of movements or poses. Several calibration methods have been developed to find the perfect trade-off between ease of use, accuracy and speed. Still, little work has been done to compare different calibration methods with each other and against a gold standard reference system [1,2]. Therefore, this paper contributes to covering this gap by assessing the accuracy and precision of a number of calibration techniques (static and dynamic) and comparing them against a gold-standard camera system.

METHODS

Seven healthy subjects with no signs of upper limb injury were recruited for this study. Five IMU sensors (Xsens DOT, Movella, The Netherlands) and five active 3-marker clusters (Optotrak Certus®, NDI, Canada), used as a gold standard reference system, were attached to the participants on the thorax, scapula, upper arm, forearm and wrist. The bony landmarks for the optical reference system presented in [3] were digitized after subjects were instrumented. Four IMU models were developed by employing different calibration techniques: 1) N-pose calibration (NP): the subject stands in neutral pose for three seconds; 2) Functional calibration (FC): the subject performs single plane movements for each joint to estimate individual rotation axes; 3) Manual alignment (MA): each sensor reference frame is manually aligned with the underlying bone frame; 4) One-Axis alignment (OA): one axis of the sensor is aligned with the long axis of the segment. The data acquisition protocol consisted of 1) Sensor calibration: a static N-pose and a series of controlled single-plane dynamic movements for shoulder, elbow and wrist; 2) Tasks: subjects were required to execute single-plane tasks for each upper limb joint and a series of multi-joint tasks that resemble common activities of daily living. A graph of an unconstrained wrist flexion/extension task at full range of motion is presented for one subject in the following paragraph.

RESULTS AND DISCUSSION

The four IMU models accurately estimated the wrist flexion/extension angle during a wrist flexion/extension task (Figure 1A). The maximum root mean squared error (RMSE) for the flexion/extension angle is 12.84±5.20° for NP, whereas the lowest RMSE is 8.76±4.16° for MA (Table 1). However, when performing the same task, the four models perform differently in estimating the radial/ulnar deviation angle (Figure 1B). In the same scenario, the highest RMSE is 34.76±9.53° for NP, whereas the lowest RMSE is 20.75±10.61° for FC.

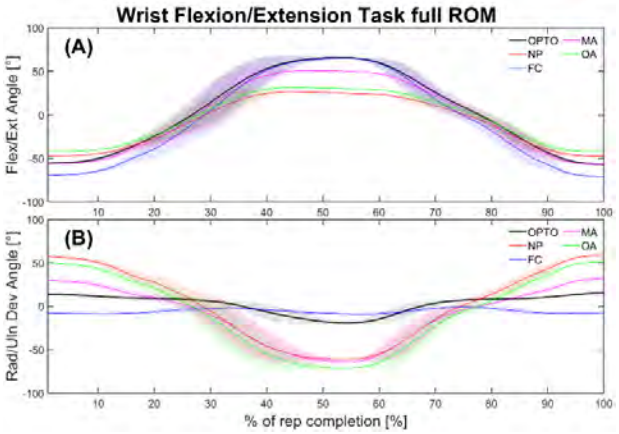

Figure 1: Plot of a wrist flexion/extension task starting from wrist fully flexed (0%) to fully extended (50%) and ending with full flexion (100%). Graph (A) displays the flexion/extension axis and graph (B) displays the radial/ulnar deviation axis.

CONCLUSIONS

All the four models presented perform rather similar in estimating the wrist flexion/extension angle, but their performance differs on the secondary rotation axis. Therefore, we advise a functional calibration approach for the best estimation of the overall wrist joint motion. However, for the highest accuracy possible on the flexion/extension axis, then we recommend the manual alignment (MA) method.

Windlass Mechanism Engagement Influences Calcaneocuboid Joint Kinematics Within a Robotic-Driven Tibial Movement Envelope: A Preliminary Study

Anthony H. Le[1,2], Jordy A. Larrea Rodriguez[3], and Amy L. Lenz[1,2]

INTRODUCTION

Windlass mechanism describes how dorsiflexion of the metatarsophalangeal (MTP) joint tensions the plantar fascia around the metatarsal head during late-stance propulsion, pulling on the calcaneus, shortening, and raising the arch, and inverting the subtalar joint, configuring the foot into a stiff lever [1, 2]. However, this complex dynamic interaction and the basic functions of the windlass mechanism remain an understudied phenomenon. Particularly, individual hind- and midfoot joint kinematic compensations have not been thoroughly explored in the context of the windlass mechanism [3]. Therefore, the purpose of this preliminary study was to evaluate hind- and midfoot joint kinematics, specifically calcaneocuboid joint kinematics, during passive range of motion (ROM) testing with and without the windlass mechanism engaged using an *in vitro* robotic simulator approach.

METHODS

Two fresh-frozen tibia-to-toe tip cadaveric specimens (2 males; age = 60 ± 6 yrs old) with no history of injury or surgery were procured. Proximal tibia was affixed to a 6-axis robot manipulator end-effector via specimen-specific fixation. Infrared marker clusters were mounted to the tibia, fibula, talus, calcaneus, navicular, cuboid, 1st metatarsal, and 5th metatarsal and tracked using motion capture (Figure 1A). Weight-bearing computed tomography scans were acquired to determine transformations from marker clusters to bone local coordinate systems. Each specimen was tested with two underfoot conditions: motion on a flat surface and motion with a 45° toe-wedge to prescribe MTP joint dorsiflexion to engage the windlass mechanism. Specimens were loaded to 25% body weight in three poses, neutral, dorsiflexed, and plantarflexed, while prescribed dorsi-/plantarflexion, varus/valgus, and external/internal rotation (EIR) tibial motion. Tibiotalar, tibiofibular, subtalar (ST), talonavicular (TN), and calcaneocuboid (CC) joint angle rotations were calculated and normalized to percent activity. Statistical parametric mapping (SPM) analyses compared joint angle rotations between conditions ($\alpha = 0.05$).

RESULTS AND DISCUSSION

SPM analysis found increased CC joint external/internal rotations with the windlass mechanism engaged during peak prescribed tibial internal rotation in the neutral and plantarflexed poses (Figure 1B and D). CC joint external/internal rotations also increased with the windlass mechanism engaged during initial prescribed tibial internal rotation and during the transition between peak prescribed tibial internal and external rotation in the dorsiflexed pose (Figure 1C). Increased ST and TN joint ROMs with windlass mechanism engagement during prescribed EIR tibial motion were also observed, indicating changes in coupled motion.

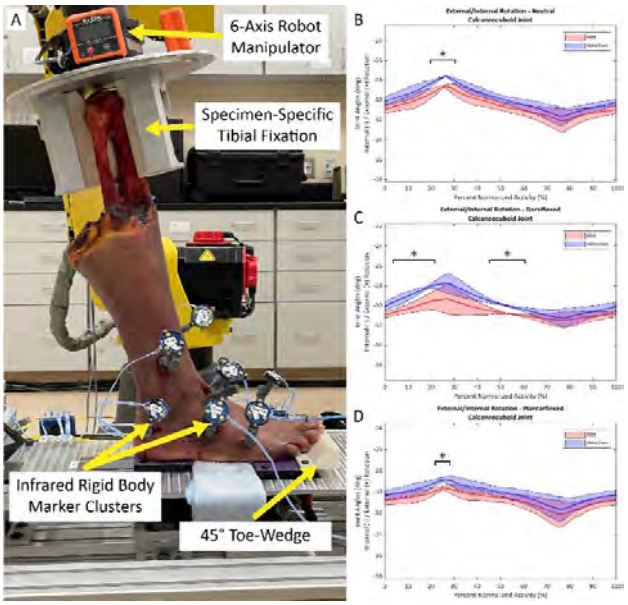

Figure 1. [A] Cadaveric specimen instrumented with marker clusters and affixed to end-effector of a 6-axis robot manipulator; Mean CC joint EIR motions during prescribed EIR in neutral pose [B], dorsiflexed pose [C], and plantarflexed pose [D] (* denotes $p<0.05$).

CONCLUSIONS

Windlass mechanism engagement increased CC joint kinematic compensations in the transverse plane. Altogether, windlass mechanism has subtle, but significant influences on midfoot kinematics. This preliminary study demonstrated a promising approach to exploring mechanistic influences of the windlass mechanism and future work will expand to include additional specimens and various foot postures.

INTRODUCTION

Estimating muscle force and stiffness remains a challenge and current methods are often time-consuming and limited to controlled movements in laboratory setups. In this regard, electromyography (EMG)-driven musculoskeletal modeling is a promising method for the estimation of muscle force and stiffness during functional activities, which could eventually guide neurorehabilitation. Despite its potential, previous validations of EMG-driven model-based estimations of force and stiffness have been solely at the joint level [1], limited by a lack of *in vivo* muscle-level measurements of force and stiffness. This study presents the first attempts to validate EMG-driven model-based estimates of force and stiffness across spatial scales (i.e., joint, muscle and tendon) against experimental measurements of the same variables.

METHODS

An experimental approach was used to obtain reference ankle torques and ankle, muscle, and tendon stiffness [2]. Four healthy young adults completed two tasks using an instrumented rotatory motor to measure ankle torque and displacement. Participants performed a torque-tracking task and an EMG-tracking task, where they were instructed to produce voluntary plantarflexion torque or average triceps surae EMG at 15% of their maximum, respectively, with the aid of real-time visual feedback. The motor moved the participants' ankle through a 20-degree sinusoidal motion at 0.5 Hz. Small stochastic perturbations were superimposed on the large sinusoidal movement to quantify ankle impedance. B-mode ultrasound of the gastrocnemius medialis muscle-tendon junction was used to track muscle and tendon displacement. We estimated ankle, muscle, and tendon impedance from the collected data using time-varying system identification [3]. We evaluated the stiffness component of these impedances.

Experimental EMGs and joint angles were used to drive an EMG-driven model [1]. For each subject, reference joint torque and stiffness from the torque-tracking task were used to calibrate the EMG-driven model, while the EMG-tracking task was used for validation purposes.

RESULTS AND DISCUSSION

Preliminary results show that the EMG-driven model accurately characterized joint-level measures of torque and stiffness, as previously reported, but that predictions of muscle and tendon stiffness were less accurate (Table 1). In particular, estimated tendon stiffness was substantially higher than that measured experimentally.

Table 1: Fitting errors, normalized by experimental RMS. Mean values across all subjects.

Fitting error	Torque-tracking task	EMG-tracking task
Joint torque (%)	11	22
Joint stiffness (%)	13	34
Muscle stiffness (%)	58	55
Tendon stiffness (%)	213	179

CONCLUSIONS

Our results emphasize the importance of validating complex musculoskeletal models across different spatial scales. Future work will use muscle- and tendon-level measurements, in addition to joint-level measurements, to calibrate model parameters. We envision that our innovative approach, which combines expertise from different scientific communities, will eventually bridge the gap between precise measurements from constrained experiments and computational models able to simulate functional conditions relevant to neurorehabilitation.

Alterations of muscle activation to reduce knee loading for people with limb loss: a musculoskeletal simulation study

Jiayu Hu[1], Ziyun Ding[1]
[1]School of Engineering, University of Birmingham, Birmingham, United Kingdom
Email: j.hu.3@bham.ac.uk

INTRODUCTION

In England, over 42,000 major lower limb amputations (above the ankle) were performed during 10 years [1]. Among them, transtibial amputees could be at an increased risk of knee osteoarthritis (OA), thus reducing the quality of life [2]. Adverse biomechanic property is well accepted as the major risk factor of knee OA, especially for the medial compartment in the intact limb [3]. Studies have reported that knee adduction moment (KAM), as an important proxy for the medial contact force (MCF), was closely associated with clinical outcomes of medial knee OA [4]. It is also reported that a combination of KAM and knee flexion moment (KFM) leads to a better prediction of MCF [5]. Muscle coordination strategy altering muscle activation could be used to mitigate the development of knee OA. We used a musculoskeletal simulation to reduce the KAM or KAM&KFM of the intact limb to inform the muscle retraining strategy in people with limb loss.

METHODS

Motion data were collected from nine male subjects with unilateral transtibial amputation (age: 34 ± 2 yrs; weight: 86 ± 9 kg; height: 180 ± 3 cm). Marker trajectories and ground reaction forces (GRFs) were captured simultaneously using 10 cameras (Vicon, Oxford, UK) at 100 Hz and three force plates (Kistler, Winterthur, Switzerland) at 2000 Hz during walking gait and sit-to-stand activities. The OpenSim Moco, a software toolkit, was used to solve the optimal control problem of musculoskeletal simulation [6]. We conducted the musculoskeletal simulation of an amputation model developed from a generic full OpenSim musculoskeletal model, with the inputs of generalized coordinates and GRFs. Firstly, we only minimized the cost function of a combination of squared muscle controls and observed motion errors with the same weight factors. Secondly, we added another cost function to minimize the KAM. Thirdly, we combined the minimization of KAM and KFM based on the first step. Finally, we compared muscle activation solutions generated by the above-mentioned three steps.

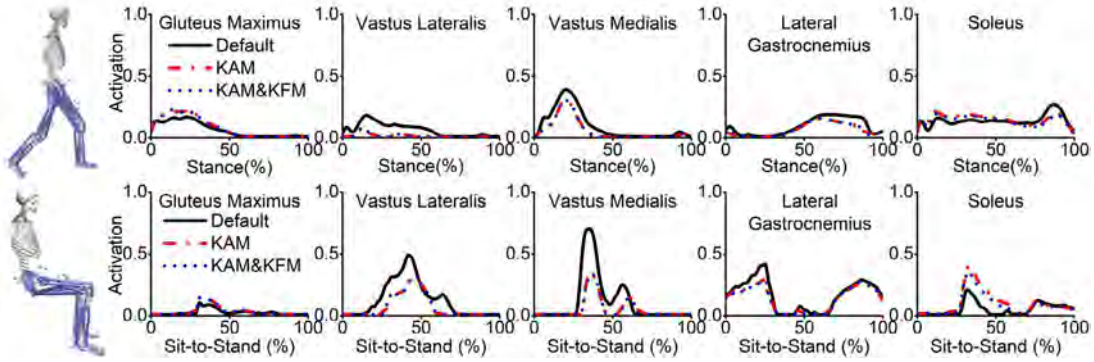

Figure 1 Muscle activations of default, minimised KAM and minimised KAM&KFM in walking and sit-to-stand for one representative.

RESULTS AND DISCUSSION

In the walking stance phase, muscle activations of the vastus lateralis and medialis, and lateral gastrocnemius, decreased by an average of 53%, 31% and 28% respectively after minimising KAM and KAM&KFM, and a similar pattern was observed in the sit-to-stand activity. In addition, muscle activations of the gluteus maximus and soleus increased in both two activities, especially for an average of two-fold increment in the soleus during sit-to-stand.

CONCLUSIONS

It was found that both gluteus maximus and soleus should be strengthened in these activities. This method could be used to develop promising treatment and rehabilitation for patients with knee disorders.

Creating subject-specific musculoskeletal models via morphometric transformation

INTRODUCTION

Musculoskeletal models (MMs) are valuable tools to investigate biomechanical capabilities. To develop new MMs, researchers currently rely on collecting anatomical information from cadavers or multiple image sources (CT, MRI and Cryo). However, there is a growing need to develop specimen-specific musculoskeletal models for living patients, for example to predict the outcome of different surgical methods. Furthermore, studies have shown that MMs yield more accurate results when subject-specific musculoskeletal geometries are taken into account [1]. However, the development of subject-specific MMs entails a large amount of data collection and is time consuming. Our goal was to develop a new workflow for creating specimen-specific MMs that would reduce the amount of data collection and time investment required.

METHODS

In general, our workflow involves collecting patient skeletal data (for example through a CT scan), and transforming an existing MM to the subject-specific skeletal anatomy. We test this approach by transforming an existing shoulder MM [2] to the skeletal data provided by the visible human project (VHP) [3]. We use the thin-plate-spline interpolation based on correspondent anatomical landmarks to warp muscle attachment points and paths from the MM to the VHP skeletal data [4]. The muscle internal information (optimal fiber length, tendon slack length) is estimated using an optimisation algorithm [5]. The accuracy of the newly created model is evaluated through comparison to muscle path and muscle internal properties calculated from the 3D muscle volume information collected from the VHP Cryo scans, through comparison to an earlier created shoulder MM using the VHP data [6], and through comparison to adjusting model dimensions using the standard scaling tool of OpenSim.

RESULTS AND DISCUSSION

The newly estimated muscle path orientations fall within the VHP 3D muscle volumes (Figure 1). The similar muscle moment arms of the supraspinatus, middle and posterior deltoid, and subscapularis across arm abduction suggests that the transformed muscle geometry is also similar to the orientations used by Garner *et al*. [6]. Optimal fiber length and tendon slack length were comparable to the estimations of [6], but deviated somewhat from our 3D muscle volumes estimations, similarly as in [6]. Overall, the transformed MM was similar to the specimen-specific musculoskeletal geometry and yielded estimations of biomechanical capacities similar to a MM developed using traditional methods. Scaling the MM to the dimensions of the VHP skeleton shows deviating muscle moment arm and moment estimations compared to using the transformation method, suggesting the latter has a greater potential for representing the specimen-specific biomechanical capacities.

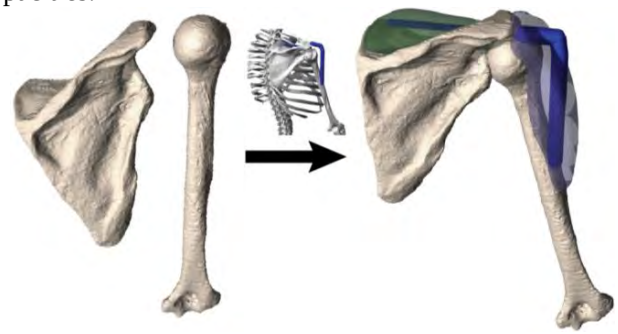

Figure 1 Creation of a subject specific model using the subject's skeletal geometry (left) and transforming a generic model (middle) to fit skeletal data. Estimated muscle attachment sites and paths fall within the patients 3D muscle volumes (right).

CONCLUSIONS

We developed a morphometric transformation workflow to create a new specimen-specific MM by transforming an existing MM. This show-case study focused on the transformation of a generic shoulder model to s specific subject, future studies will show if this method is equally successful for a greater number of subjects and a greater number of muscles and joints. The method is implemented in OpenSimCreator, an open-access software [7], which is free and easy to use.

INTRODUCTION

Golf remains popular in the elderly population even after total knee arthroplasty (TKA). However, considerable knee rotation with an almost fully extended knee during the club swing may expose implants to excessive loads that are conducive to mechanical failure and soft-tissue injury [1]. While the only study to measure *in vivo* knee contact forces during golf reported forces of up to 4.4 times body weight (BW) in the lead knee [2], our knowledge on the joint loading conditions remains limited to a small cohort with a specific implant design. Using video fluoroscopy and state-of-the-art musculoskeletal modelling, this study introduces a novel framework for non-invasive assessment of kinematics and loading of the knee during golf.

METHODS

Five experienced golf players (1f/4m, aged 73±6 years) with a fixed-bearing TKA (Persona®, Zimmer Biomet) were studied. Each subject performed three sets of 5 golf trials with the lead foot at a self-selected (ss), a 0° (0d), and a 30° (30d) externally rotated pose. In addition to the standard motion capture, the six degree of freedom (DoF) implant kinematics were measured using video fluoroscopy [3] (Fig. 1).

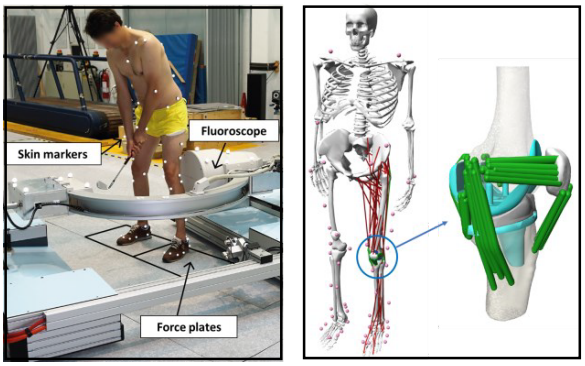

Figure 1: Measurement setup and musculoskeletal model.

A previously validated OpenSim model [4] with detailed knee structures was scaled to each subjects' anthropometry based on skin-marker locations in a standing trial. CAD models of the implant were placed within the bones based on postoperative X-ray images. Nonlinear springs representing knee ligaments and an elastic foundation contact model [4] were used to guide the 6 DoFs of the tibiofemoral and patellofemoral joint. The fluoroscopically assessed knee flexion angle together with skin-marker trajectories and ground reaction force data were used as inputs to the Concurrent Optimization of Muscle Activations and Kinematics (COMAK, [4]) algorithm. Translations and rotations of the tibiofemoral and patellofemoral joint were estimated using a cost function minimizing the sum of the squared muscle activations. Additionally, muscle, ligament, and knee contact forces were estimated throughout complete cycles of each golf swing.

RESULTS AND DISCUSSION

The very good agreement between model predictions and the fluoroscopic kinematics (Fig. 2) confirms validity of the modelling framework. Results indicated peak total tibiofemoral contact forces ranging from 1.9 to 3.9 BW, with no significant differences between 0d and 30d. These magnitudes are comparable to those measured during more challenging activities (e.g. jogging [2]). The peak patellofemoral contact force for 0d (2.1 BW) was larger than that of 30d (1.7 BW).

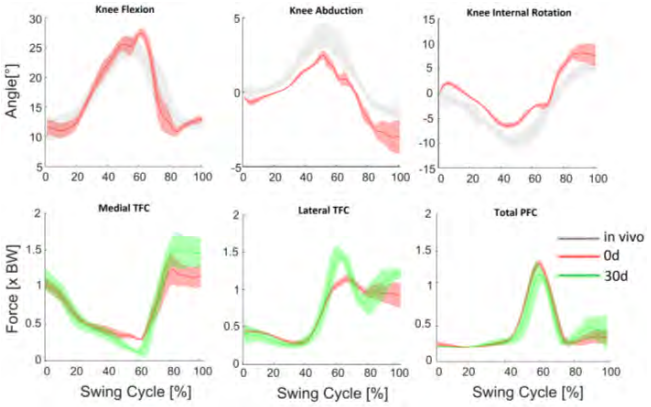

Figure 2: Fluoroscopically assessed kinematics and model predictions for an exemplary subject. TFC and PFC represent tibiofemoral and patellofemoral contact forces.

CONCLUSIONS

Clear variation across tibiofemoral and patellofemoral forces indicates that injury risk can be modulated through golfing stance and technique, and subjects should consider biomechanical optimisation of their own golfing approach according to their implant and soft-tissue status. This research continues towards elucidating the highest risk postures and techniques.

INTRODUCTION

Musculoskeletal (MS) diseases, such as osteoarthritis and tendinopathy, impose a substantial burden on individuals and healthcare systems. We have a limited understanding of how physical behaviors, i.e., whole-body mechanics, influence the tissue state, which intensifies our failure to cure these prevalent and harmful diseases. MS modeling has been considered as an efficient approach to provide insights into the biomechanics of the MS system. However, the kinetics of the MS system and biomechanics of the joint tissues have been separately researched in most of previous numerical studies, which limites the understanding on interactive effects across scales.

The purpose of this research is to develop a wearable motion capture-driven multiscale MS framework to deterministically predict the individualized biofeedback and use it to link the physical behavior and tissue mechanobiology. It could be widely used in the orthopedic field, i.e., the design of rehabilitation and artificial prosthesis. This proposal provides a deterministic way to insights into the relationship between physical behaviors and tissue state, which will significantly provide a fundamental understanding of human biomechanics and help treat MS disease.

METHODS

In this study, a MS framework incorporating the wearable motion capture system and the physics-based finite-element MS human model was developed to provide the deterministic platform in multiscale orthopedic biomechanics, as shown in **Figure 1**. The wearable motion capture system included the inertia motion capture system (Xsens Awinda, Xsens Co. Ltd., Netherlands) and insole force sensor (Pedar system, Novel Co. Ltd., Germany), which was used to acquire the kinematics, axial ground reaction force, and foot-ground contact trajectory. It is known the foot-ground contact moments, lateral-medial contact force, and anterior-posterior contact force are essential inputs in the MS model, which cannot be measured by the insole force sensor. In this study, an optimization-based model was developed with the constraint of the measured foot-ground contact trajectory and axial ground reaction force [1]. Additionally, a whole-body finite element-based MS model was developed in finite element environment (Abaqus) with python-based program based on our previous studies [2]. The CAMS knee dataset [3] has been used to verify the proposed system.

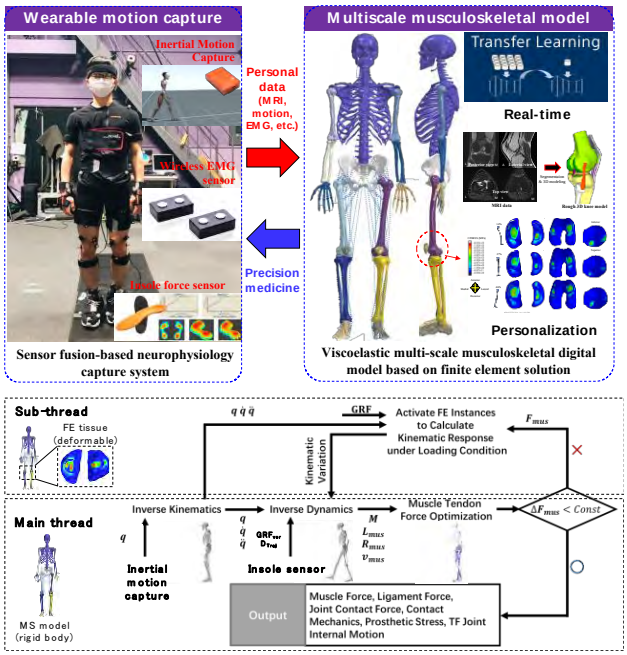

Figure 1 Framework of the proposed wearable motion capture-driven musculoskeletal model

RESULTS AND DISCUSSION

The predicted ground reaction forces and moments present good agreement (r^2>0.95) with experimental results during the gait cycle with different speeds. Additionally, the muscle activation, knee joint kinematics (r^2>0.85) and contact forces (RMSE: 0.28 body weight, r^2: 0.90) were compared with the data from CAMS knee dataset and presented a good agreement. The contact mechanics and stress were also simultaneously predicted during the simulation.

CONCLUSIONS

This study has presented an integral workflow for multiscale orthopedic biomechanics from the construction of wearable motion capture system and the subject-specific MS digital model, which can be widely used in the orthopedic field.

AUTOMATED GENERATION OF PERSONALIZED FOOT-GROUND CONTACT MODELS

Spencer T. Williams, Claire V. Hammond, Marleny Vega, Geng Li, and Benjamin J. Fregly
Department of Mechanical Engineering, Rice University, Houston, TX, United States
Email: stwilliams@rice.edu

INTRODUCTION

One of the driving goals of musculoskeletal modeling is the optimization of treatments for individual patients with movement impairments [1-3]. For this to be possible, it must be feasible to create personalized musculoskeletal models. When predicting the effect of a treatment on walking, these models require an accurate representation of a patient's foot-ground contact mechanics to predict the ground reaction forces (GRFs) and moments produced by the new gait pattern [1,2]. Unfortunately, creating subject-specific foot-ground contact models is difficult and time-consuming, and most models do not account for ground reaction moments [1,2]. This study presents a new Matlab-based software tool for automatically generating subject-specific foot-ground contact models calibrated to experimental ground reaction force and moment data.

METHODS

The software isolates two-segment foot models from a full-body OpenSim [3] model and places linear viscoelastic elements in a grid on the bottom of the shoe. It uses MATLAB's nonlinear least squares optimization algorithm to optimize stiffness coefficients, a damping coefficient, a dynamic friction coefficient, a spring resting length, and deviations from spline-fitted experimental kinematics. The cost function penalizes kinematic changes, ground reaction errors, and each stiffness coefficient's deviation from a Gaussian weighted average of its neighbors to reduce discontinuities in stiffness profile. Users provide input data files and model settings through an XML file, which enables modification of included design variables, cost function terms, and allowable errors. To validate the method, we generated right-side personalized foot-ground contact models for one subject and varied the standard deviation of the Gaussian function (σ) used to penalize stiffness deviations.

RESULTS AND DISCUSSION

All models accurately reproduced experimental kinematics and ground reactions (Table 1). As expected, increasing σ decreased the standard deviation of stiffness coefficients. Mean stiffness also decreased, suggesting that a wider Gaussian more effectively reduces high outliers. Choosing σ for a model will depend on the properties of the subject's foot and shoe. For example, a shoe with a raised heel may require a lower σ than a more uniform shoe to allow for more variation in stiffness. Generating each of the models in Table 1 required 4 to 4.5 hours of CPU time.

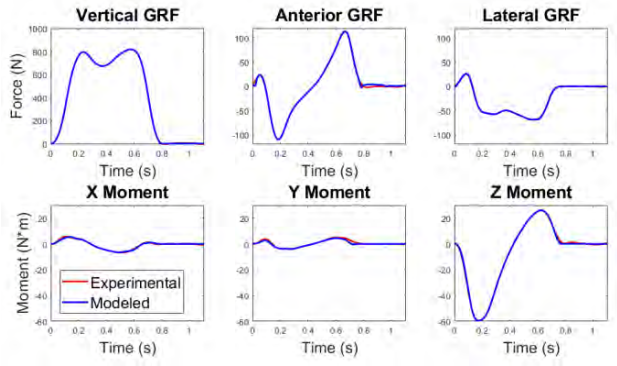

Figure 1: Modeled and experimental ground reactions for σ = 0.05.

CONCLUSIONS

This new tool automates the complex process of modeling foot-ground contact with a two-segment foot model, a critical step toward practical personalized musculoskeletal modeling. These results indicate that varying σ controls the stiffness distribution in the model without significantly impacting tracking of ground reactions and kinematics. Source code and tutorials for this tool will be available on SimTK.org as part of a model personalization pipeline plugin for OpenSim.

Introduction

The application of biomechanical simulation as a tool for the diagnosis and treatment of upper limb disorders, such as paralysis caused by stroke or rotator cuff injuries, is limited by the challenges in generating patient-specific anatomy and the complexity of the neuromuscular (NM) pathway. In this project, we utilize statistical shape models (SSMs) to efficiently generate anatomy from partial or sparse data of the upper limb. Additionally, we introduce a modelling framework for the NM pathway to provide a comprehensive neuro-musculoskeletal (NMSK) model. This model can be used to analyse the relationships between neural inputs and motor outputs, with the goal of improving diagnosis and treatment of NMSK pathologies.

Methods

To predict MSK geometry from limited data, we developed a proof-of-concept compound SSM for five bones of the left and right upper limb (total of 420 bone geometries) using the GIAS framework [1]. This SSM was used to investigate the interdependence of bone morphology in the upper limb. Furthermore, we applied the SSM to predict the forearm geometry from partial data of the upper limb.

Towards simulating the NM pathway, we developed a computational modelling framework that includes key components of the NM pathway from the motor cortex to muscle contraction (Figure 1) [2]. As a first step within this framework, a 3D MSK model with embedded motor units (MU) [3] was developed and used, for example, to measure the accuracy of MU twitch forces at the limb [4].

Results

The SSM results for the upper limb revealed, for example, that the inclination of the scapula is correlated with radial and ulnar twists, but inversely related to scapular version and humeral radius of curvature and torsion. Length scaling was generally consistent across bones, but bones in the forearm (radius and ulna) showed a greater proportional length change. The 3D MU embedded MSK model showed that MU twitch forces measured at the limb were underestimated due to force redistribution in the muscle, and that MU twitches do not linearly sum due to shear stresses in the muscle.

Conclusions

The preliminary results from the compound SSM analysis revealed the interconnection of shoulder girdle anatomy and has potential applications in surgical planning, such as shoulder arthroplasty, and in the generation of MSK models. The NM modelling results emphasized the importance of including MUs in MSK simulations. Accurate and personalized computer models can contribute to the effective diagnosis, treatment, and rehabilitation of NMSK pathologies.

Validation of smartphone-based analysis of human kinematics during 45° changes of direction

Cameron H.N. Stephen, Ezio Preatoni[1]
[1]Department of Health, University of Bath, Bath, United Kingdom
Email: chns20@bath.ac.uk, ep314@bath.ac.uk

INTRODUCTION

Anterior Cruciate Ligament (ACL) injuries have significant injury burden and have long-term consequences such as osteoarthritis [1]. Changes of direction (CoD) are the most common mechanism of non-contact ACL injury and several kinematic quantities have been identified as risk factors during this task [2]. Therefore, assessment of CoD technique can be used to screen for ACL injury risk. To be applicable in regular practice, screening tools need to be reliable and simple to implement in-field. Novel open-source software (OpenCap) [3], allows for biomechanical field testing, using only 2 smartphones. OpenCap uses pose-estimation algorithms (OpenPose) and muscle driven simulations to compute kinematics and kinetics [3]. Currently, OpenCap has been validated for walking, squats, drop jumps, and sit-to-stands [3]. Further validation for different movements are necessary for its application in clincal and performance settings.

This study aims to validate OpenCap kinematics during 45° CoD with a 3-step run-up.

METHODS

Seven healthy participants performed ten 45° CoD with a 3-step approach, with their kinematics simultaneously captured by a 15-camera marker-based motion capture system (Qualisys, 200 Hz) and OpenCap (Version 1.6) using 3 smartphone-cameras (720p, 60 Hz). Twenty-three reflective markers were placed on the participants lower extremities and torso for Qualisys motion-capture. A single trigger was used to initiate both motion capture recordings and a LED light array. The LEDs were used to synchronise data between methods. Data were cropped from initial ground contact during the CoD to toe-off. Hip flexion angle, hip abdution angle, knee flexion angle, and ankle dorsi/plantar-flexion angle were computed on OpenSim for comparison.

Root mean square error (RMSE) and Statistical Parametric Mapping (SPM) were used to compare kinematics during the CoD (α=0.05).

RESULTS AND DISCUSSION

RMSE for hip flexion (11.94°), knee flexion (9.71°), and ankle flexion (7.82°) were greater than previously validated movements, which had a mean RMSE of 7.07° 5.69°, and 7.03°, respectively [3]. However, RMSE for hip abduction (2.50°) was lower than previously validated movements (5.69°) [3].

Over-estimation in hip flexion angles were observed for the entire duration of movement, with significant differences between methods at 0-20% and 60-90% (Figure 1). Greater knee flexion angle and plantar flexion angle is correlated with reduced knee joint moments during CoD lowering the risk of injury [2]. Therefore, underestimation in knee flexion angle from 20-80% and significant underestimation in plantar flexion angle at 20-50% of the CoD may result in falsely classifying individuals for higher injury risk (Figure 1). Finally, limited mean difference and small RMSE in hip abduction angles suggest that OpenCap can accurately measure frontal plane motion, previously not investigated.

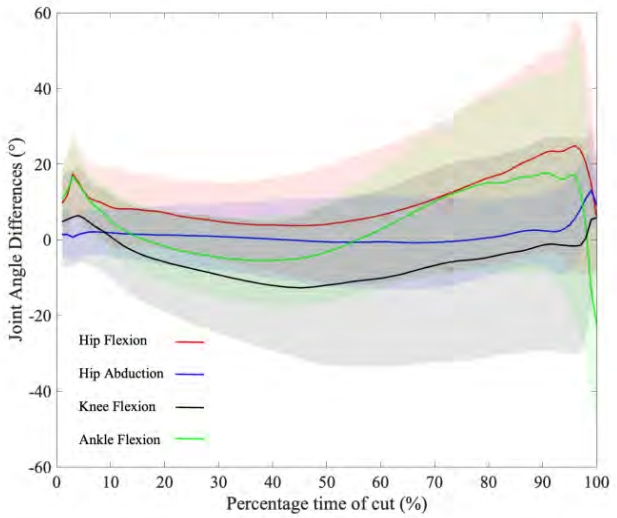

Figure 1: Mean joint angle difference between OpenCap and marker-based motion-capture. Shaded area shows standard deviation

CONCLUSIONS

OpenCap has several benefits over marker-based motion capture as it removes error from skin motion artefact and reduces time and costs of kinematic analysis. This study's results are promising for measuring frontal plane kinematics. However, further training of the pose-estimation algorithms or different experimental setup may be necessary for improving the system performance in estimating hip, knee, and ankle flexion angles, as the current outcomes may be not accurate enough to be used as an injury risk screening tool.

INTRODUCTION

People with spinal cord injury (SCI) often exhibit slow walking speed, a result of impairments in both motor and sensory functions. However, the precise causal effects of these impairments are not well understood due to the presence of various confounding factors such as level of injury, severity, time since injury, or age. To gain a deeper understanding of these effects, we propose using a combination of game theoretic approach, SHAP (SHapley Additive exPlainations) [1], and a gradient boosting machine learning model (XGBoost [2]) to study the causal impacts of motor and sensory impairments on walking speed in individuals with SCI.

METHODS

Nine individuals with SCI [5 men/4 women; age 56.2 years ± 11.4; level of injury from T4 to L4] and a control group without SCI [7 men/4 women; age 53.2 years ± 9.3] gave informed consent and participated. All participants underwent 3D motion analysis at a comfortable walking speed. Participants with SCI were assessed with manual muscle strength tests by an experienced clinician, and assigned a muscle strength score corresponding to the sum from 9 key lower extremity muscle groups. Sensory impairment was scored as a sum of the light touch scores as per the ASIA test according to international SCI guidelines. Non-impaired participants were assumed to have the maximum possible muscle strength (45) and sensory (56) scores. We created a model that incorporates a range of demographic and functional factors, including age, gender, BMI, motor level, sensory level, muscle strength score, light touch score, and assistive device, as inputs. The model output, walking speed, is intended to be indicative of walking performance. The model's goal is to map the complex relationship between performance outcomes and underlying demographic and functional factors. To ensure the validity of our results, we separated the dataset into training (90%) and testing (10%) sets. We trained our model using the XGBoost algorithm and analyzed its results using the SHAP package in Python.

RESULTS

Our model indicated that muscle strength score was the predominant factor influencing comfortable walking speed in individuals with SCI, followed by BMI and age (Figure 1A). The baseline value was the average walking speed among our training data set. For each participant, the model quantified how much each factor increased or decreased the baseline walking speed (Figure 1B).

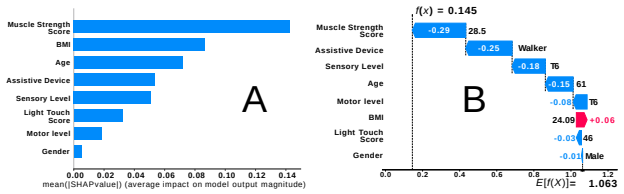

Figure 1: A. Average impact for each factor on model output; **B.** Contribution from each factor to push the model output from the base value in one participant with SCI. The numbers in each bar indicate how that factor contributes to a baseline walking speed of 1.063 m/s; for instance, muscle strength score of 28.5 (out of 45) results in a 0.29 m/s reduction in walking speed.

CONCLUSIONS

Our model has the potential to quantify how motor, sensory or other underlying factors can influence a given outcome performance measurement. In its current form, it describes how much each factor can decrease or increase a "baseline" walking speed, and has thus great potential in decoding the complex causal relationship between walking speed and sensorimotor sensory impairment, given other confounding factors such as BMI or the use of an assistive device. However, as the dataset is currently limited and the project is ongoing, it is possible that the model may be overfitted. As more data is collected in the future on this and on other patient populations, and as its ability to predict a larger set of performance outcome parameters is studied, the model has vast potential to provide clinically relevant insight into the complex factors that influence the motor performance.

VALIDITY OF ARTIFICIAL INTELLIGENCE-BASED MOTION ANALYSIS SYSTEM ～ AI ANALYSIS VS. HUMAN ANALYSIS

Takumi Ino[1,3], Mina Samukawa[2], Tomoya Ishida[2],

INTRODUCTION

Artificial intelligence-based motion analysis (AI-MA) using convolutional neural networks and deep learning approaches have recently become an attractive tool for estimating motion data using human video analysis. Until recently, human visual inspection-based motion analysis (Human-MA) has been widely used for motion data analysis. However, this approach was time-consuming and had certain limitations in terms of validity. AI-MA has a potential to solve these problems. Therefore, the purpose of this study was to compare the accuracy of AI-MA with Human-MA and to clarify the validity of AI-MA.

METHODS

Twenty-one healthy young participants (10 males and 11 females, age: 20.7 ± 1.0 years, BMI: 21.6 ± 2.7 kg/m^2) participated in this study. Three successful drop vertical jump tests were set as the movement task. We used OpenPose [1] for the AI-MA base algorithm. As a conventional analysis, Human-MA based on human visual inspection was performed by a well-trained analyst with Frame-Dias V software (DKH, Japan). The knee abduction-adduction angle was calculated by AI-MA and Human-MA using the same single-plane video image. To confirm the validity, the same parameters were simultaneously recorded by a three-dimensional VICON motion analysis system (VICON: Vicon Nexus 2.10, Vicon Motion Systems Ltd., Oxford, England). Furthermore, video distortion was corrected with using spatial calibration information from the VICON three-dimensional motion analysis system to eliminate the effects of lens distortion from the video camera. Mean errors, mean absolute errors, and Pearson's correlation coefficient for waveform pattern evaluation were obtained (AI-MA vs. VICON, Human-MA vs. VICON).

RESULTS AND DISCUSSION

No significant difference was found between AI-MA and Human-MA for mean errors or mean absolute errors of knee abduction-adduction angles (Table 1). The Pearson correlation coefficients of AI-MA and Human-MA in comparison with VICON were 0.82 and 0.88, respectively. AI-MA showed good accuracy and did not differ from the conventional Human-MA. In addition, AI-MA had a strong correlation with VICON. Qualitatively, the waveform patterns obtained from AI-MA and VICON were fairly consistent (Fig. 1). Although certain measurement errors must be addressed, AI-MA should become a useful tool and has the advantage of saving costs and time for motion analysis.

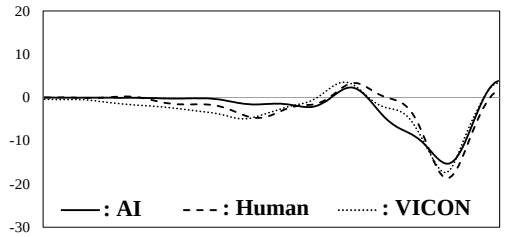

Figure 1 Example of the waveform pattern (one case)
Pearson's r vs. VICON: AI, 0.91, Human, 0.95

CONCLUSIONS

AI-MA was found a good accuracy compared to VICON and did not differ from conventional Human-MA. AI-MA has both cost-effective and time-saving advantages compared to conventional Human-MA.

INTRODUCTION

The prevalence of injuries associated with dynamic physical activity has compelled scientists to study changes in body structures after exercise, with degenerative changes to tissues and implications of these of particular concern. The function of cartilage in joints is for bones in motion to evenly transmit loads from one body segment to another at very low friction. During these events it has been shown that cartilage undergoes changes in volume, thickness, and joint space narrowing [1]. In recent years much research has been conducted in developing novel ways of joint degeneration identification and joint health assessment using Acoustic Emission (AE) [2,3].

METHODS

32 adult volunteer participants took part in the study. The participants were assigned in one of the three age groups 18-34, 35-49 and 50+. To calculate kinematic and dynamic variables nine Qualisys Oqus 700+ cameras and a Kistler Force Plate were positioned around the capture area. 28 reflective markers were placed on specific body landmarks [4]. A sensitive condenser microphone connected to the Laryngograph DSP Unit [Laryngograph Ltd., London, UK] was attached on the lateral soft part of the knee. Each participant was asked to perform a set of three sit-stand-sit (S–S–S) cycles three times for each leg on five different days. A custom-made MATLAB code was developed to process and analyse collected data. Two different Deep Neural Networks (DNNs) were used to classify the AE signals. This research project and its methodology were granted ethical approval by the Ethics Committee of Kingston University London.

RESULTS AND DISCUSSION

This project aimed to analyse the AE signal data obtained from the knee joints of people performing an S-S-S cycle. The results indicate that. although no S-S-S cycle is the same, there is a correlation between the obtained AE and the associated kinematic data. The synchronized plot of the knee angle, angular velocity & accelaration, and AE signal shows that there is a relationship between them. The AE events can be seen to coincide with the peak velocities during ascent and descent for each of the three cycles. There are also smaller AE events occuring during a change in angular velocity.

The AE signal was explored in Time & Frequency domains. The findings show that amplitudes differ between participants and within sessions, however a unique AE pattern is evident. The frequency domain indicates that the signal is predominantly low frequency; signal with the most power >1kHz.

Two different Deep Neural Networks (DNNs) were used to categorise the AE signals. These were Recurrent Neural Network (RNN) and Convolutional Neural Network (CNN). CNN was applied to the spectrograms to try to predict the age group of each participant, and overall obtained the best testing accuracy with a score of 81.82% (see figure 1).

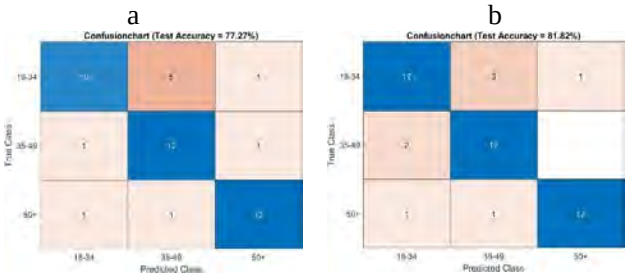

Figure 1 Best trained networks using spectrograms

CONCLUSION

The results of the experiment have shown that the characteristics of the AE signal can vary from one cycle to another, and even more so, from one day to another. However, the AE events appear to be directly correlated with the knee angular velocity. The use of DNNs shows that they can be used to categorise participants into age groups with good accuracy. To improve upon the accuracy of the model the inclusion and exploration of the kinematic features into the MATLAB model is the next step in our research.

INTRODUCTION

A multi-segment foot model incorporating the plantar aponeurosis (PA) was developed to estimate the pattern of stretch and tensile force generated by the PA during dynamic movements such as walking, running and jumping[1)]. This foot model comprised three segments (phalanx, forefoot, and hindfoot) and the PA was modeled as five linear springs connecting the origins and insertions via intermediate points (Fig . 1). The model defines the positions of these points with respect to the corresponding segment coordinate systems based on CT data of the foot of an adult male[1)]. Therefore, the lenghts of the PA during movements can be calculaetd based on the motion-caputured coordinates of the 14 markers attached to foot anatomical landmarks (Fig. 1). However, the validity of the length estimate of the PA using the multi-segment foot model has not been sufficiently investigated mainly due to the difficulty associated with measuring the true PA length during movements. The present study aimed to evaluate the accuracy of the length estimate of the PA by quantifying the true PA lengths in three different foot postures using computed tomography (CT).

METHODS

Three healthy adult males participated in the experiment. CT scans (SOMATOM go.Top 64; Siemens, Munich, Bavaria, Germany) of the foot with the attached 14 markers were performed in three different foot postures in the supine position: (1) non-weightbearing neutral posture, (2) simulated weightbearing posture with midfoot dorsiflexion and metatarsophalangeal (MP) joint plantarflexion, and (3) simulated weightbearing posture with midfoot plantarflexion and MP joint dorsiflexion (Fig. 2). The latter two postures were achieved by applying load to the foot using a loading device. The slice thickness and pixel size of the obtained images were 0.6 mm and 0.416 mm, respectively. To quantify the PA lengths of the foot from the CT scan data, semi-automatic segmentation and 3D reconstruction of the PA was performed using image analysis software Mimics 25.0 (Materialise, Leuven, Belgium). Each reconstructed 3D surface model of the PA was imported to Geomagic Design X 2020 (3D systems, Rock Hill, SC, USA) to quantify the true length of the PAs by digitizing the paths of the PA from the origins to insertions on the plantar surface of the PA. In addition, the PA lengths were estimated based on the 14 marker coordinates and the multi-segment foot model. The differences of the estimated and true PA lengths were calculated for each foot posture and subject, and expressed as the percentages of the PA lengths.

RESULTS AND DISCUSSION

The true lengths of the PA in the neutral position measured based on the CT data were 160 ± 3 mm, 165 ± 5 mm, 164 ± 4 mm, 155 ± 2 mm, and 148 ± 6 mm for PA1, PA2, PA3, PA4, and PA5, respectively (mean ± standard deviation). In the midfoot dorsiflexed, MP joint plantarflexed posture, the PAs were stretched by -2.1 ± 2.1 mm, -0.5 ± 4.3 mm, -3.3 ± 2.5 mm, -0.6 ± 0.5 mm, 0.7 ± 3.6 mm, respectively, and in the midfoot plantarflexed, MP joint dorsiflexed posture, they were stretched by 3.4 ± 4.7 mm, 0.5 ± 4.4 mm, -0.5 ± 2.5 mm, 1.5 ± 3.3 mm, 2.5 ± 3.8 mm, respectively. In the present experimental conditions, the PA lengths were maintained approximately constant regardless of variations in the foot posture possibly due to inability to stretch the PA in the simulated weightbearing postures. The differences between the PA lengths estimated based on the multi-segment model and the true values of PA lengths obtained from the CT data were less then 3 % of the PA length (Fig. 3), indicating that the estimated lengths of the PA based on the multi-segment foot model were reasonably accurate. However, further evaluation is necessary using the CT data of the foot with more stretched PAs using a weightbearing CT.

CONCLUSIONS

The estimation of the PA length using a multi-segment foot model may serve as a reliable tool to quantify the pattern of the PA stretch during dynamic movements.

INTRODUCTION

Head injuries were reported as one of the most common injuries during electric scooter (or E-scooter) accidents [1]. Bicycle helmet was previously found efficient to reduce head impact loadings but not to prevent severe head injuries during E-scooter falls induced by collision with a curb [2]. However, the efficacy of a motorcycle helmet in reducing head injuries during these falls remains to be studied. In current testing standards, bicycle and motorcycle helmets are evaluated against drop tests using an isolated headform. In real accidents, other body parts besides the head can also interact with the ground and thus influence the impact responses of the head. Therefore, the objective of this study is to 1) study the performance of a motorcycle helmet in reducing head injuries 2) and the effect of the body in influencing head impact responses in E-scooter falls.

METHODS

The finite element (FE) model of E-scooter falls was previously developed to evaluate the efficacy of a bicycle helmet in reducing head injuries [2]. A total of 27 E-scooter falls due to the collision with a curb was previously simulated, representing different initial E-scooter speeds (10, 20, and 30 km/h), orientations of the curb (30, 60, and 90°), and orientations of the E-scooter (-15, 0 and 15°) [2]. This model was still used in this work to study the performance of a motorcycle helmet in head-ground impacts during these E-scooter falls. The helmet FE model was previously validated, optimized for better head protection [3], and evaluated in head-ground impacts during karting rollover accidents [4]. This helmet FE model was fit on the rider of the E-scooter fall FE model. A similar full-restart procedure was applied as was previously done [3] to inherit the body kinematics before the moment when the head hit the ground during E-scooter falls. Thus, the head-ground impact conditions were warranted the same among the E-scooter falls (or *full-body simulations*) without a helmet and with the bicycle or motorcycle helmet.

To study the body effects in influencing head impact responses, the head-neck joint was detached from the rider FE model also with the full-restart procedure at the moment of head-ground impact. Then the isolated head without a helmet and with the bicycle (Figure 1A) or motorcycle helmet would hit the ground with the same impact conditions as in the full-body simulations. Additionally, a virtually-added mass of 5kg and 10kg was respectively attached to the center of gravity of the head for the isolated head-ground impacts to study the effects of headform mass in influencing head impact responses. Finally, four series of E-scooter fall simulations without a helmet and with a bicycle or motorcycle helmet were performed: 1) full-body, 2) isolated head, 3) isolated head+5kg, and 4) isolated head+10kg.

RESULTS AND DISCUSSION

The HIC_36 (213.7~1746.8) and BrIC (0.23~1.18) predicted in full-body simulations with the motorcycle helmet were significantly ($p<0.01$) lower than those without a helmet (1780.0~42324.7 and 0.38~1.73) or with the bicycle helmet (337.9~30755.0 and 0.53~1.77) (Figure 1B and C). The HIC_36 was above the injury threshold (1000) in 24 (88.9%) and 14 (51.9%) E-scooter falls with a bicycle and motorcycle helmet respectively, with the BrIC above the injury threshold (1.0582) in 12 (44.4%) and 2 (7.4%) falls with a bicycle and motorcycle helmet respectively. The HIC_36 predicted in isolated (no added mass) head-ground impacts with the motorcycle helmet was significantly ($p<0.01$) higher than that predicted in full-body simulations. Otherwise, HIC_36 and BrIC predicted in isolated head-ground simulations were always significantly ($p<0.01$) lower than those predicted in full-body simulations, not depending on the helmet type or virtually-added mass to the head (Figure 1).

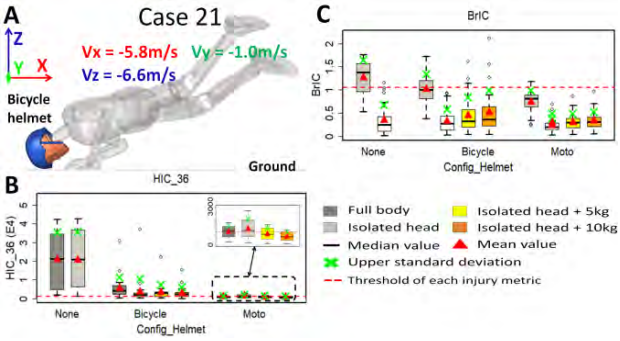

Figure 1 (A) An example of a full-body (transparent) E-scooter fall and an isolated (colored) head-ground impact simulation; (B) BrIC and (C) HIC_36 during E-scooter falls for full-body and isolated simulations with and without a helmet.

CONCLUSIONS

The motorcycle helmet was more protective than a bicycle helmet, but could not fully eliminate risks of severe head injuries during E-scooter falls. No matter the virtually-added mass, isolated head-ground impacts generally underestimated body effects in increasing head injury metrics and thus overestimated the helmets' efficacy in E-scooter falls.

INFLUENCE OF MIDSOLE COMPRESSION ON ACCELERATION MAGNITUDE IN RUNNING

Robin Trama, John W. Wannop, Emily Smith, Darren J. Stefanyshyn
Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Calgary, AB, Canada
Email: robin.trama@ucalgary.ca

INTRODUCTION

Due to the repetitive movement of running, a large number of foot-ground impacts will be sustained over the course of a single run. From the repetitiveness of these impacts, the body is exposed to substantial impact-related mechanical stress [1]. Aside from the mechanical impact, runners will also experience mechanical vibrations in the bones and the soft tissues (i.e., muscle, tendon, fat, and skin) of the leg, which can lead to discomfort, fatigue, and muscle damage [2, 3]. A recent review found that shoes with thicker and more viscous midsoles were effective in limiting vibration magnitude [3], however, the actual compression of the midsole was not quantified. Only one study quantified the compression of the midsole during the stance phase of running, and found that when midsole compression was increased the foot, sacrum, and head accelerations were reduced [4]. However, the direct relationship between midsole compression and acceleration at different locations on the body has not been examined. Therefore, the purpose of this study was to investigate the influence of midsole vertical and horizontal compression on the magnitude and frequency of soft tissue vibrations and bone accelerations during running.

METHODS

Forty-eight individuals were instructed to run at their self-selected pace on an instrumented treadmill for four bouts of 5 minutes, wearing four different shoes. The different footwear conditions had identical uppers with only changes in the midsole construction via 3D printing. Vertical hardness of the midsole was quantified with mechanical testing, and the shoes were classified from soft to stiff (106 to 144 $N \cdot mm^{-1}$). A total of 7 reflective markers forming 3 clusters were glued on the lateral side of the midsole of the left shoes [4]. During the last minute of each run vertical and horizontal compression of the midsole over the stance phase was quantified by tracking the displacement of the markers at 200 Hz with optoelectronic cameras. In addition, ground reaction forces were recorded at 2000 Hz with force plates, and acceleration data at 6 locations (heel, tibia, calf, quadriceps, sacrum, head) was collected at 1600 Hz with tri-axial accelerometers. A continuous wavelet transform was used to analyze acceleration data and obtain the total energy of vibration at each frequency from 2 to 200 Hz. Non-parametric regressions with permutation tests were performed between the vibration energy and the maximal compression of the midsole.

RESULTS AND DISCUSSION

The midsole compression for the different shoes ranged from 1.0 to 8.2 mm (vertical) and 1.1 to 7.2 mm (horizontal), with greater compression occurring in the softer shoes. Regression analysis depicted that a more compressive midsole was significantly correlated with less vibration energy at each impact (Figure 1). Tibia and calf muscles were the locations where the greatest reduction occurred, especially with vertical compression. Energy at lower frequencies (4-15 Hz) of the sacrum and head was also reduced. A more compressive midsole can absorb more energy from the ground impact and lead to a less jerky running pattern, potentially increasing running comfort [2] and smoothness [4].

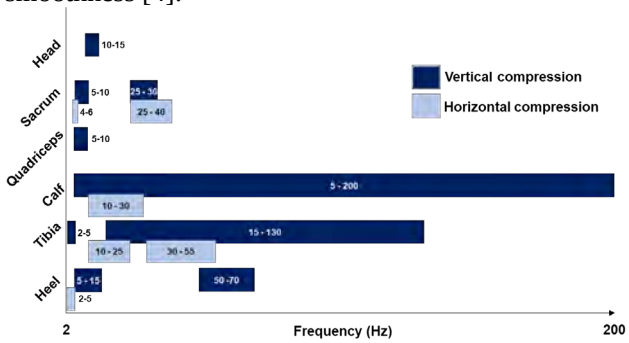

Figure 1 Summary of non-parametric correlations between midsole compression and vibration energy. Indicated are the frequencies where vibration energy was reduced when compression increased.

CONCLUSIONS

Alteration in midsole stiffness via 3D printing technology allowed the modification of midsole compression during running and reduced vibration exposure. Quantifying midsole compression and determining lower and higher bounds for optimal compression are yet to be done.

ACKNOWLEDGEMENTS

The authors would like to thank adidas for providing the shoes. This study was partially funded by the NSERC CREATE (We-TRAC No. CREATE/511166-2018), and the Eyes High program of the University of Calgary.

INTRODUCTION

Falls and slips are serious trauma accidents and the leading cause of death every year, and reducing falls is important. Understanding reactive strategy for not slipping can be helpful in developing intervention techniques to reduce risk of falling. The reactive strategy can be confirmed by analyzing the activity of muscles during walking on slippery surface. Therefore, the aim of this study was to investigate the difference of muscle activation patterns when walking down a non-slip slope and slippery slope. Also, we analyzed the effect of prior notice for slippery slope as well.

METHODS

A total of 18 young healthy persons (14 males and 4 females; mean age 24.28±2.42 years) who could walk independently on a slope were recruited. The aprticipants walks on the wooden slope with an inclination angle of 15° was fabricated. The walking path was divided into 5 zones, and the slippery zone is 4th. (Figure 1) Participants conducted 3 gait trials: T1) walking down a non-slip slope, T2) walking down a slippery slope encountered unexpectedly, and T3) walking down a slippery slope with a prior notice The electromyographic (EMG) activity waw recorded from the muscles in the stance (right/slipping) leg, including the Vastus Lateralis (VL), Medial Hamstring (MH), Tibialis Anterior (TA) and Medial Gastrocnemius (MG) at 1111 Hz using Delsys Trigno wireless EMG (Boston, MA) with a bandpass filter (10–500 Hz). The raw EMG signal was time-normalized by dividing 1 stance phase into 10 equally spaced intervals and root mean square (RMS) values were calculated for individual muscles during each time interval. Maximum Voluntary Isomeric Contraction (MVIC) values for each muscle were expressed as a ratio of the maximum RMS value during walking down a non-slip slope. And the onset time was estimated as the first point when the smoothed signal exceeded the threshold (mean+15*standard deviation). In order to compare and analyze muscle activity during non-slip and slippery slope walking, the paired t-test was used.

RESULTS AND DISCUSSION

Explosive increases in the MVIC value were observed from all muscles in overall stance phase except for initial contact during T2 compared to T1. ($p<0.05$) (Fig.2)

And decreases in the MVIC value were also observed from all muscles in overall stance phase except for initial contact during T2 compared to T1 ($p<0.05$) There was no statistically significant difference in MVIC value During T3 compared to T1, and there was no significant difference in onset time as well. ($p<0.05$)

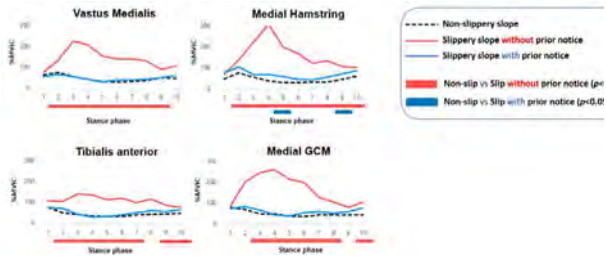

Figure 1 Comparison of Maximal Voluntary Isometric Contraction (MVIC) values of each of the muscles (Vastus Lateralis, Medial Hamstring, Tibialis Anterior and Medial Gastrocnemius) during walking down a non-slip slope

CONCLUSIONS

In all muscles, the magnitude of muscle activity was significantly increased about 260% during walking down on a slippery slope encountered unexpected compared to during walking down a non-slip slope.

In the presence of slip anticipation, it was expected that there would be a difference from walking on a non-slip slope due to non-slip compensation, but showed a similar muscle activation pattern as during walking a non-slip slope.

INTRODUCTION

The riot-control water cannon is a kind of large non-fatal weapon equipment that takes water as the main medium to control and disperse the crowds. However, the safety issues of the water cannon, especially the potential cranio-cerebral injury, is seldom reported. Therefore, the present work analysed numerically and theoretically the influence of riot-control water cannons on the cranio cerebral ensemble, and predicted the injury risk of the skull, cerebrum and neck under different impact situations.

METHODS

The spatial-temporal distribution of anti-riot water cannon pressure was studied by two-phase waterjet simulation and Vander Waals equation (Eq. 1).

$$p\left(V-m_{gas}b\right)^{\gamma}=p_0\left(V_0-m_{gas}b\right)^{\gamma} \qquad (1)$$

By considering the different working distances, different impact positions and different impact angles, the dynamic response of the human brain was systematically investigated. Combining four criteria (Skull Strength Criteria, Neck Injuries Criteria, Intracranial Stress Tolerance Criteria and WSTC/HIC Criteria), the injury risk was estimated and evaluated.

RESULTS AND DISCUSSION

The results showed that the peak value of equivalent pressure pulse decreased while the rising time of positive pressure shortened when the standoff distance becomes longer. (Fig. 1) Within a standoff distance of 7m, the dynamic response of the skull, brain and neck all exceeded the safety usage threshold(Table 1). When impacting different positions of the human brain at the same distance, the risk of injury of the frontal, temporal and occipital areas was 8.61%, 2.24% and 0.98%, which showed that When the oblique load was applied to the human brain, the neck injury coefficient increased by 160.2%, and the peak stress of the skull and cerebrum increased by 66.7% and 94.0%, respectively.

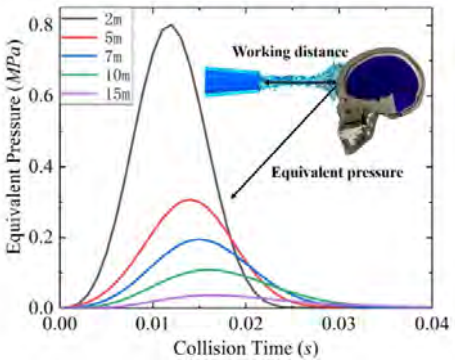

Figure 1 Equivalent pulse pressure curve of different working distances.

CONCLUSIONS

By using Skull Strength Criteria, Neck Injuries Criteria, Intracranial Stress Tolerance Criteria and WSTC/HIC Criteria injury criteria, cranio cerebral injuries can be described more accurately and comprehensively. The safe distance of this kind of riot-control water cannon should be greater than 7m. Compared with the normal impact, the oblique impact of the water cannon has a more severe influence. The frontal part was more susceptible to cause injury. The experimental verification and validation of the anti-riot water cannon impacting the brain model will be carried out in the future.

ACKNOWLEDGEMENTS

The project is supported by NSFC (Grant no: 12272053).

SUBJECT-SPECIFIC FE ANALYSIS TO INVESTIGATE HOW DIFFERENT REHABILITATION EXERCISES INFLUENCE TENDON STRAINS IN ACHILLES TENDINOPATHY PATIENTS

Alessia Funaro[1], Vickie Shim[2], Ine Mylle[1] and Benedicte Vanwanseele[1]
[1] Human Movement Biomechanics Research Group, KU Leuven, Leuven, Belgium.

INTRODUCTION

Achilles tendinopathy is characterized by altered tendon material properties and geometry, in particular decreased Young's modulus and tendon thickening [1]. Strain is a crucial factor for tendon adaptation and a strain dose of 5-6% has been shown to reverse early-stage pathological changes in Achilles tendinopathy patients [2]. However, it still remains unknown if current rehabilitation exercises provide this optimal strain dose in Achilles tendinopathy patients [3]. Finite element (FE) models of the Achilles tendon (AT) can be used to investigate the effects of tendinopathic material and geometrical changes [4] on regional tendon strain under load. The aim of this study was to develop subject-specific FE models of the AT with subject-specific material properties, geometry and muscle forces during common rehabilitation exercises to investigate their effect on AT strains.

METHODS

Six participants with mid-portion Achilles tendinopathy (4 males, 2 females; age: 58 ± 18 years; weight: 72 ± 10 kg; height: 176 ± 9 cm; VISA-A score: 76 ± 17) participated in the study. The subject-specific geometries of the free AT were obtained from 3D freehand ultrasound. Free form deformation method was used to develop subject-specific FE models. Our models also incorporated the twisted structure of AT subtendons [6]. Incompressible, transversely isotropic, hyperelastic material descriptions were used as in our previous study [5] with the subject-specific Young's modulus, which was calculated as the slope of the line fitted to the stress-strain data between 30% and 60% of the peak force for each patient (Young's modulus: 512.9 ± 145.7 MPa). Subject-specific muscles forces were obtained using a combination of 3D motion capture and musculoskeletal modelling of each patient. Five different rehabilitation exercises were measured: 1) unilateral heel rise, 2) unilateral heel drop with flexed knee and 3) with extended knee, 4) walking and 5) toe-walking. The muscle forces at the time of peak total muscle force were used as boundary conditions for the subject-specific FE analysis. The average of the maximum Lagrange strain, in the mid portion of the AT, was calculated to identify the differences between the rehabilitation exercises by using a repeated measures ANOVA. Statistical significance was accepted at $p<0.05$.

RESULTS AND DISCUSSION

Average strain in the mid-portion of the AT were significantly different between exercises (ToeWalk: 0.063 ± 0.021, UniDrop: 0.079 ± 0.022, Walk: 0.080 ± 0.018, UniRise: 0.081 ± 0.026, UniDrop Bent: 0.089 ± 0.026, mean ± SD). At the time of peak total muscle force, most of the exercises induce a strain higher than the reported optimal strain [3]. Even if walking is generally considered a safe form of exercise, average strains were also higher than the optimal. The average strain and the ranking of the rehabilitation exercises showed large variation across patients. The AT strains are not only task-dependent but also influenced by patients' material properties and geometry.

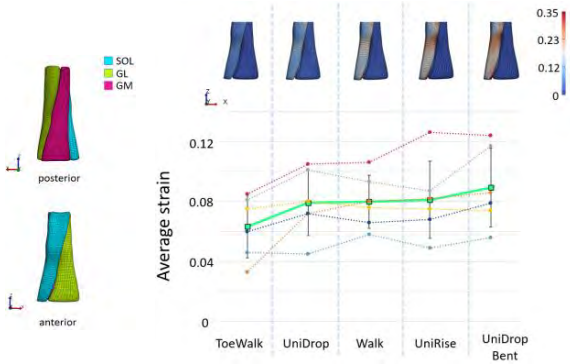

Figure 1 On the left, an example of FE model with the three twisted subtendons arising from Triceps Surae muscles. On the top right, a representative example of the distribution of the strain for the exercises. On the bottom right, the green line represents the mean and SD of the average strain for the exercises, in the mid-portion of the AT models. The dotted lines represent the average strain for the exercises for each participant, in the mid-portion of the AT models.

CONCLUSIONS

These FE models showed that the AT strains are influenced by subject-specific material properties, geometry and muscles forces, highlighting the need to develop personalized rehabilitation protocols. Future studies should investigate the influence of this large variability amongst patients with Achilles tendinopathy and the use of subject-specific analysis to design personalised rehabilitation protocol.

Effects of brace wearing and rehabilitation on foot muscle thickness and cross-sectional area after ankle inversion trauma

Rosemary Dubbeldam[1], Alexander Milstrey[2], Magdalena Sicher[1], and Sabine Ochman[2]
[1] Institute of Sport and Exercise Sciences, University of Münster, Münster, Germany
[2] Department of Trauma surgery, University Hospital Münster, Münster, Germany.
Email: r.dubbeldam@uni-muenster.de

INTRODUCTION

Patients suffering from chronic ankle instability (CAI) after ankle inversion trauma have lower intrinsic foot muscle volume compared to healthy controls [1]. These muscles are however progressively recruited in increasing postural demand [2], an activity which is impaired in CAI patients. While rehabilitation improves balance performance and extrinsic foot muscle strength in CAI [3], it is not clear if the intrinsic foot muscle strength also increases. Furthermore, little is known about the effect of brace wearing on intrinsic foot muscle strength after acute ankle inversion trauma. This study aims to analyse the effects of brace wearing and rehabilitation on intrinsic and extrinsic foot muscle thickness and cross sectional area (CSA) of patients suffering from acute and chronic ankle instability.

METHODS

Fourteen patients with a mean age of 24 (SD 6) years (7 males) suffering from acute (6) or chronic (8) ankle instability participated in a rehabilitation programme focussing on restoring functions and activities. The acute patients received an ultrasound assessment within one week of their injury (Philips Affiniti 50g). This was followed by a brace wearing period of 6 weeks, whereafter the rehabilitation started. An ultrasound assessment was performed of both limbs for all participants at the beginning and after 12 weeks of rehabilitation. The muscle thickness and CSA of the following 3 extrinsic and 3 intrinsic foot muscles were assessed: Tibialis anterior (TA), Peroneus longus (PL), Flexor digitorum longus (FDL), Hallux abductor (AbdH), Flexor hallucis brevis (FHB), and Flexor digitorum brevis (FDB). The muscles were analysed individually and as group of intrinsic or extrinsic muscles. A paired t-test was performed in SPSS to analyse the effects of the 6-week brace wearing in the acute patient group and the effects of 12-week training in both groups on the foot muscles. Also, the impaired and non-impaired limb were compared. Significant differences were reported for $p < 0.05$.

RESULTS AND DISCUSSION

There were no significant differences in muscle thickness or CSA between the impaired and non-impaired limbs, although the impaired limb's muscles tended to be smaller. The 6-week brace wearing caused a significant reduction in muscle thickness of the FDB from 0.76 (0.12) to 0.71 (0,12) cm and of the FHB from 1.35 (0.17) to 1.19 (0.10) cm (Figure 1). On the contrary, the TA thickness increased from 0.58 (0.12) cm to 0.70 (0.17) cm. During the 12-week rehabilitation training phase, a significant increase of the intrinsic foot muscles in thickness or CSA was observed (Table 1). The PL tended to increase in thickness after 12 weeks.

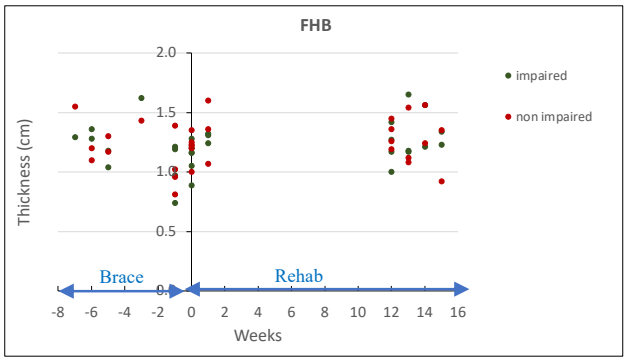

Figure 1 Decrease in FHB thickness during bracing phase (acute patients), followed by an increase in FHB thickness during rehabilitation phase (week 0 to week 12, all participants).

Table 1: Average (SD) thickness (cm) and CSA (cm^2) of the foot muscles for week 0 (start rehabilitation) and week 12.

Muscle	Week 0	Week 12	P
Sum intrinsic (cm)	2.86 (0.33)	3.18 (0.14)	0.04
Sum intrinsic (cm^2)	3.63 (0.69)	4.06 (1.03)	0.04
FDB (cm)	0.77 (0.13)	0.8 (0.14)	0.05
FHB (cm)	1.13 (0.17)	1.30 (0.17)	0.03
AbdH (cm^2)	1.93 (0.53)	2.09 (0.68)	0.05
PL (cm)	1.37 (0.29)	1.54 (0.27)	0.07

CONCLUSIONS

Brace wearing in the acute phase after injury is associated with up to 12% loss of intrinsic foot muscles and suggests the need to activate these muscles, e.g., isometrically and non-weight bearing, during this phase. During the rehabilitation phase, the intrinsic foot muscles recover with training. However, future studies should compare, if the muscle volume is able to fully recover to the level of healthy subjects.

INTRODUCTION

Side-step cutting manoeuvres are an important performance determinant in multi-directional sports, yet these manoeuvres are also linked to anterior cruciate ligament (ACL) injury [1]. Strategies for reducing ACL injury risk during side-step cutting have been developed, yet these often conflict with performance recommendations [2]. Identifying movement strategies that reduce hazardous knee loads during side-step cutting without affecting performance may enhance injury prevention uptake. We used a predictive simulation approach to identify biomechanical solutions that reduced potentially hazardous knee loads during side-step cutting without sacrificing performance.

METHODS

10 elite women's Australia Football players (25.0 ± 4.6 y; 1.71 ± 0.05 m; 67.9 ± 3.8 kg) participated. We used three-dimensional kinematic and kinetic data from an unanticipated 35-55º side-step cutting task. One successful trial from each participant was randomly selected to drive predictive simulations. A generic musculoskeletal model of the lower limbs and torso [3] was scaled to each participant and adapted to include: (i) a 3 DoF knee joint; (ii) idealised torque actuators at each joint; (iii) rolling-on-surface constraints at the feet to avoid ground penetration; and (iv) contact spheres on the cutting foot to estimate ground reaction forces (GRFs). We used the scaled musculoskeletal model with inverse kinematics and dynamics during the ground contact phase of the side-step cut to estimate joint angles and torques, respectively. A series of torque-driven simulations were conducted for each participant in OpenSim Moco [4]. First, a tracking simulation found the actuator signals that minimised errors in joint angles and torques, and GRFs estimated via the contact spheres versus experimental data – with this solution used as the initial guess for subsequent predictive simulations. Second, we generated a reference predictive simulation (i.e. '*reference*') of the side-step cut where only a lowly weighted goal tracking joint angles was used. Third, we repeated the prior simulation with an additional goal to minimise the frontal and transverse plane knee torques during the side-step cut (i.e. '*safer*'). In all simulations – the start and end point of the pelvis centre-of-mass (CoM), and time to complete the movement were constrained to match experimental data – to emulate performance. We compared full-body kinematics between the *reference* and *safer* simulations using one-dimensional statistical parametric mapping (SPM1D) paired t-tests ($\alpha = 0.05$ with Benjamini-Hochberg correction).

RESULTS AND DISCUSSION

Tracking and *reference* simulations had qualitatively similar joint angles and torques, and GRFs to experimental data. We observed large reductions in mean absolute frontal and transverse plane knee torques between the *reference* and *safer* simulations (0.41 ± 0.17 vs. 0.03 ± 0.01 Nm·kg^{-1} and 0.17 ± 0.10 vs. 0.02 ± 0.01 Nm·kg^{-1}, respectively), while achieving performance constraints (i.e. pelvis CoM and movement time). Visual inspection of *safer* simulations typically demonstrated better alignment of the GRF vector to the knee (i.e. reduced moment arm). Compared to *reference* simulations, *safer* simulations had increased ankle plantarflexion and reduced ankle dorsiflexion across the entire ground contact phase ($p = 0.034$). This demonstrates a shift to a fore-foot landing approach in *safer* simulations, in line with experimental [5] and simulation [6] works showing reduced knee loads with this approach. We identified no further statistically significant differences in kinematics between *reference* and *safer* simulations. The lack of differences alongside reductions in knee loads may be indicative of small kinematic changes having a large effect, or variable strategies being used across individuals.

CONCLUSIONS

A fore-foot landing approach to side-step cutting may be an effective global injury prevention recommendation that does not sacrifice performance. Further individualised kinematic changes may be necessary to minimise knee loads during side-step cuts.

INTRODUCTION

Tendinopathy, including tendinitis and tendinosis, is one of the most common soft tissue injury in the mordent society. Tendon is a poor self-limiting tissue, to overcome this shortage that many tissue engineering strategies were developed. Previous studies showed that loading to the injured tendon during healing is needed and many studies have shown that the passive loading could enhance the mechanical strength, however, the role of muscle contraction is missed in previous researches Moreover, the mechanical properties and most of all, adhesion, of the injured tendon after mechanical loading intervention post newly developed regenerative medical interventions are still missed [1]. The purpose of this study is to investigate the effects of isomatric muscle contraction post adipose-derived stromal vascular fraction (ADSVF) gel injection on the mechanical behavior and tendon adhesion in the rat Achilles tendinosis model.

METHODS

Thirty Sprague-Dawley male rats (~250g, 8 weeks old) were use and assigned to 2 treatment groups including ADSVF gel injection (SVF) and electrical stimulation induced isometric muscle contraction after ADSVF gel injection (SVF+IMC) groups. After skin shaved, all rats were anesthetized and injected with 0.1 μL collagenase type-I solution (0.1% w/v, CLS-1, Worthington, Lakewood, NJ) into the Achilles tendon on the both side under sonography guidance [2]. The treatment started after 2 weeks of injury induced. Rats were harvest at 7, 14, and 28 days after intervention. The ADSVF gel was conducted from donated rats' fat. The fat were cutting, centrifugation, and emulsification according to previous publication [3]. To induce the isometric muscle contraction, the rats were anesthetized and fixed on a customize loading frame with the ankle joint at 0° of plantar flexion. The gastrocnemius muscle was stimulated by a commercial electro therapy device (Dynaprog 527A, Dynaprog, Taiwan). A material testing system (MTS; Tension, Taiwan) with a 1000N load cell were used to evaluate the *in vitro* mechanical properties of the tendon, including tensile strength and tendon gliding. The Achilles tendon were cannulated to the loading frame of the system by the fixation of calf muscle and the calcaneal bone. After 10 times of preconditioning, the samples were pulled until failure. For the tendon gliding, all process was similar to mechanical strength except the insertion of the Achilles tendon were carefully dissected from the calcaneal bone. Two-way analysis of variance with Bonferroni post-hoc exam was used to compare the ultimate tensile strength and among groups. Statistic significant level was set at α=0.05.

RESULTS AND DISCUSSION

The ultimate tensile strength and tendon gliding were improved in both SVF and SVF+IMC group from 1-week post intervention to 4-week post intervention. The SVF+IMC group demonstrated significantly better ultimate tensile strength and lesser tendon adhesion comparing to SVF alone. That is, the isometric muscle contraction could improve mechanical strength and reduce adhesion. Our results indicated that the loading of the tendon is probably necessary after regenerative medicine treatment for the degenerative tendon.

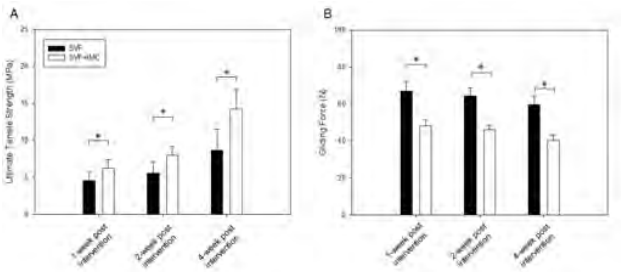

Figure 1. The ultimate tensile strength (A) and tendon gliding force (B) between different treatments and time duration. * denote $p < 0.05$. N=5 in each group and at each time point

CONCLUSIONS

In this study, we found that the tendon adhesion after ADSVF intervention might be reduced and the mechanical properties could be further improved with isometric muscle contraction.

Wearable Ultrasound Sensor for Lateral Epicondyle Tendinopathy Surveillance

INTRODUCTION

Lateral epicondyle tendinopathy (LET) or tennis elbow is an overuse injury caused by repetitive use of the forearm muscles [1]. It is a common cause of injury in various occupational groups who are exposed to repetitive use of the wrist and elbow. More than a million cases are diagnosed as LET each year in the United States [2,3]. Injuries to a tendon or ligament require a significant period of recovery and surgical or non-surgical treatment resulting in diminished quality of life [4,5]. It is thus critical to closely monitor the fatigue level of the fibrous connective tissues in order to prevent overuse of those tissues. This study aims to construct an ultrasonographic system that can quantitatively observe the morphological changes of the common extensor tendon (CET) and determine the fatigue state of CET during exercise.

METHODS

A total of 18 (10 males, 8 females) healthy university students participated in the study (IRB No: 7002340-202208-HR-019). To monitor the morphological changes as the fatigue was accumulated in the CET, a single-element ultrasound (US) transducer (2.25 MHz, Olympus, USA) was placed near the lateral epicondyle using a custom elbow brace. The US measurements were performed for the relaxed muscle condition, isometric maximum voluntary contractions (MVCs) at 0˚ forearm flexion, and isometric MVCs at 0˚ forearm pronation before and after the first and second fatigue exercises, respectively. To induce the CET fatigue, a gyroscopic hand exercise ball was used. Each subject was asked to maintain a minimum of 5000 rpm for 20 seconds and repeat three or five times. The CET thickness was calculated based on the time difference (Figure 1. red triangles on the left; t_2 -t_1), which correspond to the upper and lower layer of CET. The CET elevation was calculated using t_2, which corresponds to the lower layer of CET (Figure 1; red arrow). The nonparametric Wilcoxon Signed-Rank test was used to test the hypothesis (α=0.05).

RESULTS AND DISCUSSION

For the isometric forearm flexion condition, the mean CET thickness decreased by 26.6% (≈ -0.96 mm, p<0.001) and the mean CET elevation increased by 8.3% (≈ +1.04mm, p<0.001) (Figure 1). Similar results were observed for the isometric forearm pronation condition (Table 1). The results imply that the muscle-tendon unit was getting taut as the fatigue inducing exercise was repeated possibly due to the post activation potentiation. Even if it is partly due to the post activation potentiation, the morphological changes in the muscle-tendon unit during exercise can be still used as an indirect marker for injury prevention. Therefore, further studies are warranted to accurately quantify the accumulated fatigue level and correlate it to any morphological changes to prevent injury.

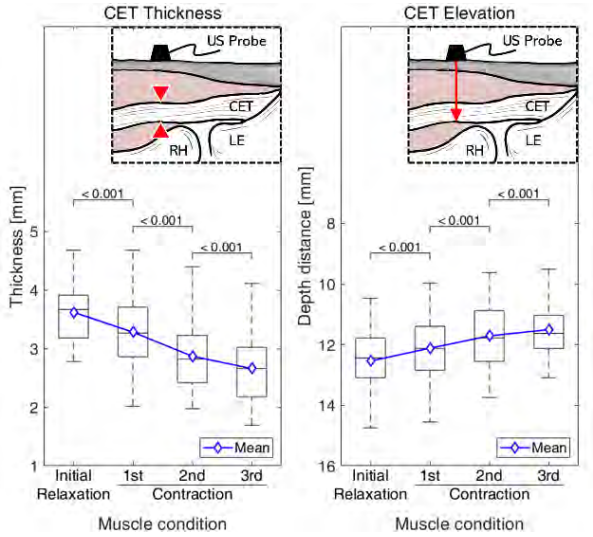

Figure 1 Morphological changes for the isometric forearm flexion

Table 1: CET changes in isometric forearm pronation

	Isometric forearm pronation
Mean CET thickness	-26.3% (≈ -0.90mm, p<0.001)
Mean CET elevation	+8.7% (≈ +1.09mm, p<0.001)

CONCLUSIONS

This study shows that the CET fatigue can be quantified by the changes in the CET thickness or elevation. This suggests that overuse-related Musculo-skeletal injury can be prevented by monitoring morphological changes in the muscle-tendon unit.

INTRODUCTION

The incidence of non-contact anterior cruciate ligament (ACL) injuries is high in womens team handball, particurlarly among young female players. During the early stance phase of side-cutting hip external rotator strength (HERS) is required to counteract the excessive hip internal rotation joint moments, which is contributing to the knee joint valgus position and thereby stressing the ACL. Thus, reduced HERS has been inditified as a risk factor of non-contact ACL injuries in handball [1] and other sports [2]. Therefore, the purpose of this study was to compare transverse hip and frontal plane knee angles and moments during side-cutting, and potential age-differences, between female handball players with low and high HERS.

METHODS

Sixty female handball players (32 children age: 12.5 ± 0.6 years and 28 adult's age: 23.8 ± 5.5 years) voluntarily participated in one test session. Maximum isometric HERS was measured with a handheld dynamometer. All players performed three maximum voluntary contractions in a seated position with the hip and knee in 90° flexion. HERS was normalised to body weight. Only the highest value was used for further analysis. Subsequently, players performed 5 side-cuts where peak hip internal rotation (IR) and knee abduction (Abd) angles and external moments for the dominant leg were recorded with a Vicon system and an AMTI force plate. Post data-collection, players were allocated to the low (≤ 2.0 N/kg BW) or high (> 2.0 N/kg BW) HERS group, respectively. A two-way ANOVA, with an alpha level of 0.05, was used to compare interactions effects and between groups and age differences.

RESULTS AND DISCUSSION

The low and high HERS groups had an average strength of 1.8 ± 0.2 N/kg BW and 2.3 ± 0.2 N/kg BW, respectively. The ANOVA showed no interaction effect (Table 1). The low HERS group displayed significantly lower peak hip IR moments during side-cutting (0.25 ± 0.13 Nm/kg BW, p = 0.045) compared to the high HERS group (0.33 ± 0.17 Nm/kg BW), and a tendency to higher peak hip IR angles (p = 0.070). Furthermore, the children displayed significantly higher external knee Abd moments (p = 0.034) than the adults , see Figure 1.

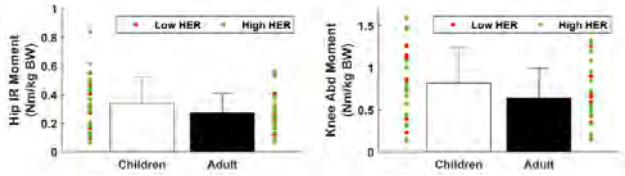

Figure 1. Mean ± SD external moments for children and adults, the individual players values are color-coded to their HERS score.

CONCLUSIONS

Regardless of age, female handball players with high HERS (>2.0 N/kg BW) was able to counteract higher hip IR moments during side-cutting, without greater peak IR angles, than players with low HERS. Moreover, low HERS was not associated with greater knee Abd angles or moments, but pre-teen players generally displayed higher knee Abd moments than adult players.

INTRODUCTION

Bone stress injuries particularly afflict runners. They occur as a result of microdamage accumulation alongside insufficient recovery. Loading magnitude is the most important contributor to bone damage accumulation [1], but loading quantity (e.g., number of steps) is also important. With increasing running speed, there is an increase in loading magnitude [2] but a decrease in the number of loading cycles to complete a given distance. Increased tibial loading as a result of running-induced fatigue accumulated over a run has been suggested to increase risk of stress injury [3]. The aims of this study were to 1) compare tibial loading between recreational (RR) and competitive runners (CR) throughout a demanding 10 km run; 2) quantify changes in tibial loading magnitude and rate of tibial damage accumulation throughout the duration of the run.

METHODS

Male runners who self-reported a 10 km season-best run slower than 47:30 min (RR) and faster than 37:30 min (CR) participated. The 10-km running protocol was performed at 105% of their season's-best time on a force-instrumented treadmill. Kinematics were synchronously collected, and data were obtained at 0km, 0.2km, 0.5km, 1 km and every km thereafter until 10km. Bending moments (M_{BE}) were estimated about the medial-lateral (ML) tibial axis at a distal 1/3rd centroid. Internal forces and moments were quantified by ensuring static equilibrium at each 1% of stance [4]. Muscular forces were estimated using static optimization with a cost function minimizing the sum of cubed muscle stresses. Peak M_{BE} was obtained, and cumulative damage was estimated using the following equation [5]:

$$\text{Cumulative damage} = \left[n \int_{t_i}^{t_f} (x_s)^b \, dt\right]^{\frac{1}{b}}$$

where n = number of steps, t_i,t_f = beginning and end of stance, respectively, x_s = ML M_{BE}, b = tissue-dependent weighting factor, 6.6 [6]. Two-way mixed ANOVAs (level of running x distance completed) were used to identify differences in ML M_{BE} and rate of damage accumulation per km.

RESULTS AND DISCUSSION

There were no interaction effects for peak M_{BE} or rate of damage accumulation. On average, peak M_{BE} was 31% higher in CR than RR, and decreased from the start to the end of the run by 5% (Figure 1A). There was a trend for greater rate of damage accumulation in the CR than RR ($p = 0.058$, $n_p^2 = 0.154$) and a decrease across both groups by 4% from the start to the end of the run (Figure 1B). Factors in addition to the loading experienced by the bone affect risk of bone stress injury – e.g. the tibiae of CR may be better adapted than RR to withstand loading.

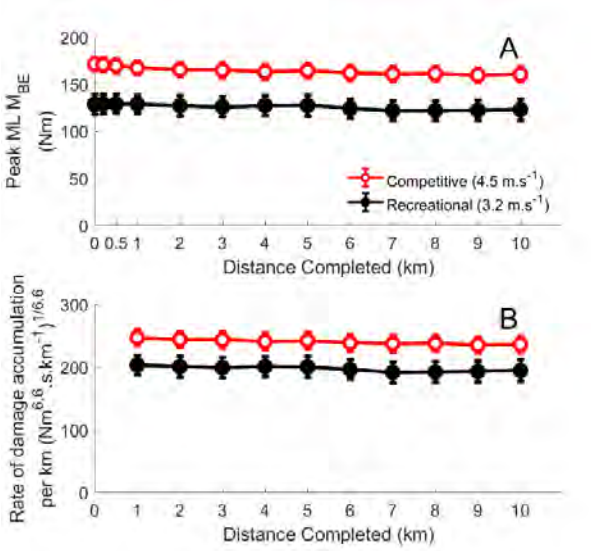

Figure 1: A) Peak ML M_{BE} in CR and RR throughout the 10km run; B) Rate of damage accumulation per km in CR and RR. Data points are mean values with standard error bars.

CONCLUSIONS

Competitive runners experience greater peak tibial loading than recreational runners when running 10km, due to the faster running speeds. There was also a trend for greater cumulative damage in CR than RR. Thus, completing a given running distance at a faster speed may increase the risk of a stress injury. Tibial loading decreases throughout a demanding 10km run suggesting that, in contrast to previous suggestions [3], running-induced fatigue-related changes in running mechanics may not be a primary mechanism for stress injury development.

INTRODUCTION

Kinematics of the knee during gait has mostly been studied using optical motion capture systems (MCS). The presence of soft tissue artifacts (STA) between the skin markers and the underlying bone presents a major impediment to obtaining a reliable joint kinematics assessment[1,2]. In this study, we determined the effects of STA on the calculation of knee joint kinematics during walking and running, through the combination of high-speed dual fluoroscopic imaging system (DFIS) and magnetic resonance imaging technique.

METHODS

Ten male subjects walked and ran while data was collected simultaneously from MCS and high-speed DFIS. A paired t-test was used to compare the results obtained from MCS and high-speed DFIS. The error between the MCS and high-speed DFIS results was used to calculate knee joint rotation errors. The kinematic data obtained from the high-speed DFIS was considered as the "gold standard" of measurement. The statistical significance level was set at $*p < 0.05$.

RESULTS AND DISCUSSION

The average error values across all timepoints of skin markers-derived knee flexion, external, and varus rotations during walking were -3.2 ± 4.3°, 4.6 ± 3.1°, and 4.5 ± 3.2°, respectively (Table 1). At the before contact and initial contact of walking, knee external rotation and varus rotation calculated from skin markers were all significantly greater than the high-speed DFIS. At after contact, external and varus rotations calculated from skin markers were significantly greater than those from the high-speed DFIS (Fig. 1 and Table 1).

The average error values across all timepoints of skin markers-derived knee flexion, external, and varus rotations during running were -5.8 ± 5.4°, 6.6 ± 3.7°, and 4.8 ± 2.5° respectively (Table 1). A significant difference in knee internal-external and valgus-varus rotations was reported in skin markers-derived kinematics with respect to the high-speed DFIS, evidenced at the before contact during running. At initial contact and after contact, the external and varus rotations calculated from skin markers showed significantly greater rotations than the high-speed DFIS during running, however, the knee flexion was significantly smaller (Fig. 1 and Table 1).

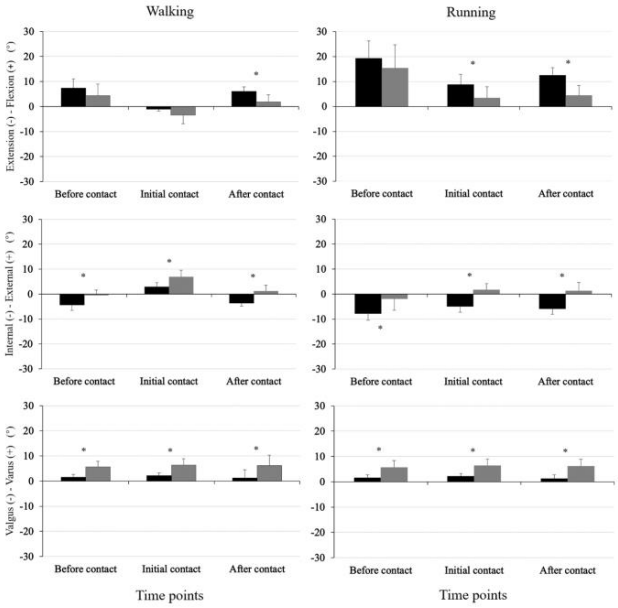

Figure 1 Means of knee joint rotations for walking and running were measured using MCS (grey) and high-speed DFIS (black).

CONCLUSIONS

The data indicated that STA will reduce the ability to accurately measure knee kinematics. The error values of knee kinematics obtained in this study offer a reference for differences between MCS and high-speed DFIS, and will be valuable in optimizing methods for analyzing knee kinematics during gait.

INTRODUCTION

Incomplete translation of modified running biomechanics in untrained environment after gait retraining has been reported. [1] Theoretically, better retention and generalizability can be facilitated by introducing task variations during training, [2] such as changes in elevation. Gait retraining studies that reported success in reducing peak tibial acceleration (PTA) with the use of feedback, were conducted on level surfaces using a fixed training target. Runners demonstrate grade-specific biomechanical adaptations [3] which could affect PTA. Setting a single threshold based on running on a level surface may not be suitable for training on slopes. We propose the use of an adaptive feedback model for training along routes with elevation changes. To our knowledge, this is the first study to examine the effect of gait retraining on sloped conditions after completion of training along an outdoor running route with changes in elevations.

METHODS

An experienced female runner completed this exploratory study. Three identical in-field tests were conducted to obtain the baseline PTA value. Each test consisted of a five km run, with one 1600-m level, two 800-m uphill (3.2%) and two 800-m downhill (-3.2%) sections. An accelerometer (Blue Trident, Vicon, UK) was attached to the right leg of the runner to measure axial PTA and a GPS-enabled smartwatch (vívoactive HR, Garmin, US) was used to record elevation and speed. A treadmill test was conducted after the in-field tests. The treadmill test consisted of three sloped conditions (0%, 4% and -4%) at speeds that matched the corresponding sloped conditions during the in-field runs. The training consisted of six training sessions along the same route as the in-field tests. The training thresholds for each sloped condition were set at 80% of the baseline PTA values averaged across the corresponding sections of the in-field tests (Figure 1). An audio beep was provided through headphones when the training threshold was exceeded. The runner was instructed to land softer and avoid the beep. After the training, the runner repeated the in-field tests and six running bouts (two in each sloped condition) on the treadmill at the speed that matches the in-field tests at baseline and after the training. The reliable change index (RCI) between baseline and after training for each sloped condition was calculated, a value greater than 1.96 indicates a significant change in PTA with 95% confidence. [1]

RESULTS AND DISCUSSION

At baseline, the running speed for level, uphill and downhill conditions were 3.55, 3.46 and 3.83 m/s respectively. The running speeds for all sloped conditions were slower after the training, the adjusted speeds were 2.97, 3.00 and 3.09 m/s. Significant changes in PTA were observed in all sloped conditions, for both in-field (RCI>2.4) and treadmill (RCI>3.3) tests, when running at the adjusted speed. The largest change in PTA was observed during in-field downhill running, with a 59% (-10.3 g) reduction (Figure 1). However, when running on the treadmill at the same speed, no significant reduction was observed in the level and uphill conditions. A significant change was observed in the downhill condition (RCI=4.1) with a 15.7% (-1.8 g) reduction. In contrast to traditional treadmill-based training, running speed was not constrained in this study. Our findings suggested that speed adjustment may be a viable strategy for reducing PTA.

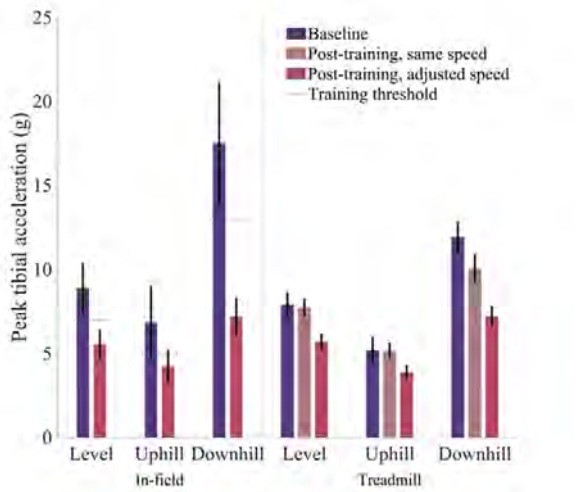

Figure 1 Peak tibial acceleration measured during in-field and treadmill tests. Bars and vertical lines indicate mean and SD respectively. Training thresholds are indicated by horizontal lines.

CONCLUSIONS

This exploratory study supports the use of adaptive feedback in gait retraining to reduce PTA. Among the sloped conditions, the training was most effective in reducing PTA during downhill running.

INTRODUCTION

In this study, we aimed to investigate how novice runners modulate running biomechanics while gaining experience in running. Our previous study from neural development perspective has reported that novice runners expressed a more efficient muscle activation pattern across 6 months of running [1]. Since running speed has been reported to equal to the multiplication of step frequency (SF), contact length, and stance averaged ground reaction force (avgGRF) [2], how these three variables varied in this group of novice runners across the 6 months of running remains unclear. We analysed the biomechanics data of the same group of novice runners, and hypothesized that SF would increase while avgGRF would reduce as the runners continued running.

METHODS

This study was a further analysis of the data published by Cheung et al., 2020 [1]. Eleven novice runners (<3 months of running experience) completed 3 treadmill running trials on a self-paced force-measuring treadmill before (baseline), 3-month, and 6-month after regular running training.

We recorded GRF at 1,000 Hz and filtered it using 4th order low-pass Butterworth filter with a cut-off frequency at 50 Hz. We then identified ground contact and toe-off using a 50 N threshold. We calculated SF based on ground contact information, and calculated contact length by multiplying contact time for the right leg with each participant's running speed. We calculated avgGRF as the average vertical force that was applied during the stance phase of running, and normalized it by body weight (BW). We constructed three linear mixed models to assess the effect of training on SF, contact length, and avgGRF, with each participant treated as a random factor. We set the level of significance at 0.05.

RESULTS & DISCUSSION

Training significantly affected SF ($F=4.62$, $p=0.04$), that SF increased by 3 steps/min for every 3-month interval (Fig. 1a). Participants did not significantly alter their contact length across the period that we tested ($F=0.26$, $p=0.61$, Fig. 1b). On average, changes in contact length between 3-moths, 6-months, and baseline are <1%. Training time significantly affected avgGRF ($F=13.5$, $p<0.001$), with 0.03 BW reduction in avgGRF for every 3-month interval (Fig. 1c).

After 3 months of running training, participants showed on average 7.6% increase in their SF in compared to baseline. After 6 months, 6 participants reduced their SF to a level that was comparable to baseline (< 3% difference), and the other 5 participants increased their SF on average by 10.7% compared to baseline. While our results are in line with previous findings, that a high SF has been considered to associate with better running economy [3], we also noticed large individual variance after 6 months of running. We previously reported that ~50% of novice runners presented with a merging muscle activation pattern, featuring a co-activation of ankle plantarflexors and knee extensors [1] after 3 months of running, but only ~30% of them still expressed such merging pattern after 6 months. We suggest studies with follow-ups longer than 6 months will be required to investigate changes in biomechanics and neuromuscular control for novice runners.

According to the equation that speed equals to the multiplication of SF, contact length, and avgGRF, while our participants increased their SF, they decreased avgGRF when running at the same speed after 3 and 6 months of running. When compared to baseline, all runners reduced their avgGRF on average by 4.8% after 6 months, which supports our hypothesis. Previous studies have suggested that avgGRF reflects the demand from the lower limb muscles to support the runner's weight during stance phase of running, and a reduced force application during stance phase of running has been associated with better running economy in distance runners [4].

Our previous study suggested that novice runners who expressed a more efficient muscle activation pattern ran with less mechanical energy loss [1], and our current results further support it from biomechanical perspective, that as novice runners continue to run, their running biomechanics also be modulated to benefit running economy.

CONCLUSIONS

Novice runners increased SF and reduced force applied after 6 months of running training. Such changes in running biomechanics could be a result from muscle activation pattern change as novice runners gained experience in running.

INTRODUCTION

The pacing behavior used by elite runners during a race is one of the most important tactics for success in distance running [1]. Humans change their running speed by altering a combination of step length and step frequency. Although faster running speeds can be achieved by increasing either step length or step frequency, changing these parameters independently is difficult because it is well-known that step length is inversely proportional to step frequency when running at a given speed [e.g. 2]. On the other hand, there exists inter-individual differences in step length and step frequency that have often been classified as aerial and terestrial runners [3]. Basically, the evaluation of the running style of athletes, whether they are aerial or terrestrial runners, is performed based on their running kinematics at a pre-defined speed. However, even though the running speed changes frequently as tactics during a race, no study has focused on the individual pattern of change in step length and step frequency as the running speed changes. Therefore, the purpose of this study was to elucidate the inter-individual differences in step length and step frequency changes across running speeds.

METHODS

Nineteen athletes, who compete in long distance running and whose best marathon record is less than 3 hours or equivalent, were recruited. A total of 68 reflective markers were attached to the athlete. Kinematic (250 Hz) and kinetic (1000 Hz) data were recorded simultaneously using a 24-camera motion capture system and three force plates. To minimize the influence of footwear, all athletes performed in a properly sized racing flat (Sortiemagic RP5, ASICS). All athletes were then asked to perform 15-30 straight running trials on a 50-m runway at various running speeds ranging from approximately 3.0 to 6.5 m/s. To encourage the athletes to run with their natural running styles, there was no restriction on the foot strike to a force plate; a trial was judged as successful if either of athlete's feet was in contact with any of the three force-plates with a natural running style.

Step length and step frequency were calculated for a single step for each trial. Step length was defined as the distance travelled by consecutive contralateral foot-strikes, calculated from the most-posterior heel markers of each foot. Step frequency was then calculated as the reciprocal of the time spent during a step cycle. Running speed was then calculated by multiplying step length and step frequency. The relationships between running speed and step length or step frequency were tested using Pearson's product moment correlation coefficient for each athlete. The association between the slopes of regression lines between running speed and step length (SL-Slope) and between running speed and step frequency (SF-Slope) were also tested. The significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

The significant positive correlations between running speed and step length were observed for all athletes ($r > 0.94$, $P < 0.01$). On the other hand, the correlations between running speed and step frequency were not always as strong as those between running speed and step length, only explaining 55% of the variance for the lowest case ($r = 0.74$, $P < 0.01$). The relationship between the regression slopes of the above relationships showed significantly negative correlation. This result indicates that every runner has a different ratio of step length changes and step frequency changes across running speeds.

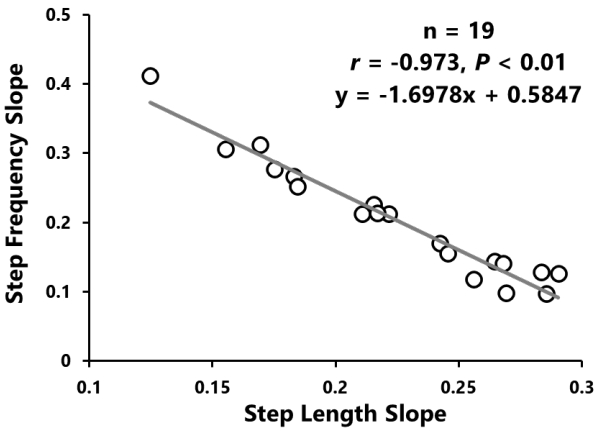

Figure 1 The association between the SL-Slope and SF-Slope

CONCLUSIONS

Judging running style, whether aerial or terrestrial, only by step length or step frequency at a given single speed is not necessarily sufficient to evaluate an individual's running style as it does not adequately capture the changes in step length and/or step frequency across running speeds. Instead, the combination of the SL-Slope and SF-Slope may be the possible method to assess the running style.

Variation in tibia-fibular geometry is associated with strain-related changes during running.

1. School of Exercise and Nutrition Science, Deakin University.
Email: mf.keast@gmail.com

INTRODUCTION

Naturally occurring variation in lower limb skeletal geometry has the potential to alter strain magnitude and distribution during locomotion. Tibial size is one geometric variation that has been cited for modifying the risk of developing tibial stress injuries [1]. Recent research using statistical shape models has identified several natural variations in tibia-fibula geometry. [2,3]. Some of these variations have been investigated using synthetic models that isolate individual geometries [3]. This methodology of isolating shape characteristics provides a clear way to isolate the effect of geometry on tibial strain. These methods, however, potentially represent an unrealistic tibia-fibula where concurrent shape variation is ignored. Estimating strain using participant specific bone models and finite element analysis provides the ability to examine the effects of geometric variations on strain in realistic skeletal geometry. We investigated the effect of tibia-fibula geometric variation on tibial strain magnitude during running at various speeds using participant-specific models.

METHODS

Participant specific three-dimensional models of the tibia-fibula were created using lower limb computed tomography (CT) scans from the right tibia and fibula of 30 cadavers (28.7± 6.7 years, 70.22 ± 11.36kg, 176.06 ± 11.61cm). Finite element (FE) models of the tibia-fibula were developed in FEBio. In each FE model: (i) generic joint reaction and muscle forces extracted from running at 3, 4 and 5m·s-1 [4] were applied to the tibia at the tibia-talus interface; (ii) the tibial plateau and medial malleoli were fixed; and (iii) the tibia-fibula interaction was modelled with tied contact and springs representing ligaments. Effective strain was then extracted from the tibial shaft (15 – 75% of tibial length). We used a non-parametric permutation method [5] to conduct classical hypothesis testing. We used this approach with linear regression models to evaluate the relationship between geometric characteristics (i.e. dependent variable) and effective strain along the tibial shaft (i.e. independent variable). Dependent variables were select principal component (PC) scores from three previously created statistical shape models [2], with 10 PC scores selected for statistical analyses. The principal component scores (i.e. dependent variables) were then input alongside the effective strain across the tibial shaft (i.e. independent variable) in separate linear regression models. An alpha level of 0.05 was used to calculate the critical t-value which denoted statistical significance.

RESULTS

We observed a statistically significant relationship between the thickness of the midshaft to upper tibia and condyle size to effective strain across areas of the tibial shaft. A higher score for this shape characteristic (i.e. increased thickness of the midshaft to upper tibia with increase in condyle size) was related to increases in effective strain at points along the distal anterolateral and proximal posterior regions of the tibial shaft at all three speeds. We also observed a statistically significant relationship between medulla cavity and midshaft cortical thickness to effective strain across areas of the tibial shaft. A higher score for this shape characteristic (i.e. decreased width of the medulla cavity and increased midshaft cortical thickness) was related to increases in effective strain across at specific points along the medial aspect at the distal end of the tibial shaft at a speed of 5 m/s.

CONCLUSIONS

Variations in tibial geometry can affect the magnitude of effective strain when running loads are applied to bone. Changes to thickness in the mid to upper portion of the tibia and to midshaft cortical thickness has the potential to increase strain in the distal portion of the tibia. It is possible that the increased thickness in the more proximal region caused the strain to be redistributed to the areas that are more susceptible to the applied loads (i.e. the distal end). An unbalanced degree of thickness between the upper and distal portions of the tibial shaft could potentially have a negative impact on tibial stress injury risk. Overall, our findings enhance understanding of the mechanisms underpinning tibial stress injury risk. However, it is still unknown the impact combinations of geometric variations have on tibial strain. Further investigation of the interactions between multiple shape characteristics is warranted.

INTRODUCTION

Patellofemoral pain syndrome is one of the most prevalent running-related injuries[1]. Interventions that are frequently used to reduce patellofemoral joint stress (PFJS) are alterations in running speed and step frequency. Remarkably, the combined effect of running speed and step frequency on PFJS parameters has not yet been investigated. The objective of this study was to investigate whether the load modifying effect of step frequency alterations was equally effective at different running speeds. More specifically, the peak PFJS and the cumulated PFJS per km were investigated.

METHODS

Twelve healthy recreational runners performed an incremental speed protocol on an instrumented treadmill. The protocol started at an initial running speed of 8km/h and increased by 2km/h every minute until 16km/h was reached. The protocol was completed three times: at habitual step frequency, 10% increased step frequency and 10% decreased step frequency. Kinematics data of the lower limbs and trunk were collected by 13 cameras of a passive marker-based motion capture system (100Hz, Vicon, UK). Markers were placed according to the Liverpool John Moores University model. Ground reaction forces were measured using two force plates embedded in the treadmill (1000Hz, Motek Medical, NL). Patellofemoral joint contact forces were calculated in OpenSim 3.3 using the Catelli model[2] and a standard modelling workflow[3]. The PFJS was then calculated by dividing the patellofemoral joint contact force by the angle-specific patellofemoral joint contact area, based on MRI data from the literature[4]. The cumulated PFJS was calculated by multiplying the PFJS impulse (PFJSi) per step by the number of strides per km. Main effects of running speed, step frequency and their interaction effect were evaluated using two-way repeated measures ANOVA's. In case of a significant effect, linear regression analyses were chosen as post-hoc analyses.

RESULTS AND DISCUSSION

For peak PFJS, significant main effects were confirmed for running speed and step frequency. Higher running speeds resulted in higher peak PFJS and increased step frequency resulting in lower peak PFJS (Table 1). There was no statistically significant interaction effect. The regression analysis of the peak PFJS showed separated parallel lines that increased similarly with increasing running speed (Figure 1). For the PFJSi per km, significant main effects for running speed and step frequency as well as a significant interaction effect were found. The regression analysis showed decreasing and converging lines as the running speed increased, suggesting that step frequency alteration was more effective at low running speed.

Table 1: P-values for the two-way repeated measures ANOVA's for peak PFJS and PFJSi per km.

	Running speed	Step frequency	Interaction
Peak PFJS	*p<0.001*	*p<0.001*	*p=0.338*
PFJSi per km	*p<0.001*	*p<0.001*	*p<0.001*

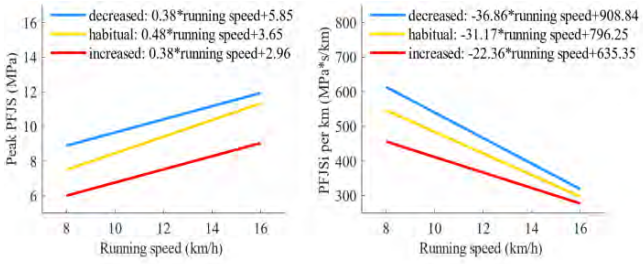

Figure 1: Regression lines for peak PFJS and PFJSi per km for each step frequency condition.

CONCLUSIONS

Whilst step frequency alterations are equally effective at low and high running speeds to change peak PFJS, the effectiveness on cumulated PFJS is higher at low running speeds. These findings are very relevant to optimise load management strategies for patients with patellofemoral pain syndrome.

INTRODUCTION

Generic musculoskeletal models often present substantial errors in the prediction of joint function after total knee arthroplasty (TKA) [1]. Therefore, subject-specific modelling is necessary to investigate knee mechanics and personalize surgeries. This study introduces an advanced modelling framework towards understanding the influence of different surgical parameters on the knee joint mechanics after TKA. The framework was validated using a detailed musculoskeletal model personalized to a subject measured within the CAMS-Knee project [2]. Loading and kinematics of the knee during level walking and squat from simulation results were accurately matched with data obtained from *in vivo* measurements.

METHODS

The subject-specific skeleton geometry was derived from CT images of a TKA patient in the CAMS-Knee datasets (K5R [2]). Bone segments were then linked to form a multibody model with hip, knee, and ankle joints. (Fig 1). Implant components were positioned within the subject-specific model based on their 3D pose within the CT images.

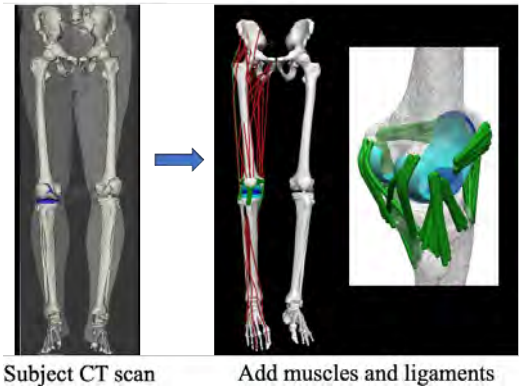

Figure 1 Model development framework.

Knee ligament footprints were identified based on anatomical literature. Ligaments were modelled using bundles of nonlinear spring elements connecting the ligament footprints. Ligament and muscle parameters were scaled and adjusted from previously developed models [3,4].

The tibiofemoral and patellofemoral joints were modelled with 12 degrees of freedom (DOFs) and guided by elastic foundation contact between the implant surfaces. Skin-marker trajectories and ground reaction force data were inputs to the COMAK tool [5] to estimate knee kinematics and loading during five trials of simulated level walking and squat. The outcomes were validated against *in vivo* measurements of contact force from an instrumented implant and tibiofemoral kinematics from fluoroscopy.

RESULTS AND DISCUSSION

Overall, the model was able to accurately predict tibiofemoral kinematics and loading patterns measured *in vivo* (Fig 2). Predicted knee contact forces reached 2.5 and 3.3 BW during walking and squatting, which indicate slight overestimation of the loads likely due to non-personalized parameters (e.g., muscle strength, ligament properties and muscle coordination strategy). Importantly, the framework also enables estimation of ligament and muscle forces as well as patellofemoral joint mechanics and thus allows further exploration towards understanding interrelationships between different joint structures and TKA surgical decisions.

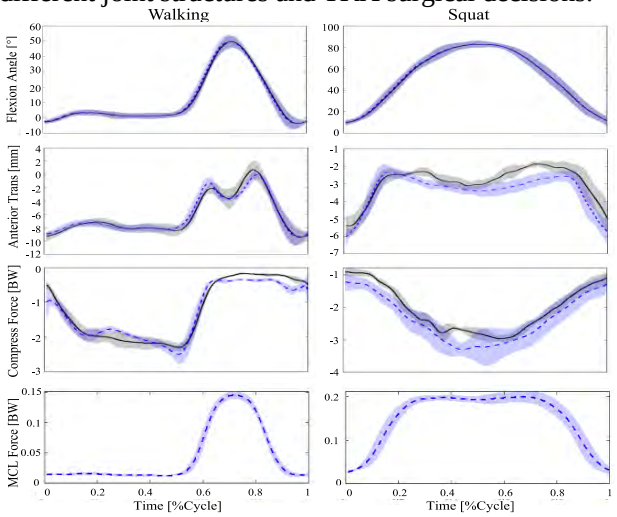

Figure 2 Forces and kinematics at knee during walking and squat (blue model, black experiment).

CONCLUSIONS

Our modelling framework enables reliable estimation of the knee joint mechanics during dynamic and quasi-static activities, thus providing a predictive tool for future investigations into the influence of surgical parameters (e.g., ligament release and implant alignment) on the joint function after TKA.

DYNAMIC SIMULATION OF RUNNING USING A FULL-BODY MODEL WITH TRUNK MUSCLES

INTRODUCTION

A model of the human musculoskeletal system that includes a detailed representation of the torso has not previously been used to perform dynamic simulations of whole-body movement. Such a model would allow for a better understanding of trunk muscle function during dynamic activity by predicting the activations and forces of the deep and superficial muscle layers, thereby lending insight into the relationships between trunk muscle strength and athletic performance. The main aim of the present study was firstly, to create an anatomically-accurate and computationally-efficient full-body model that includes a detailed representation of the trunk musculature; and secondly, to implement this model in a dynamic simulation of medium-paced running.

METHODS

The model was created using OpenSim 3.3 [1] by combining the trunk muscles included in the model published by Raabe and Chaudhari [2] with the lower-limb model developed by Lai et al [3]. This was done because the lower-limb model developed by Lai et al. [3] is better suited to the higher hip and knee flexion angles present in maximum-effort activities such as running and jumping. The constraints controlling lumbar spine motion used by Raabe and Chaudhari [1] were replaced with a single-segment lumbar spine, yielding a two-segment trunk model. The specific tension of the trunk muscles was then modified to match that assumed for the lower limbs (60 N/cm^2) [3]. To enhance computational efficiency of the model, a simplified set of trunk muscles was created by grouping muscle-tendon units (MTUs) in the Raabe and Chaudhari trunk model [2] and replacing each group with a single MTU. MTUs were grouped to ensure that each major trunk muscle was still represented by at least one equivalent MTU. New origin and insertion sites and muscle fibre parameters were defined based on either a summation or average of values defined in the original set of MTUs. Muscle moment arms and muscle fibre parameters were then compared against literature data. The model was scaled in OpenSim 3.3 [1] and used to perform inverse kinematics, static optimization, and computed muscle control (CMC) for one subject running at 5.0 ms^{-1}.

RESULTS AND DISCUSSION

The final model consisted of 17 segments, 16 joints and 36 degrees of freedom, and was actuated by 116 MTUs. The model was used to perform a dynamic simulation of sprinting at 5.0 ms^{-1}, providing predicted muscle activations and muscle forces for 80 lower limb and 24 of the 36 trunk MTUs. Representing the lumbar spine as a single segment necessitated further modification of the remaining 12 MTUs to ensure the trunk segments could be adequately controlled. Model-predicted activations of the trunk muscles during medium-paced running (5 ms^{-1}) were consistent with those reported for running at 3.5 ms^{-1} derived using static optimization [2]. However, model-predicted activations obtained in the present study were typically higher and lasted for a longer duration due to the additional work that the trunk muscles must undertake to overcome larger ground reaction forces at higher running speeds. RMS errors for kinematic tracking vs. CMC predicted motion are given in Table 1 below. Future work will entail increasing the number of trunk muscles to 36 and performing simulations for both countermovement and squat jumps.

CONCLUSIONS

A full-body model incorporating 24 trunk muscles was used to perform a dynamic simulation of medium-paced running at 5.0 ms^{-1}. The model reproduced measured 3D joint motion using muscle activation patterns consistent with measured EMG.

Unravelling adaptation strategies in sit-to-walk using predictive neuromuscular simulations: pain

Eline van der Kruk[1], Thomas Geijtenbeek[1]
[1] Biomechanical Engineering, Delft University of Technology, Delft, The Netherlands.
Email: e.vanderkruk@tudelft.nl

INTRODUCTION

Standing up from a chair is a key daily life activity (>60x per day) that is sensitive to functional limitations as we age. Most stand-up movements transfer directly into walking (sit-to-walk). Predictive neuromusculoskeletal models could possibly shed light on the interconnectivity and interdependency of neuromuscular capacity, reinforcement schemes, sensory integration, and adaptation strategies during stand up. The aim of this study was to develop and validate a planar neuromusculoskeletal model with reflex-based muscle control to simulate the sit-to-walk movement. The framework was used to simulated the sit-to-walk movement in different conditions (seat height, foot placement), reduced muscular capacity, reduced neural capacity, and altered movement objectives (pain). In this abstract we focus on the following hypothesis: “Altered trunk flexion strategies, which previously were shown to be related to muscle weakness, may also be related to pain avoidance” which was put forward in a recent review [1].

METHODS

In summary, a planar sit-to-walk musculoskeletal model (11 dof, 20 muscles) and controller were developed and optimized in SCONE [2] using a shooting-based optimization method. The sit-to-walk controllers consist of a two-phase stand-up controller (P1, P2) based on proprioceptive feedback from muscle length feedback (L), force feedback (F), velocity feedback (V), constant excitation (C), and vestibular feedback. The delayed feedback pathways were both monosynaptic an antagonistic. The free parameters were optimized to minimize the cubed muscle activation and gross cost of transport, at a prescribed minimum gait velocity, while avoiding falling, and ligament injury. We ran multiple parallel optimizations with the same initial guess and used the best set as start for the next set of optimizations. Final results were compared to a subset of recorded kinematics, ground reaction forces (GRF), and muscle activation (sEMG) from young (18-35 year) and older (>65 year) adults (n = 50), in which participants were asked to stand up and walk to a table at self-selected speed [3].

RESULTS AND DISCUSSION

The simulation resulted in altered trunk flexion when there was an increase of task demand (reduced seat height) or a decrease of muscular capacity (reduced VAS muscular strength). Pain avoidance, which we assumed would lead to an objective of reduced knee load, led to altered muscle recruitments (reduced ipsilateral activation of VAS and HAM, compensated by increased activation of the GMAX), and not to increased trunk flexion. The predictive simulations thus showed that increased trunk flexion is most likely the result of lack of muscular reserve rather than pain avoidance.

This is in line with the difference in kinematics and muscle activations that was found between moderate and severe knee osteoarthritis (OA) patients in experimental data. The increase of trunk flexion was only found in severe knee OA patients, whereas moderate knee OA patients maintained the same movement trajectory as healthy individuals but with altered muscle recruitment [1]. If we assume that severe OA patients have less muscular reserve than moderate OA patients as a result of reduced daily life activity, severe OA patients will employ increased trunk flexion in standing up to compensate for lack of strength. Over time, the unloading of the knee to avoid pain could be the cause of muscular weakness in specific muscles. In the simulations we saw that already in standing up, unloading the knee leads to reduced activation of the VAS muscle. Assuming this leads to reduced VAS strength this eventually results in a negative spiral. The compensation strategies increased the loading on ipsilateral and contralateral joints, likely leading to increased wear of other joints.

CONCLUSIONS

The simulation showed how increased trunk flexion, as observed in severe OA patients, is most likely the result of muscular weakness rather than pain avoidance. Whereas altered muscle recruitment is a way to reduce joint loading, like previously observed in moderate OA patients. Based on the results it might be beneficial to treat pain in knee OA patients early on to avoid compensatory muscle recruitments which lead to underuse of specific muscles.

INTRODUCTION

Glenohumeral (GH) stability is a delicate interplay between bony congruence, muscle contraction and ligamentous or capsular stability. The bony congruence confines the translational kinematics. While muscles provide stability to the humeral head in midrange motion, ligamentous and further connective tissue structures constrain the joint at endrange motion [1]. An imbalance can cause pathologies such as shoulder instability, osteoarthritis or rotator cuff tears, however, the underlying effect is not yet well understood.
The few shoulder models implementing GH translation define GH joint stiffness based on a reverse engineering approach of measured humeral head translations [2]. A musculoskeletal shoulder model applying biomechanical properties of bony, muscular and ligamentous structures would enable further investigation of pathological mechanisms.
We aimed to develop an advanced musculoskeletal shoulder model, considering bony contact forces, muscle active and passive stability and ligament mechanical properties, to calculate GH translations using force-dependent kinematics (FDK) [3].

METHODS

Motion capture data of 15 participants performing three 0° to 30° abduction-adduction cycles (VICON, UK) with 0 to 3kg handheld weight were incorporated into a musculoskeletal model of the right shoulder (Anybody 7.3, repository AMMR v.2.3.1) for subject scaling and to drive subject-specific motion [4]. Segmented glenoid, labrum and humeral head contact surfaces were developed from MRI images. GH and coracohumeral ligament stiffness, slack length and insertion sites were defined generically. The Hill muscle model was calibrated to subject size. Based on the acting joint forces and constraints, GH translations were calculated in each time step using FDK[3]. Resulting GH translations were compared between abduction-adduction cycles with different handheld weights and to existing measured inferior-superior translations from dynamic fluoroscopy imaging of the same subjects.

RESULTS

At 0kg handheld weight, seven shoulder models presented an anterosuperior GH escape and three an initial inferior drop. The remaining six models converged, and mean inferior-superior translations decreased from 3.5 to 1.8mm for 0 to 3kg handheld weight, however, did not match the 1.6mm and 0.8mm measured in patients with 0 and 2kg handheld weight, respectively (Figure 1).

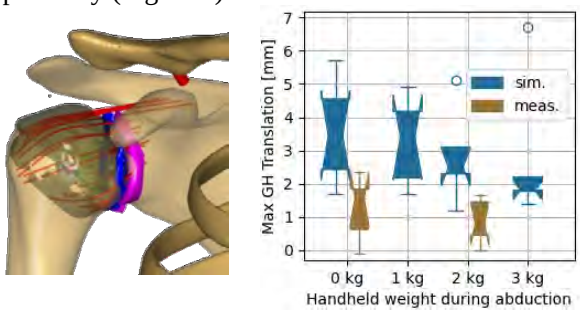

Figure 1 *(A) FDK Shoulder model and (b) Comparison of measured (meas.) and simulated (sim.)* inferior-superior GH translations

DISCUSSION AND CONCLUSIONS

This work presents a novel pipeline for more physiological shoulder modelling. GH translations calculated with this model are significantly higher than measured values especially at lighter handheld weights, indicating that muscular stabilisation is currently underrepresented. Enforced muscle recruitment with greater handheld weights led to the required stabilisation effect of the GH joint. Future work will focus on emphasizing the muscular recruitment for joint stability to subsequently further apply this model to assess pathological shoulders.

A DYNAMIC FOOT MODEL FOR PREDICTIVE SIMULATIONS OF GAIT

Lars D'Hondt[1], Friedl De Groote[1] and Maarten Afschrift[2]

INTRODUCTION

Predictive simulations that generate de novo gait patterns based on a musculoskeletal model (without using experimental gait data as input) are a powerful tool to explore causal relations between musculoskeletal properties and gait mechanics. State-of-the-art predictive simulations capture many features of human gait, yet generating realistic ankle mechanics remains a challenge [1]. Humans use their calf muscles and Achilles tendon to efficiently produce large positive ankle power at push-off. This strategy requires the foot to act as a stiff lever [2]. The human foot is compliant, but can be stiffened by muscle contraction and by tensioning the plantar fascia (an elastic structure that connects the heel and toes). This stiffening mechanism is associated with a 18±2° range of motion observed between hindfoot and forefoot [2]. State-of-the-art predictive simulations use a model with a 2-segment foot, thus do not account for midfoot motion. We present a 3-segment foot model that improves the realism of 3D predicitive simulations of gait.

METHODS

We adapted the musculoskeletal model used by Falisse et al. [1] to include a 3-segment foot model (hindfoot, midfoot-forefoot, toes) with a deformable longitudinal foot arch. Hindfoot and midfoot-forefoot segments are connected by a midtarsal joint with a single degree of freedom. We modelled ligaments with non-linear stiffness. We considered the plantar fascia as a single elastic element originating on the calcaneus, wrapping around the metatarsals, and inserting on the proximal phalange. We modelled plantar intrinsic muscles by a single Hill-type muscle with the same path as the plantar fascia. We reduced normalised Achilles tendon stiffness to 8 at 4 % strain, because this results in more realistic fibre lengths of the gastrocnemius medialis [1]. To model foot-ground contact, we placed five Hunt-Crossley spheres under each foot guided by foot anatomy and plantar pressure data: heel pad, lateral longitudinal arch, ball of the foot (2 spheres), and toes. Mechanical parameters were tuned to be consistent with heel pad properties from literature. Using our previously developed simulation workflow [1], we simulated walking at self-selecting speed based on a series of models to evaluate the effect of ankle and foot morphology on gait.

RESULTS AND DISCUSSION

Predictive simulations based on our 3-segment foot model better capture ankle kinematics and power than simulations based on a 2-segment foot model (Figure 1, thick lines). Simulated gait patterns were especially sensitive to heel pad, Achilles tendon, and arch stiffness (Figure 1, thin lines). (1) Stance knee flexion required a sufficiently stiff heel pad. (2) The Achilles tendon had to be sufficiently compliant to obtain ankle dorsiflexion and energy storage during mid stance. (3) Reduced ability to stiffen the foot (no plantar intrinsic muscle, very compliant plantar fascia, low arch height) resulted in exaggerated knee flexion during the second half of stance and reduced negative ankle power.

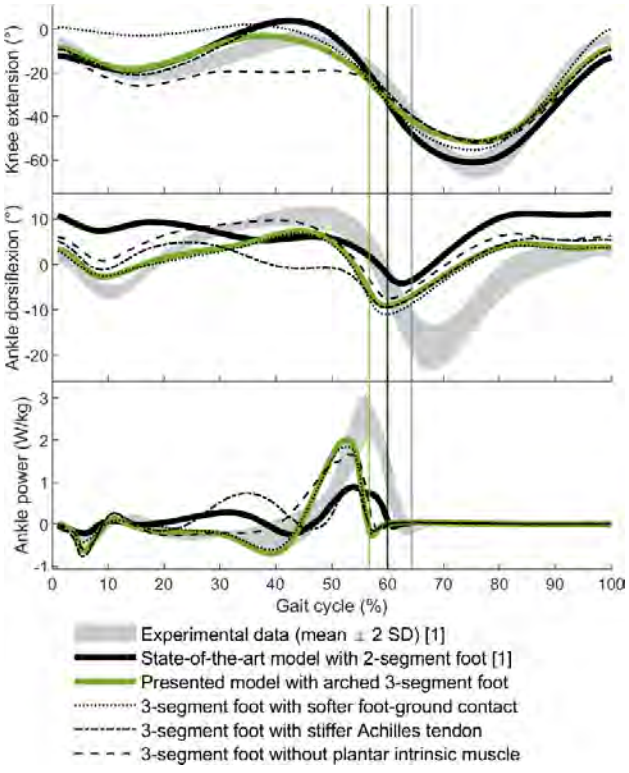

Figure 1 Predicted gait for different foot models.

CONCLUSIONS

Simulations can help elucidate how foot and ankle morphology shape whole body gait mechanics, which has implications for understanding foot pathologies and evolution, and for the design of bipedal robots.

INSIGHTS INTO THE DIFFERENT STATE-OF-THE-ART OPTIMISATION APPROACHES FOR SOLVING THE SHOULDER MUSCLE REDUNDANCY PROBLEM

Maxence Lavaill[1], Saulo Martelli[1], and Peter Pivonka[1]

[1] School of Mechanical, Medical and Process Engineering, Queensland University of Technology, Brisbane, Australia.

Email: maxence.lavaill@qut.edu.au

INTRODUCTION

Estimating muscle forces *in vivo* is critical for understanding the internal biomechanics of shoulder motions. Current techniques solve the muscle redundancy problem either by static optimisation (SO), which assumes optimal control, by constraining the muscle forces to the available electromyography measurement (EMG-assisted methods) [1] or by stochastically sampling the entire spectum of possible muscle forces within admissible constraints [2]. This study aims to compare predictions of muscle and glenohumeral forces obtained using SO, EMG-assisted and stochastic methods to corresponding electromyography and glenohumeral contact force measurements reported in previous work [3].

METHODS

Data were previously obtained from a female participant (73 y.o., 168 cm, 72 kg) with an instrumented shoulder hemi-arthroplasty [3]. She was asked to perform a shoulder abduction-adduction task while fourteen bony landmark's locations (thorax, scapula, upper arm and forearm) were captured using an *Optotrack* system (Northern Digital Inc., Canada) at 50 Hz. Ten surface electrodes, placed on top of the Trapezius, Deltoideus, Pectoralis Major, Biceps and Triceps muscles, simultaneously recorded EMGs at a sampling rate of 1000 Hz. Filtered EMG envelopes were extracted. A previously developed upper-limb musculoskeletal model, consisting of 7 segments, 10 degrees-of-freedom and 91 muscle elements [4], was linearly scaled to match the anthropometry of the participant. Joint angles and moments were computed *via* inverse kinematics (IK) and inverse dynamics (ID) through *OpenSim 3.3*.

First, muscle recruitment was estimated using SO (*OpenSim 3.3* GUI) by minimising the sum of the muscle activation squared at each frame of the motion task. Second, a calibrated EMG-assisted method was adopted. This method consisted of 2 steps. Step one was calibrating the model's muscle parameters using the CEINMS toolbox [5] and data from a subsidiary shoulder abduction trial. Step two was running CEINMS on the main data in EMG-assisted mode. This mode combinedly minimised the glenohumeral joint torque errors, the muscle excitation errors for experimentally recorded muscles and the overall sum of the muscle excitations squared. Finally, a stochastic method, as presented in [2], was used. Based on the known moment arms, the method sampled 200000 muscle recruitment solutions satisfying the joint torques. Muscle forces were bound from 0 to 70% of their respective maximum force. Resultant glenohumeral joint forces were estimated using the muscle forces estimated from all three methods.

The experimental total glenohumeral joint force was compared against the stochastic range to determine whether the solution is part of the model. Then, each method was compared against the others in terms of muscle forces and resulting glenohumeral joint force and validated against the experimental EMG signals and instrumented glenohumeral joint force.

RESULTS AND DISCUSSION

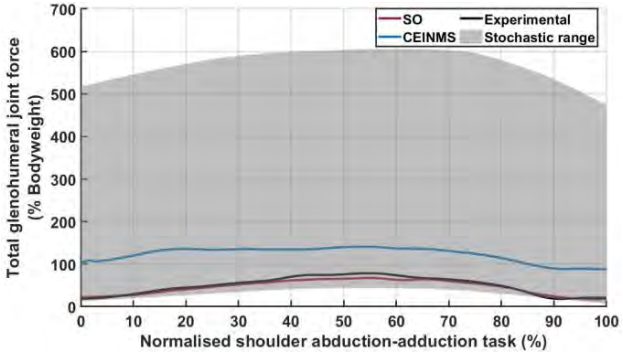

Figure 1 Normalised glenohumeral loads from the instrumented prosthesis (black) and from the estimated solutions using static optimisation (red) and EMG-assisted optimisation (blue).

The whole glenohumeral joint force measurement was within the stochastic range meaning that it represented a possible solution of the model (Fig. 1). Root mean square deviation (RMSd) between SO and experimental glenohumeral joint force was 41N. CEINMS overestimated the joint force (RMSd = 522N) due to higher co-contractions [1]. Moreover, SO expectedly stood close to the lower bound of the stochastic range (RMSd = 116N with lower bound). The whole stochastic range was 3800N wide on average.

CONCLUSIONS

The shoulder model's solutions included the joint measurements, as well as the CEINMS and SO solutions; the latter being the closest to the instrumented implant measurements. Future results including more patients and movements are currently being processed.

INTRODUCTION

Volleyball is a physically high demanding sport. Volleyball games contain different types of sprinting, change of direction, and jumping activities. Volleyball players often suffer from upper extremity, trunk, and lower extremity overuse injuries. Monitoring the training load of volleyball players is a great strategy to prevent injuries and improve sports performance. Training load derived from inertial measurement unit has been an indicator to monitor the athletes' activities during training and games [2,3]. Few studies investigated the percentage contributions of individual axis to training load of volleyball players. The purpose of this study was to investigate the percentage contribution of each individual axis to total training load of female university volleyball players during practice games.

METHODS

Thirteen female university volleyball players (173.5 ± 9.5 cm; 63.1 ± 4.2 kg; 22.1 ± 3.5 yrs.) were recruited in this study (3 outside hitters, 2 opposites, 4 middle blockers, 2 setters, 2 liberos). Inertial measurement unit (50Hz, Goalgo T1, Tromin, Taiwan) was placed on the players' left shoulder and used to collect the triaxial acceleration data of the players during practice game. The acceleration raw data was filtered at 10Hz using a low-pass Blackman filter (AcqKnowledge 4.1). The total training load was calculated as the sum of the squared instantaneous rate of change in acceleration of triaxial axes (Equation 1). The percentage contributions for the x (antero-posterior), y (medio-lateral), and z (vertical) axes were calculated by dividing sum of the squared instantaneous rate of change in acceleration of each axis by that of triaxial axes (Equation 2) [1,2,3]. One-way repeated ANOVA was used to reveal the differences among three axes percentage contributions. The significant level was set as $p < .05$.

Training Load
$= (a_{x1} - a_{x-1})^2 + (a_{y1} - a_{y-1})^2 + (a_{z1} - a_{z-1})^2$
Equation 1 Total Training Load.

Percentage contribution of each axis
$= (a_{x1} - a_{x-1})^2 / ((a_{x1} - a_{x-1})^2 + (a_{y1} - a_{y-1})^2 + (a_{z1} - a_{z-1})^2)$
Equation 2 Percentage contribution of each axis.

RESULTS AND DISCUSSION

The vertical training load reaches about 37.5% of total training load. Antero-posterior training load reaches about 32.3% of total training load. Medio-lateral training load reaches about 30.1% of total training load. The percentage contribution of vertical training load was significantly larger than those of antero-posterior and medio-lateral training load (Table 1). Previous study also revealed higher vertical load of soccer players in season games. However, the percentage contributions of antero-posterior and medio-lateral axes of volleyball players were higher than those of soccer players [1]. This result may be owing to more antero-posterior and medio-lateral axes of sports-specific movements in volleyball practice games.

CONCLUSIONS

Vertical training load contributes to significantly higher percentage of total training load in female university volleyball players during practice games. No significant differences exist among antero-posterior and medio-lateral training load. The injury prevention or strength and conditioning program of female university volleyball players should emphasize more on vertical axis of movements training to cope with the higher physical demands in vertical direction.

INTRODUCTION

Measuring the center of pressure (CoP) and vertical ground reaction forces (vGRF) during gaits is integral for the assessment of balance performance and lower limb injuries. Pressure sensor insoles are very popular and practical tools for detection and monitoring in clinical context [1]. However, the large number of sensors in valid systems results in high product costs and limited accessibility in therapeutical settings [2]. Therefore, research attempted to simplify pressure sensor insoles by reducing the number of required sensors [2]. Since the required sensor number has been unclear, the purpose of this study was to compare multiple layouts with different sensor numbers and assess the accuracy of CoP and vGRF.

METHODS

Fifteen healthy participants performed two gaits (i.e., walking and jogging) at self-selected slow and fast speed. Kistler force plates (1000 Hz) and Pedar-X insoles (100 Hz) obtained CoP and vGRF. Based on anatomical points [1], eight different simplified insole sensor layouts were simulated, comprising 3–17 sensors. CoP and vGRF from simplified layouts were compared with force plate data to assess concurrent validity. Multivariable regression models estimated absolute vGRF for simplified sensor layouts. Pearson's Product-Moment correlation coefficient (r) and Lin's Concurrent Correlation Coefficient (CCC) were calculated for each participant over the entire time of ground contact of one step at $p<0.05$.

RESULTS AND DISCUSSION

Correlation and concordance between sensor layouts and force plates ranged between 0.71 and 0.97 (Table 1). Correlation and concordance differed between gaits for CoP ($\chi^2_{(7)}$: 0.70–0.83, $p<0.05$) and vGRF (η^2_p: 0.28–0.66, $p<.05$). Root mean square error (RMSE) of CoP was higher in walking (15±3 mm) than in jogging (10±6 mm). RMSE of vGRF (Figure 1) was calculated from absolute values that were estimated via a regression model for the sensor layout with the lowest sensor number with strong validity (>0.9) across gaits and speeds (i.e., 11-sensor layout).

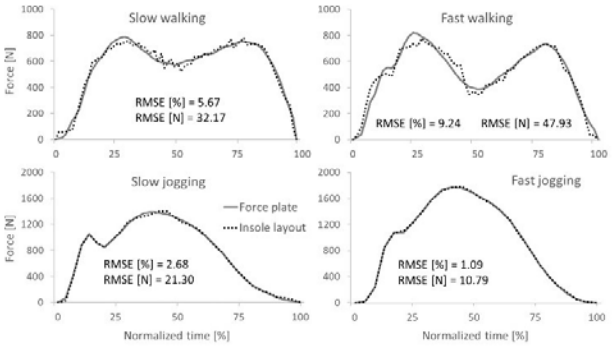

Figure 1 Representative absolute vGRF derived from the 11-sensor layout in comparison with force plate data; retrieved from [3].

CONCLUSIONS

The 11-sensor layout was identified as a promising compromise between sensor number and measurement accuracy across gaits and speeds. However, the observed differences in accuracy between gaits may suggest limited transferability of the current findings to other motor tasks. Future research is advised to optimize sensor layouts using 11 or more sensors, accounting for a wider range of common tasks.

IMU METRICS ASSESSED DURING 2KM OF INDOOR TRACK VS SIDEWALK RUNNING

Hannah L. Dimmick[1], Andrew J. Pohl[1], Zoe Y.S. Chan[1] and Reed Ferber [1]

[1] Faculty of Kinesiology, University of Calgary, Calgary, Canada

Email: hannah.dimmick@ucalgary.ca

INTRODUCTION

Inertial measurement units (IMUs) are a popular tool to study running gait outside of a laboratory setting. However, for environmental control (i.e. interruptions, grade, surface/weather changes) and convenience, researchers frequently use indoor or outdoor track surfaces as a "real-world" condition. Despite previous studies demonstrating biomechanical differences between track surfaces and concrete/grass surfaces [1], it is often assumed that data collected on track surfaces will translate to other overground conditions. Therefore, the goal of this study was to determine the extent to which commonly-used IMU metrics differ between indoor track and outdoor sidewalk conditions.

METHODS

Twelve recreational runners (5F, 7M, age = 24.7 ± 4.3 yrs) completed 3 testing sessions on 3 separate days. Each session involved two experimental protocols. Following a 5-min warmup, two, 2km runs were performed in a randomized order: one on a 200m indoor track and one outdoors on a sidewalk route. Participants were encouraged to perform each run at the same self-selected speed. During each session, an IMU containing a tri-axial accelerometer (Shimmer3®; Shimmer Inc., Ireland: 200 Hz) was securely attached to the low back between L3-L5 vertebrae with axes X, Y and Z aligned in the mediolateral (ML), vertical (VT), and anteroposterior (AP) directions. The first and last 5% of each trial were excluded to reduce the effects of acceleration and deceleration. For each trial, individual steps were extracted using previously published methods [2]. Six features were derived from the acceleration signal: step time (ST), vertical oscillation (VO), braking speed (BR), and the peak acceleration of each axis ($PEAK_{ML}$, $PEAK_{VT}$, $PEAK_{AP}$). Because there was a significant difference between the track and sidewalk conditions for speed (indoor = 3.19 ± 0.33 m/s; outdoor = 3.31 ± 0.45 m/s; $p = 0.03$), each feature was corrected for speed by fitting a subject-specific polynomial model and using the residuals for further analysis. A multivariate Gaussian distribution was assumed to adequately model the variability of measures within each feature and fit to subjects' data via maximum likelihood estimation. For each testing session, the Hellinger distance (H), a distance measure describing the similarity between two probability distributions (0 = complete similarity, 1 = no similarity), was calculated to determine the similarity between the two conditions. A linear mixed model was used to detect differences in H between features.

RESULTS AND DISCUSSION

A visualization of distributions and calculated H is shown in Figure 1. When compared to all features, mean H of ST was significantly lower (0.19 ± 0.07, $p = 0.03$) and BR was significantly higher (0.41 ± 0.21, $p < 0.01$). The H for other features were not significantly different (VO = 0.24 ± 0.14, $PEAK_{ML}$ = 0.27 ± 0.09, $PEAK_{VT}$ = 0.28 ± 0.11, $PEAK_{AP}$ = 0.26 ± 0.10, $p > 0.05$). Although there is no standard H to determine a meaningful distance between distributions, these results imply there is some difference between biomechanical patterns on a track surface vs. sidewalk, most obviously in BR. Additionally, although H is directionally agnostic, further investigation indicated that the directionality of the individual variables was not consistent (i.e., some showed sidewalk > track, others opposite), indicating that there is likely not a straightforward bias from one condition to the other, but instead subject-specific functional differences in biomechanical gait patterns.

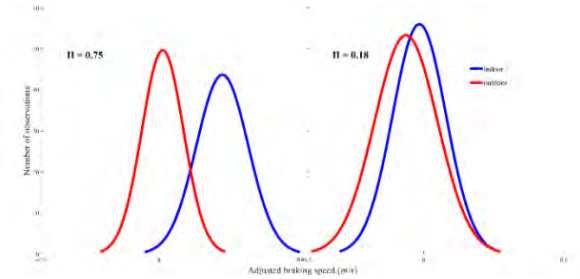

Figure 1. Example data for two subjects demonstrating large (left) and small (right) H for BR

CONCLUSIONS

Although researchers frequently use an indoor track to study overground, outdoor running, the large subject-specific H between probability measures observed in this study suggest that these conditions produce meaningfully different running gait biomechanical metrics. Thus, caution is warranted in assuming that IMU gait metrics from an indoor track can be effectively translated to other overground conditions.

A hybrid machine learning model predicts ankle and knee moments in multiple tasks from a single IMU

INTRODUCTION

Monitoring ankle and knee joint moments in the field is important for assessing the risk of sports injury and monitoring rehabilitation. Inertial Measurement Units (IMUs) provide a low-cost and accessible opportunity to assess movement outside the laboratory, but it remains to be seen whether IMUs can predict joint moments across a wide range of sporting tasks. Here we present a hybrid machine learning (ML) model which first classifies each movement, then applies a task-specific regression model to predict time-series joint moments using a single ankle-mounted IMU as input.

METHODS

Four male collegiate basketball players performed repeated tasks (n), including walking (17), jogging (20), running (15), sidestep cutting (17), max-height jumping (17), and stop-jumping (16), resulting in a total of 102 movements. Optical motion capture, ground reaction forces and ankle-mounted IMU data were simultaneously collected (using VICON-IMeasureU and Bertec force plates). Scaled musculoskeletal models were created and flexion-extension ankle and knee joint moments estimated using the inverse dynamics (ID) tool within OpenSim [1]. ID results were considered the target for our ML model, using IMU data as input.

The hybrid ML model consisted of two stages. First, we classified each task used a Rocket classification model [2] (sktime). Second, a random forest regression model (sklearn) reconstructed the time series joint moments. IMU data were rolled into 0.1s time windows; then features were extracted from rolled time series (tsfresh). Finally, the selected features were fit to the regression model.

To verify the effect of this hybrid approach, we trained a generic model to predict all tasks and participants and compared this result as a baseline.

Leave-one-out cross-validation was performed and root mean square error (RMSE) and coefficient of determination (R^2) were used to compare the predicted joint moment to the ID joint moment. Accuracy score was used to measure the classification model accuracy.

RESULTS AND DISCUSSION

The accuracy score of the classification model was 0.99. Overall, the prediction effects of the hybrid model were better than the generic model (Table 1, Figure 1). This hybrid approach shows the potential to improve joints moment prediction effects in sports. However, the tasks in this study still cannot include all sports tasks, which limits the application scope of the model. The sample size of this study was not large, but additional participant data is being collected to test the approach across a larger cohort.

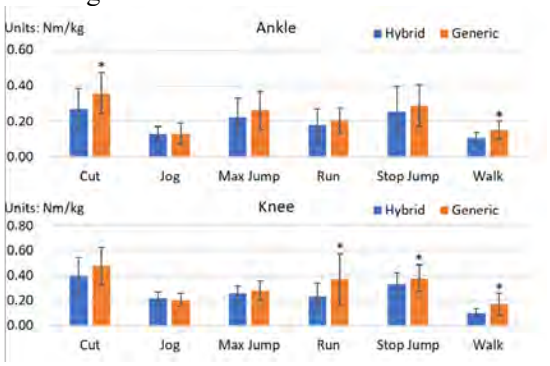

Figure 1 RMSE for cross-validations between predicted and ID joint flexion-extension moments.

CONCLUSIONS

A hybrid ML model can predict knee and ankle joint moments across a wide range of tasks using a single ankle-mounted IMU.

The relationship between "Hitting the Wall" phenomenon and gait changes during a full marathon

Nao Hirakawa[1], Yuki Ko[1], Masanori Sakaguchi[1]
[1] Institute of Sport Science, ASICS, Kobe, Japan.
Email: nao.hirakawa02@asics.com

INTRODUCTION

During a marathon, many runners experience "Hitting The Wall" (HTW), which is characterized by a significant slow-down in running pace. Although some studies have reported that gait changes occur even at moderate levels of fatigue that do not lead to HTW [1], such gait changes may not be a direct predictor of HTW [2], and no study has tracked the changes in runners prior to the onset of HTW. The purpose of this study was to investigate the differences in gait changes between runners who actually experienced HTW in a full marathon and those who did not, particularly prior to HTW.

METHODS

Ninety-three recreational runners were equipped with a GPS-integrated inertial measurement unit (CMT-S20R-AS, CASIO COMPUTER Co., Ltd.) at the waist; To investigate gait changes during the marathon race, parameters such as interval pace, cadence, step length, contact time, and vertical stiffness, and duty factor were calculated every 1 km or 0.25 km using a validated algorithm. We normalized the values by the ratio of the median value of each segment to the median value of a reference segment, which is the segment with the highest speed, for all variables of interest because the biomechanical variables are highly subject-specific [1]. In addition, each runner was asked to provide a pre-race expected record, an actual record, and a self-score (100-point scale). To investigate the effect of race progression on gait parameters between segments in each group of the runners who experienced HTW (HTW group) and those who did not experience HTW (non-HTW group), we applied the Friedman test, a nonparametric test using the median of each window in the eight segments from the start to 40 km. The Bonferroni test was used to compare the difference in each segment. Whether or not each runner experienced HTW during the race was defined as the group that experienced a slowdown of at least 25% at least 5 km, based on previously reported methods [3].

RESULTS AND DISCUSSION

Nineteen of 93 participants were labeled as the HTW, which is less than reported in previous studies. The HTW group had lower goal times (4:27:59 vs 3:30:00, $p<0.01$), a greater difference between expected and actual times (2084.4sec vs 259.9sec, $p<0.01$), and lower self-evaluations than the non-HTW group (56.8 vs 72.7, $p<0.01$). The section at which HTW began was 31.3 km ± 3.67 km, which was consistent reported in several previous studies. Two main effects of race progression on gait parameters were observed in this study. Changes in vertical stiffness after the start and remaining segments would indicate a global response of the spring-mass model to acute fatigue [1]; after 25km, a decrease in pace, shortening of step length, and prolongation of contact time and duty factor were significant. The difference between the HTW and non-HTW groups was that only the non-HTW group showed a change in vertical stiffness early in the race, it might be natural to assume that this is simply due to the larger sample size of the non-HTW group. Conversely, only the HTW group slowed down significantly even after 30 km; a decrease in cadence also occurred. Although runners tend to slow down probably due to induced-fatigue regardless of the occurrence of HTW, the decrease in cadence may indicate that they had reached a higher stage of fatigue.

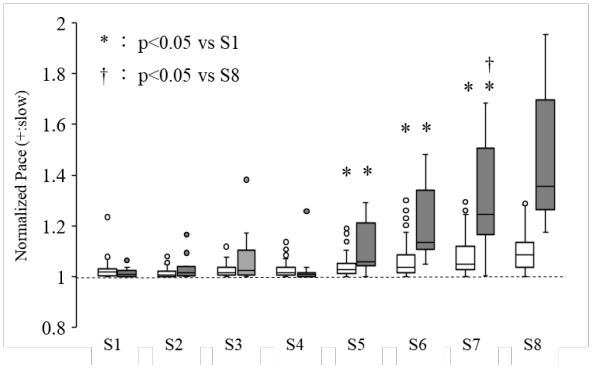

Figure 1. Normalized pace of the non-HTW group (white) and HTW group (grey)

CONCLUSIONS

While HTW has a significant impact on each runner's goal achievement and satisfaction, the gait changes measured in this study were not sufficient to predict the occurrence of HTW. When runners are fatigued, they may be more likely to make a decision to slow down before manipulating kinematic variables. Furthermore, of the kinematic variables that determine running speed, pace slow-down was found to result from shortened step length, with a small contribution from cadence for many runners. A decrease in cadence may be observed when the runner is in a high-fatigue state where HTW are more likely to occur.

INTRODUCTION

Human locomotion is typically studied independently of the cardiovascular system, although the two are intrinsically linked. An example of their interaction is cardiac-locomotor coupling (CLC), which refers to the entrainment of heart rate (HR) and step rate (SR) during rhythmic exercise at a 1:1 ratio. Actively synchronizing the stepping with each diastole of the cardiac cycle, has been shown to provide improved cardiometabolic efficiency, demonstrated by a decrease in HR and in ventilation [1]. Active CLC can therefore be one way to improve hemodynamic efficiency, ensuring greater endurance performances. Previous studies investigated the presence of CLC in laboratory settings whereas observations during daily activities are still lacking. We do not know if and when CLC occurs physiologically. The aim of this study is to investigate the extent and the probability of CLC during unsupervised daily activities in contrast to random chance.

METHODS

We used a retrospectively acquired dataset, called PMData [2] (healthy, 13 men and 3 women, 34.85 ± 11.67 years of age). During five months, their HR and SR were recorded every minute by a Fitibit Versa 2 (Fitbit.Inc, San Francisco). We considered only SRs above 60 steps/min, indicative of physical activity [3]. Coupling is defined via the ratio between SR and HR as follows:

$$0.99 < \frac{\text{SR (steps/min)}}{\text{HR (beats/min)}} < 1.01$$

As HR and SR are correlated, observation of CLC may be attributed to chance. Thus, we compared the observed ratios to a random combination of SR and HR computed using Monte Carlo for each subject. A two-sample Kolmogorov-Smirnov test was used to test if the observed and random ratio distributions were different. All differences were tested with Wilcoxon signed rank.

RESULTS AND DISCUSSION

CLC occurs in every subject for 3 to 7% of the observed time. The median ratio per subject ranges from 0.87 to 1.00. In our cohort, CLC seems to be a spontaneous phenomenon during everyday activities.

The observed and random distributions are different ($p<0.001$ for every subject, Figure 1). In particular, the observed distribution has a median closer to the unity, it is more symmetric and less spread than the random. Hence, the result suggests that subjects tend to adapt their gait cycle to their cardiac cycle or vice versa, instead of these two systems being independent and random.

The probability of coupling is 34% higher for the observed distribution (0.042 vs 0.028, $p<0.001$, Figure 1), than for the random distribution. This shows that CLC could come from an active interaction rather than from chance.

Our findings raise new question whether there is a mechanism of interaction between the cardiovascular and the locomotor system. Our body's spontaneous predisposition to CLC indicates that we can actively achieve CLC and thereby improve our cardiac efficiency. This motivates new rehabilitation and training techniques to be investigated. A limitation of the present study is that such wrist-worn sensors are affected by artifacts in measuring HR.

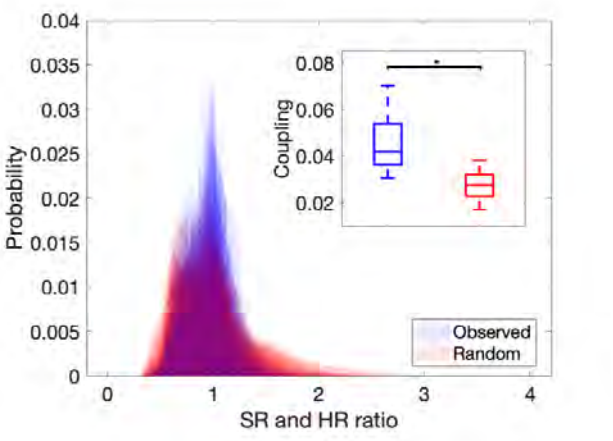

Figure 1 Ratio distribution curves of all subjects (N=16) and coupling probability. *Significant difference between conditions, P<0.001.

CONCLUSIONS

Spontaneous CLC occurs in every subject during unsupervised daily activities. Our small and healthy cohort supports that the incidence of CLC is not due to random chance. Future work will address the extent of diastolic CLC in a heterogeneous cohort through more robust chest-worn sensors.

NEW PERSPECTIVE FROM OLD DATA: A CONTEMPORARY, QUANTITATIVE ANALYSIS OF THE FIRST REPORTED CERVICAL FACET DISLOCATION PRODUCED IN THE LABORATORY

INTRODUCTION

Cervical facet dislocation (CFD) is frequently associated with spinal cord injury, yet the biomechanics underlying this devastating injury are not well understood [1]. In 1978, Adelaide Orthopaedic Surgeon Robert Bauze, working in Oxford in 1972/3, published the first study (of only two to date) to systematically produce CFD in cadaver spines [2]. The importance of this work is only now being fully realized [1]. Although the measurement techniques employed were innovative for the time, the manuscript was written in the narrative style of the day, and therefore didn't report quantitative kinematic or force data. A more nuanced analysis of this rich dataset may provide new insight regarding CFD mechanisms. The aim of this study was to re-examine in detail the cineradiograph films and strip charts of the Oxford study to determine the intervertebral rotations movements and axial forces that occurred during these simulated CFDs.

METHODS

In the original study, quasi-static axial loading was applied to fourteen cervical spines (occiput-T2) that were fixed caudally via a bone pin through the vertebral body and spindle within the canal (Fig A). Flexion-extension of the occiput was restricted but anterior translation was unconstrained. Sagittal cineradiograph films were available for ten spines; these were digitally scanned at high resolution, and global and intervertebral kinematics were determined at each frame (Fig B). Corresponding axial force charts were available for six specimens. These were scanned, and force data at each cineradiograph frame (indicated by synchronization pulses on the charts) were extracted (Fig C). Peak axial force and force at injury were determined. Descriptive statistics were obtained.

RESULTS AND DISCUSSION

Of the ten experiments with cineradiographs, anterior occiput translation (eccentricity) without rotation occurred for seven specimens, creating upper neck extension and lower neck flexion; CFD occurred at the level of transition from extension to flexion (1×C4/C5, 4×C5/C6, 2×C6/C7). The occiput detached from the loading platen during two experiments, permitting hyperflexion, and CFD was not observed. One specimen failed through the fixation spindle, so these data were omitted from analysis.

At the point of injury, the intervertebral angle (20.6±6.6°) and anterior shear displacement (4.1±2.9 mm) at the level of CFD were two- and four-times physiological limits [3], respectively. The upper cervical spine remained in extension, with 54.9±8.1 mm anterior eccentricity of the occiput. Four of the six specimens with force data underwent CFD at an axial load of 617±73 N, which was preceded by a peak axial force (1094±239 N) coinciding with posterior ligament rupture.

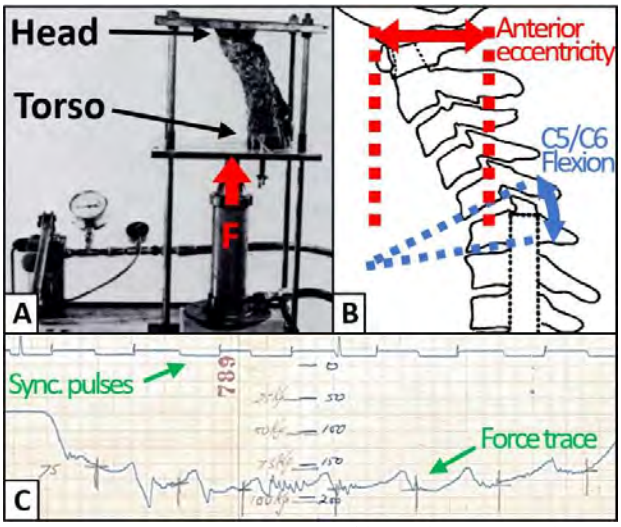

Figure 1 A) Bauze's test setup; B) kinematics measures from cineradiographs; and, C) annotated force chart.

CONCLUSIONS

This study provides new evidence supporting the contemporary hypothesis that the "ducking posture" (extended upper, flexed lower neck), not hyperflexion, is necessary for dislocation during axial loading. The kinematic and kinetic data may inform neck injury criteria specific to CFD to facilitate the development of novel safety devices.

DIFFERENCES IN TRUNK ROTATION BETWEEN PEOPLE WITH AND WITHOUT LOW BACK PAIN DURING VARIOUS MOVEMENTS

Batbayar Khuyagbaatar[1], Batlkham Dambadarjaa[2], Ganbat Tumen-Ulzii[1] and Munkh-Erdene Bayartai[2]

INTRODUCTION

In clinics, range of motion (ROM) during trunk rotations and functional tasks is commonly examined as part of musculoskeletal assessments to diagnose low back pain (LBP), and changes in the ROM are related to impairment or instability of the trunk [1]. Although there are many studies have identified movement abnormalities during either simple clinical tests or gait, the three-dimensional (3D) kinematics of the trunk has not been investigated for different functional tasks. In this study, we determined differences in 3D trunk kinematics during trunk rotations and functional tasks between people with and without non-specific LBP.

METHODS

We recruited 45 LBP patients (LBP group: 9 males and 36 females; age, 33±10 years; height, 162±8 cm; weight, 67±16 kg) and 45 healthy people (Control group: 14 males and 31 females; age, 24±8 years; height, 163±8 cm; weight, 59±10 kg). The full-body Xsens system (MVN, Xsens technologies, Netherlands) was used to record the 3D movements during the trunk rotations (flexion-extension, lateral bending, and axial rotation) and functional tasks (single-leg standing, walking, hurdle step, squad, and squat lifting). Each subject performed three times of each specific movement and functional task. The trunk ROM in the sagittal (SP), frontal (FP), and transversal plane (TP) were calculated using a relative orientation between pelvis and thorax segments and averaged for the LBP and control group.

RESULTS AND DISCUSSION

The LBP group exhibited smaller trunk ROMs than controls during the trunk rotations in three planes of motion. In contrast, trunk ROMs were larger in people with LBP during functional tasks except for rotation in TP during single-leg standing. But significant differences were observed during extension-flexion in FP and TP, bending in TP, rotation in FP and TP, single-leg standing in SP, walking in SP and FP, hurdle step in TP, and squat in FP, respectively ($p<0.05$) (Figure 1). These results were similar to previous studies, where they reported that patients with LBP exhibit smaller trunk rotations during clinical tests [2], and greater trunk ROM during functional tasks, which is possibly correlated with movement control impairment [3].

CONCLUSIONS

Our results showed differences in ROM during trunk rotation as well as functional tasks. People with LBP exhibited smaller trunk ROMs during trunk rotations, while it was larger during functional tests. Therefore, it is important to know which specific task is more useful to indicate the movement impairments due to the LBP.

Effect of the draw-in maneuver on lumbar spine and hip motion during sit-to-stand for prevention of low back pain and urinary incontinence

INTRODUCTION

Sit-to-stand (STS) is frequently performed during daily life and may be associated with low back pain (LBP) and urinary incontinence (UI) due to lumbar kyphosis and contraction of the rectus abdominis muscle (RA), respectively. Exercises that contract the oblique and transversus abdominis (TrA) muscles and stabilize the spinal column are considered to be helpful against LBP. The draw-in maneuver (DI) selectively contracts the oblique and TrA muscles. We hypothesized that DI inhibits lumbar spine motion (lumbar kyphosis) and increases the hip flexion angle during STS, and could thus prevent LBP. UI is associated with dysfunction of the pelvic floor muscles (PFM), and therefore PFM training is recommended. Contraction of the trunk muscles influences the PFM, and contraction of the IO and TrA muscles leads to simultaneous PFM contraction. The PFM is less likely to contract, however, during contraction of the RA. We hypothesized that selective contraction of the oblique and TrA muscles without activation of the RA during STS by DI would prevent UI. Here, we investigated the effects of DI on the lumbar spine and hip joint angles, and trunk muscle activity during STS.

METHODS

Fifteen healthy adult males aged 18–22 years were included in the study. STS was measured 3 times. Subjects were then instructed on performing DI, and STS was measured another 3 times. The lumbar flexion and hip flexion angles, and activities of the RA, external oblique abdominis (EO), IO/TrA, and gluteus maximus muscles with and without DI were compared. The change from each joint angle in the sitting position to the peak angle during standing was measured. Electromyography was performed for 3 s from the start of the movement.

RESULTS AND DISCUSSION

DI during STS significantly decreased the maximum lumbar flexion angle (Table 1). In addition, EO and IO/TrA muscle activities were significantly increased (Figure 1), supporting the results of a previous study in which DI was shown to stabilize the lumbar spine by simultaneously contracting the EO and IO/TrA muscles [1] and demonstrating that DI had a stabilizing effect on the lumbar spine even during STS.

Furthermore, DI selectively activated the IO/TrA muscles without activating the RA even during STS, thereby allowing the PFM to contract more efficiently [2]. This finding suggests that DI might also have preventive effects against UI.

These comparisons in healthy subjects demonstrate the potential of DI during STS to prevent LBP and UI. Future intervention studies in patients with LBP or UI are thus warranted.

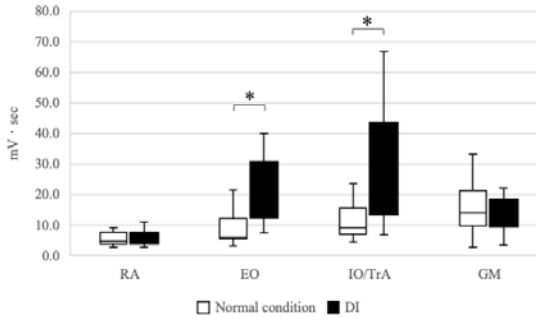

Figure 1: Muscle activity during STS (integral electromyography)

CONCLUSIONS

We demonstrated that DI during STS can decrease the maximum lumbar flexion angle and activate the EO and IO/TrA muscles without activating the RA. These results indicate that DI may be useful for preventing LBP and UI.

INTRODUCTION

Back muscles are the motors to drive spinal movements and responsible for stabilizing and supporting the trunk at the same time. Most back muscle studies have focused on sagittal flexion–extension tasks [1]. Comprehensive paraspinal muscle activity patterns during various spinal movements have not yet been fully investigated. Clarification of back muscle behaviors can reveal the underlying prerequisit control of spinal movements and understand its link to back disorders. Electromyography (EMG)-based measures of the trunk muscles have been used for the identification of biomechanical impairments in patients with low back pain, but the results are conflicting [2,3]. Potential confounding sources of variance, such as age and gender, could contribute to inconsistences. Accordingly, this study was performed to investigate the effects of age and gender on paraspinal muscle activation when performing different functional spinal movements.

METHODS

Thiry-one healthy participants (aged 66±10 years, 13 males and 18 females) over the age of 50 were recruited. Subjects who had difficulty performing daily living activities, or were with neuromuscular disorders, spinal pathologies, needing walking assistance, body mass index of greater than 35, and FRAIL score of 3 or greater were excluded. Surface EMG activities of bilateral paraspinal muscles at L3 level were measured (MA300; Motion Lab Systems, Inc.). Subjects were first instructed to perform quiet standing for 30 sec and then tasks including forward flexion (Flex), extension (Ext), maximal extension (MaxExt), object lifting (Lifting), sit-to-stand (S2S), level walking (Walking), right/left sidebending (SideB), right/left horizontal rotation (Rot), and right/left diagonal rotation (DRot) were performed. The quiescent level was set at 2.5 x standard deviation of EMG activity during the quiet standing task and used as the denominator of the normalized EMG for all tasks. Only dominant side muscle activations were used for analysis, with leg dominance being defined as the preferred leg for kicking a ball. A multiple linear regression model was used to access the association of the muscle activation with gender and age. Significance was set at 0.05 level.

RESULTS AND DISCUSSION

Twenty-three participants were right-dominant. The results showed a down trend of muscle activation with aging, especially in males (Figure 1). The muscle activations during the MaxExt, S2S and DRot-R tasks demonstrated the strongest relationship (adjusted R^2 = 0.17, 0.16 and 0.17, respectively) with marginal significance (p-value all smaller than 0.07).

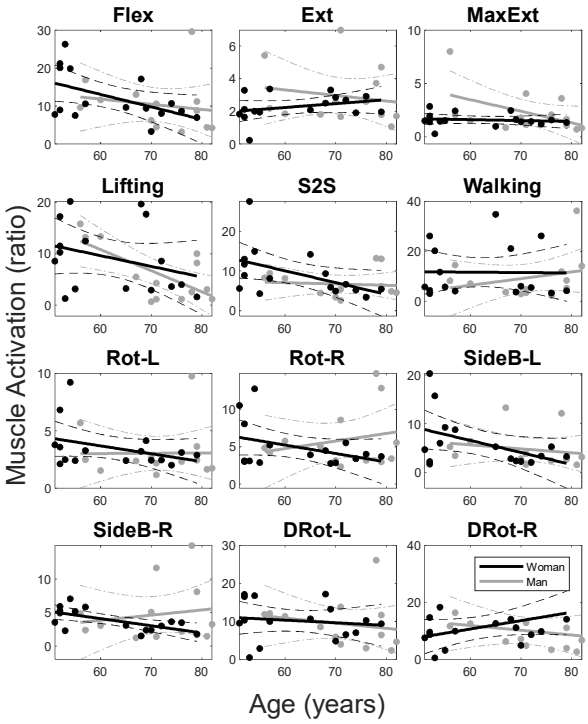

Figure 1 Regression plots of the paraspinal muscle activations for men (grey) and women (black) with their ages in different tasks.

CONCLUSIONS

This study quantified paraspinal muscle activations in a pain-free population of older adults. The results showed a down trend of muscle activation with aging. Such responses could lead to decreased trunk stiffness and may contribute to low back disorders. Further work is needed to incorporate a greater sample population to verify the trend.

BIOMECHANICAL INFLUENCE OF THE CAGE LORDOSIS IN AN ANTERIOR LUMBAR INTERBODY FUSION AT L4-L5 – A SIMULATION STUDY

Robin Remus[1], Marc Neumann[1], Andreas Lipphaus[2] and Beate Bender[1]
[1] Chair of Product Development, Dept. of Mechanical Engineering, Ruhr-University Bochum, Germany.
[2] Biomechanics Research Group, Dept. of Mechanical Engineering, Ruhr-University Bochum, Germany.

INTRODUCTION

Low back pain is one of today's most common health problems. Fusion surgery may be considered when pain persists and conservative treatments fail to provide relief in a patient with degenerative disc disease [1]. One of the most successful fusion approaches, with success rates up to 97 %, is the anterior lumbar interbody fusion (ALIF) [2]. After removal of the affected intervertebral disc, an angle and height variable cage is placed between the cranial and caudal vertebral bodies. The global lumbar lordosis (LL) is patient-specific and affected by the cage lordosis (CL) choice. To reduce the probability of progress of adjacent segment diseases, the reconstruction of a physiological LL is essential in this regard [3]. In the light of customary discrete CL decisions of stand-alone ALIF, this simulative study investigates biomechanical effects of L4-L5 CL variances on adjacent spinal structures.

METHODS

We utilize a validated active hybrid model of the ligamentous lumbosacral spine [4] (Fig. 1A) built in ArtiSynth [5]. Unfused rigid vertebrae L1-S1 are interconnected with hyperelastic fibre-reinforced finite element (FE) intervertebral discs, ligaments, and facet joints. The intra-abdominal pressure is considered as a force on the thorax via muscle forces acting on the abdomen. Twelve sagittal symmetric muscle groups are implemented using 258 muscle fascicles with a Hill-type muscle model. The muscle redundancy problem is solved using an inverse-dynamic tracking controller which provides a solution of the forward dynamic simulation. Values of the cost function are the muscle activities squared as well as the target poses of the thorax and the lumbar vertebrae. Thus, all bones cranial to the stationary sacrum are free to move in space. For the stand-alone ALIF, L4 and L5 are rigidly connected with different CL of 14 ± 3°. Muscles and adjacent lumbar structures are undisturbed. Varying postures from extension to flexion (-10°, 0°, and +30°) with loads of up to 20 kg held in both hands are simulated.

RESULTS AND DISCUSSION

In relaxed upright standing (LC#1) pre-operative LL is 45° and a CL of 14° corresponds best to the unfused L4-L5 intervertebral angle (IVA). The post-operative LL change in LC#1 is maximal at CL = 17° with -1.3%. For all CL, the L5/S1 IVA increase, while L1/2 IVA decrease. Adjacent segments compensate for the L4/5 CL variances. A negative correlation between CL and IVA change is present in L3/4. Except in 30° flexion (LC#2), a significant increase in facet joint contact forces at larger CL is seen at L3/4. In LC#1 and LC#2 the intradiscal pressures (IDP) are lowest pre-operative. Large CL have the greatest influence on the IDP in LC#2. In percentage terms, the IDP increase at 11° CL is greatest in LC#1. In all postures without additional load and CL > 11°, the lumbar section of the M. longissimus exerts notably more force (9-125%) than in the pre-operative state. Except in extension, the M. multifidus is also more activated.

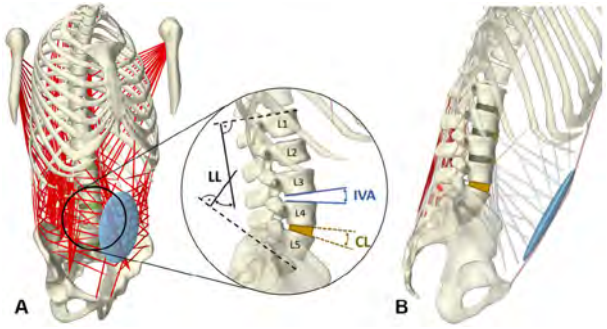

Figure 1 A) Active hybrid model and visualization of the sagittal spinal parameter in LC#1. B) LC#2 with right side muscles hidden.

CONCLUSIONS

From a biomechanical perspective, this simulation study confirms that replicating a physiological LL is important. For global sagittal balance, IVA changes are compensated by the musculoskeletal system, as in ALIF, which in turn leads to locally modified loads on adjacent lumbosacral structures. In upright standing with and without an additional load a L4-L5 CL larger than the pre-operative IAV, for example, reduces the IDP at all levels while decreasing cranial and increasing caudal the facet joint forces. In flexion, however, this results in more stress being placed on the cranial segments. Furthermore, other anatomies with diseases should be considered. Likewise, the hybrid approach may provide future opportunities to directly analyze the stresses between cage and FE bone for a faster fusion.

DEEP PARASPINAL MUSCLE VOLUME ASYMMETRY IN ADOLESCENT IDIOPATHIC SCOLIOSIS

INTRODUCTION

Adolescent Idiopathic Scoliosis (AIS) is characterised by a three-dimensional (3D) spine deformity that progresses between 10 and 18 years. An asymmetry in paraspinal muscle size and, therefore, force generating capacity may contribute to an asymmetry in the forces applied to the growing spine and leading to asymmetrical vertebral growth.[1] We have recently shown asymmetry in *grouped* deep (but not superficial) paraspinal muscles size at the level of the scoliotic curve apex, which is related to curve severity and skeletal maturity in those with AIS.[2] Here we aim to define *individual* paraspinal muscle volume (a)symmetry in the presence of AIS using magnetic resonance imaging (MRI) and segmentation techniques with far greater precision than has been previously possible.

METHODS

Data obtained from MRI's [T1-weighted 3D Gradient Echo sequence, voxel size: 0.2*0.2*5mm] is presented from: 11 female adolescents [all with right thoracic (Th) scoliotic curves (mean±SD); Cobb angle: 38±19°; curve apex: T7-10; age: 13.8±1.3 years; height:159±5 cm; Risser Grade for skeletal maturity: 0-4, who attended the Queensland Children's Hospital Spine Deformity Unit; and 11 control participants [with symmetrical spines (mean±SD); age: 13.7±1.9 years; height:163±6 cm; Risser Grade: 0-4].

At the level of the curve apex (and matched vertebral level for controls), the multifidus, spinalis, iliocostalis, and longissimus muscle cross-sectional areas (CSA; mm^2) were determined by manually delineating muscle boundaries from the MRIs. The CSA of consecutive slices, from the upper to the lower vertebral body boundaries, were multiplied by MRI slice thickness and summed, to calculate the muscle volume (mm^3) associated with the individual vertebral segment. A muscle volume asymmetry index [Ln(concave/convex volume)], was determined. When using this index, a value of 0.2 approximates a 20% larger volume on the convex side.[3]

RESULTS AND DISCUSSION

The multifidus volume was mean 28±18% greater on the concave than the convex side of the curve apex in AIS. This asymmetry was significantly larger ($p<0.01$) than that observed in the control group, mean -4±13% (Figure 1). No other between-group differences in asymmetry were observed (all $p>0.05$).

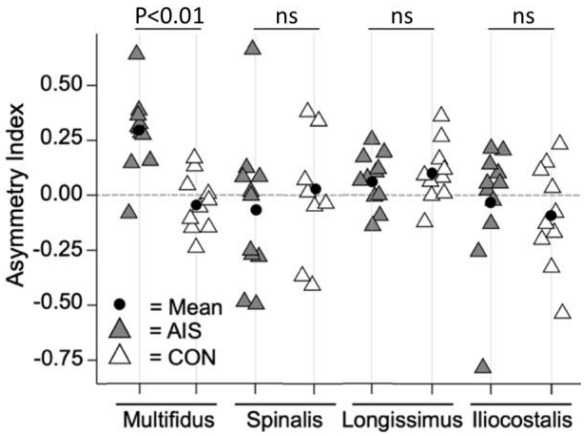

Figure 1 Muscle asymmetry at the scoliosis curve apex of adolescents with scoliosis (AIS: grey) and controls (CON: white). Individual (triangles) and group mean (circles) data shown, ns= not-significant.

CONCLUSIONS

The asymmetry found in AIS participants' deep paraspinal muscles, in particular the multifidus, lies outside the typical asymmetry range observed in adolescents with symmetrical spines. As scoliosis progresses, the vertebrae and spinous process rotate towards the curve's concavity with a decrease in the concave pedicle and vertebral body height.[4] Multifidus is intimately associated with these bony landmarks, spanning between the vertebral body, transverse and spinous processes, acting to stabilize, extend and rotate the spine. This supports the need for further work that considers the potential role of the multifidus in AIS presence and progression. Future outcomes from a larger dataset will quantify a greater number of anterior and posterior paraspinal muscle volume (a)symmetries (from vertebral levels T4-L4) and consider other factors that contribute to muscle force generation, including intramuscular fat, fascicle architecture, fibre composition and muscle activation.

INTRODUCTION

Military personnel are often required to carry heavy equipment and supplies on their bodies. These loads place increased strain on the body and may lead to lower back injury [1]. Understanding the effects of heavy load carriage on spinal loading has implications for interventions aimed at reducing injury. Magnetic resonance imaging, the gold standard in spinal assessment, is costly and not practical for use during standing load carriage. Ultrasonography has been reliably used to estimate spinal loading via measurement of distances between vertebral processes with participants in a seated or recumbent position [2,3]. However, no studies have assessed its use during standing heavy load carriage. The aim of this study was to assess the test-retest reliability of ultrasonography to quantify spinal compression via measurement of distances between the transverse processes of the lumbar vertebrae in healthy adults during load carriage.

METHODS

5 males and 6 females (age: 33 ± 5 years; height: 155 ± 51 cm; mass: 75 ± 18 kg) attended the laboratory for two test sessions on two separate days. After 30 minutes of supine resting, ultrasound images were taken of the transverse processes of each lumbar vertebra (L1-L5) immediately on standing while unloaded, and after 30 minutes of standing while loaded with a 25 kg weighted vest. The same tasks were completed in both sessions.

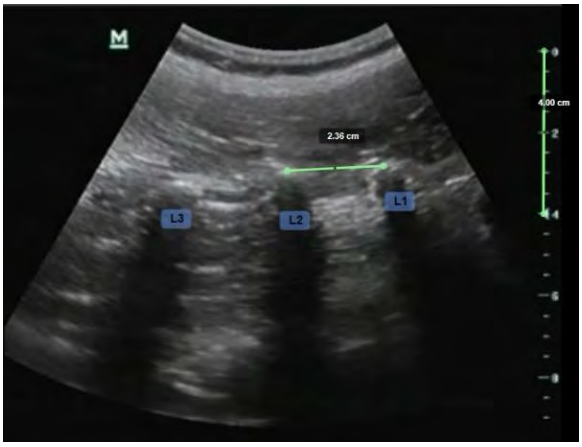

Figure 1 An example ultrasound image showing the measured distance (green horizontal line) between the L1 and L2 transverse processes.

Kinovea software (version 0.8.15, www.kinovea.org) was used to measure the intervertebral distances between transverse processes from L1-L5 (Figure 1). Within- and between- day reliability were assessed using coefficients of variation (ratio of standard deviation to mean; CV) and intraclass correlation coefficients (ICCs) with 95% upper and lower bound confidence intervals (95% CI). Intervertebral distances between loaded and unloaded conditions were compared using paired t-tests ($p<0.05$).

RESULTS AND DISCUSSION

Within- and between- day reliability was good to excellent with ICCs between 0.83 and 0.99 for all measurements. Within-visit between-participant CVs were between 7.1 and 12.1 for all measurements. The loaded condition resulted in significantly reduced inter-transverse process distances between L2-L3, L3-L4 and L4-L5 (Table 1).

Table 1: Distances between transverse processes for loaded and unloaded conditions and within-visit coefficients of variation (CV) from both visits. Results are presented as mean ± standard deviation.

Vertebra	Condition	Distance (mm)	CV (%)	P value
L1-L2	Unloaded	29.6 ± 3.41	12	0.190
	Loaded	29 ± 2.56	8.9	
L2-L3	Unloaded	32 ± 2.37	7.4	0.015
	Loaded	31.1 ± 2.54	8.2	
L3-L4	Unloaded	31.7 ± 3.21	10	<0.001
	Loaded	29.2 ± 2.19	7.5	
L4-L5	Unloaded	29.1 ± 2.56	8.8	0.003
	Loaded	27.3 ± 2.62	9.6	

CONCLUSIONS

These results indicate that ultrasonography may be a practical, cost effective, and reliable method for measuring the effects of heavy loads on the lumbar spine and assessing the effects of interventions aimed at reducing spinal compression during heavy load carriage.

TARGETED MULTIFIDUS MUSCLE ACTIVATION REDUCES FIBROSIS OF MULTIFIDUS MUSCLE FOLLOWING INTERVERTEBRAL DISC INJURY

Hodges P[1], James G[1], Ahern BJ[2], Goss B

[1] 1NHMRC Centre of Clinical Research Excellence in Spinal Pain, Injury and Health, School of Health and Rehabilitation Sciences, The University of Queensland, Brisbane, QLD, Australia

INTRODUCTION

Low back pain and injury are associated with structural remodelling of the multifidus muscle including increased connective tissue (i.e., fibrosis). Experimental intervertebral disc (IVD) degeneration in animal studies induces fibrotic changes that include increased fibrogenic gene expression (Collagen I and III) and increased cross-sectional area of connective tissue across the multifidus muscle, as well as increased thickness of the epimysial layer of connective tissue that around the muscle [1]. These changes would impact the capacity of muscle to generate torque and regulate loading of the spine. Whole body aerobic exercise has been shown to partially attenuate these fibrotic changes but does not completely restore multifidus health [2]. More targeted exercise of the multifidus muscle might induce more complete resolution of fibrosis. This study aimed to investigate whether neurostimulation of the multifidus muscle could reduce fibrosis of the multifidus muscle in a model of IVD degeneration in sheep.

METHODS

IVD degeneration was surgically induced in 18 merino sheep via a partial thickness unilateral annulus fibrosus lesion to the right side of the L1/2 and L3/4 IVDs. All 18 sheep received an implantable neurostimulation device, that provides stimulation of the L2 medial branch of the dorsal ramus (ReActiv8, Mainstay Medical). Three months after surgery, the animals were divided into two separate groups, Non-Activated and Activated. The Activated animals received two 30-minute neurostimulation sessions per day for 3 months. The Non-Activated group received no stimulation. Six months after surgery, the multifidus muscle was harvested adjacent to the spinous process adjacent to L2 and L4 and. The muscle tissue underwent Van Gieson's and Sirius Red staining, and Collagen-I &-III immunostaining, examine tissue fibrosis. Expression of fibrotic genes was assessed using quantitative PCR.

RESULTS AND DISCUSSION

Targeted activation of the multifidus muscle reduced levels of fibrosis in the Activated group, compared to the Non-Activated group in the multifidus at L4 (which includes fascicles activated by the L2 nerve root stimulation). Connective tissue cross sectional area and Collagen-III expression were reduced across the whole multifidus muscle at L4 in the Activated group, but not at any individual region, suggesting the impact of the changes extends beyond the fascicle that is activated. No differences were detected to the cross-sectional area of muscle or adipose tissue, or Collagen-I expression at L4 between groups. The multifidus muscle adjacent to the L2 spinous process was not activated by neurostimulation of the L2 nerve root. No measures of the multifidus muscle at L2 differed between the Non-Activated and Activated groups.

CONCLUSIONS

These data reveal that targeted activation of the multifidus muscle reduces histological and genetic signs of muscle fibrosis induced by IVD degeneration.

INTRODUCTION

Movement velocity, joint position, and contraction type are not the only parameters that influence muscular activation but aging also has an effect on it. Research shows that in the elderly, increased coactivation of antagonist muscles and slower reaction times are observed, as well as a decrease in muscle force [1]. These changes lead to an increased risk of falls, as well as a reduced ability to independently perform Activities of Daily Living (ADL) [2]. The aim of this work is to analyse changes in muscular coordination patterns of upper extremity muscles with age as a function of angular velocity, joint angle and type of contraction.

METHODS

The muscular activation of the biceps (BI), brachioradialis (BRA) and triceps (TRI) was recorded from 20 healthy elderly (7♂, 13♀, avg. age 74.9 ± 5.8 years) by surface electromyography (sEMG) while performing flexion and extension of the elbow. The movement of the elbow joint, which was carried out at different angular velocities and with a constant load of 1kg over the entire range of motion, was as well recorded with a 3D motion capture system. Once the sEMG signals were processed according to SENIAM recommendations, the sEMG envelope of each muscle was further categorized into angular velocity (five intervals between 20 – 120°/s), elbow joint angle (five intervals between 25° - 125, where 0° represents full extension) and type of muscle contraction (concentric or eccentric). The results of these measurements were compared with data previously recorded under the same conditions in young healthy adults (7♂, 8♀, avg. age 26.2 ± 3.2 years) [3].

RESULTS AND DISCUSSION

In the flexion phase, an increase in the sEMG envelope was observed in all three muscles in the elderly group as angular velocity and joint angle increased. These results were consistent with those of the young adult group. However, the sEMG envelope in all three muscles was higher in the elderly group compared to young participants. Whereas in the young subjects the amount of activation was the same in all three muscles, in the elderly, muscular activation of BRA and TRI was higher than that of BI. This co-activation might be a strategy of the elderly to perform the movement at a controlled velocity and improve the stability of the elbow joint. Regarding the extension phase, the sEMG envelope of BI decreased with increasing angular velocity while sEMG envelope of BRA increased [3]. In contrast, in the elderly group, muscular activation of both BI and BRA increased with increasing angular velocity. As observed in the flexion movement, the sEMG envelope of TRI and BRA was higher than BI in the elderly group. Since in the young adults group, the increase in the muscular activation of BRA with increasing extension velocity cannot be explained by the force-velocity relationship, it has been assumed that BRA is mainly used to control velocity and position [3]. This seems to be different in the elderly, where age-related co-activation is observed, as the ability to generate force decreases with increasing angular velocity due to fewer, mostly large, functioning motor units. This goes along with a loss of fine motor skills in the elderly.

In contrast to the young subjects and to the force-length relationship, sEMG envelope of BRA and BI decreased with increasing extension angle. This may be due to two theories proposed in the literature on aging: 1) increased intramuscular connective tissue that would raise muscle force as it lengthens or 2) slower muscle contraction and fewer fast-twitch fibres that would reduce rate of torque development [1,2].

CONCLUSIONS

Muscular coordination patterns of the upper extremity muscles are altered in the elderly. This was proven by increased co-activation and different activation patterns of the BRA to execute the movement. However, this goes along with a loss of fine motor skills. Additionally, changes in the muscle characteristics and architecture seem to influence the changes in muscular coordination patterns in the elderly. This should be taken into account when implementing training routines that allow for an optimal physical activity and less dependency to perform ADLs.

ACKNOWLEDGEMENTS

INTRODUCTION

Excessive knee varus results in altered tibio-femoral joint (TFJ) contacts and loading, and medial knee osteoarthritis onset [1]. High tibial osteotomy (HTO) is performed to delay end-stage osteoarthritis. This allows for tibial plateau realignment and medial condylar decompression [1], targeting normal knee function. Despite the good results achieved, issues concerning fixation plate design and implantation, and patient functional performance [2] still exist. To overcome these, a new customized HTO procedure has been developed [3]. Based on medical imaging, multiplanar deformities are addressed by 3D pre-operative (PRE) planning and implantation of a custom-designed 3D printed fixation plate, carefully placed by patient-specific instrumentation. To date, good preliminary post-operative (POST) results have been reported using an original multi-instrumental analysis [4]. The aim of this study is to corroborate the preliminary findings on the novel customized HTO procedure by extending the original method [4] to a larger patient group.

METHODS

25 patients (BMI<25; 40-65 years) with <20° knee varus underwent the new customized HTO procedure (3D Metal Printing Ltd, Bath, UK) [3,4]. PRE and POST (at 6 months) clinical and instrumental evaluations [4] were performed. Gait analysis (GA) was executed during level walking and stair climbing/descending using a 9-camera motion capture systems (Vicon®, UK), wireless EMG, ground-reaction-force (GRF) platforms, and an original protocol with additional markers on the tibial plateau rim for registration purposes. Patients also received weight-bearing computed tomography (WBCT, Carestream®, NY- USA) while still wearing the GA markers. CAD models for the femur, tibia, patella and markers were reconstituted from DICOM. 3D trajectories of markers collected during motion were then registered to the corresponding CAD models via SVD. Resulting transform matrices were used to register GRF data on the tibial CAD model and to calculate the GRF vector intersections with a virtual plane on the tibial plateau. Differences in PRE-vs-POST TFJ and patello-femoral joint (PFJ) contacts, and discrepancies in planned-vs-POST tibial plateau alignment and plate shape were performed via Distance-Map-Analysis (DMA, Geomagic®, SC-USA) based on relevant CAD models.

RESULTS AND DISCUSSION

After HTO, physiological knee function was assessed by clinical scoring and GA, showing POST joint kinematics and kinetics within the normality. Normal POST ab/adduction moments were observed, confirming reduced stress on the knee medial compartment. GRF registration on patient-specific tibial CAD was achieved with <2.4 mm error. POST GRF intersections with the tibial plateau were found to be significantly more lateral when compared to PRE ones (Figure 1a); in % of plateau width, this lateralization was 70.1±21.0 during walking and 79.4±30.0 in stair climbing/descending, and correlated well with POST kinetics. DMA showed: a) planned-vs-POST discrepancy (Figure 1b) in plate shape and plateau alignment <1.7 mm; b) POST plate-to-tibia adherence <2.4 mm, in line with that desired for proper bone healing; c) more homogeneous contacts between the two TFJ compartments and lateralized PFJ contacts, showing decompression at both TFJ and PFJ level.

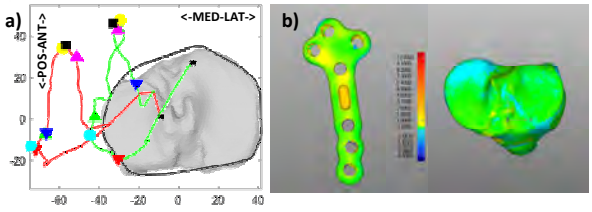

Figure 1 a) PRE (red) and POST (green) GRF-to-tibia intersection; b) Planned-vs-POST discrepancy as observed via DMA (green=0 mm) in plate shape and tibial plateau alignment.

CONCLUSIONS

The new customized HTO procedure restored normal knee biomechanics with concurrent reductions in reported pain. In detail, the study showed proper knee realignment, kinematics, kinetics and joint contacts after HTO, as well as consistency with pre-op plans. Preliminary results were confirmed here on a larger scale and with more evidence.

EFFECTS OF UNEXPECTED SLIP AND TRIP-INDUCED PERTURBATIONS ON DYNAMIC STABILITY AND SUPPORT MOMENT

Shabnam Shokouhi[1], Hossein Mokhtarzadeh[1], Lee Vee Sin Peter [1]
[1] Department of Biomedical Engineering, University of Melbourne, Melbourne, Australia.
Email: sshokouhi@student.unimelb.edu.au

INTRODUCTION

Injurious falls are predominantly caused by unexpected slips or trips during walking. In recent years, perturbation-based balance training (PBT) has been proven beneficial as a task-specific fall prevention intervention. However, the most effective perturbation type and intensity for fall prevention training is still an open question. In this study, we aimed to, first, identify which type of treadmill-induced perturbation, slip or trip, disturbs dynamic stability the most by using the perturbation response (PR) measure [1] ; and second, to investigate which type is more mechanically demanding by comparing support moment in the first recovery step post perturbation.

METHODS

Twenty-four healthy young adults (age=24.2±2.5, BMI=22.19±2.3) participated in our study. Trip and slip-like perturbations were administered using a split-belt treadmill by rapidly decelerating and accelerating the right belt, respectively. 3D Marker positions and ground reaction forces were recorded throughout the experiment. An inverse dynamic approach was used to find joint moments. The support moment was calculated as the summed ankle, knee, and hip extension moments for the first recovery step. Dynamic stability was measured using the margin of stability (MoS) [2]. The perturbation effect was then quantified using the Perturbation Response (PR) measure (Eq1) over six steps post-perturbation.

$$PR = \sqrt{\sum_{i=1}^{6}\left(\frac{MoS(i) - \overline{MoS^*}}{\sigma_{MoS^*}}\right)^2} \qquad (1)$$

where $\overline{MoS^*}$ and σ_{MoS^*} are mean and standard deviation of MoS at heel strike (HS) of 20 unperturbed gait cycles, and $MoS(i)$ represents MoS at the HS of the i^{th} cycle post-perturbation. Statistical Parametric Mapping (SPM) paired *t-test* was used to perform pairwise comparisons of support moment values and patterns between slip and trip recovery steps and Normal (unperturbed) walking. A paired-sample *t-test* was applied to compare PR between slip and trip.

RESULTS AND DISCUSSION

Trip-like perturbation resulted in a larger perturbation response (PR) on MoS compared to slip (Table 1), meaning that trip-like perturbation had a more destabilizing effect on MoS compared to slip perturbation. Moreover, participants used significantly greater support moments during the midstance (26-72%, $p<0.001$) of the recovery step following the trip-like perturbation compared to slip (Figure 1). This indicates that compared to slip, participants needed more extension moments from lower limb joints to prevent the centre of mass from collapsing following the trip perturbation.

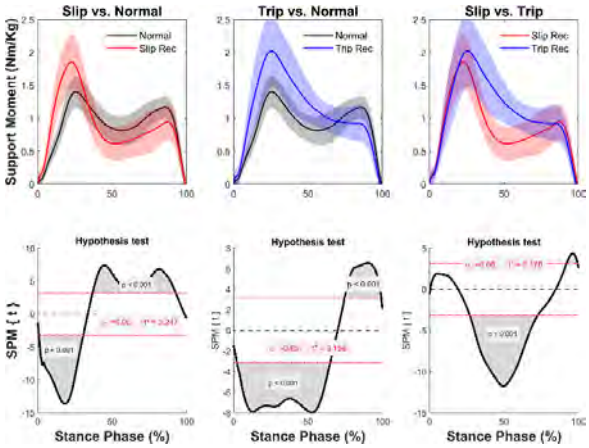

Figure 1 Support moment in Normal (black) vs slip-recovery (red), and vs trip-recovery (blue) with the statistical SPM results.

CONCLUSIONS

These findings indicate that trip-like perturbation was more challenging and had more destabilizing effects on gait stability and required a larger support moment from the lower-limb joints to keep the body upward and prevent collapsing. Therefore, it is more likely to result in falls and must be included in the PBT protocols. These findings could contribute to designing more efficient fall prevention interventions.

INTRODUCTION

Vacuum-assisted delivery (VAD) can be performed during the second stage of labor to assist complicated vaginal deliveries. In VAD, a vacuum cup is placed on the scalp of the fetus and traction is applied during uterine contractions. Despite its common use worldwide, VAD is associated with higher neonatal morbidity compared with natural vaginal delivery. Furthermore, biomechanical evidence for safe VAD traction forces is still limited, although recent studies have shown that traction forces are often underestimated [2], and that high forces may lead to severe fetal delivery outcomes [3]. To date, accurate methods to evaluate VAD are lacking, which hinders development of VAD safety [1]. The aim of this study was to develop an experimental VAD testing setup and to investigate the impact of traction forces on fetal brain deformation.

METHODS

The experimental setup included three parts; a fetal head phantom, an assessment of traction forces and brain deformations, and a VAD device. A patient-specific fetal head phantom was developed based on segmentation of the brain, skull, fontanelles and sutures in CT scans of a newborn [4] using Slicer 3D 5.0.3. The brain phantom was cast in a 3D-printed mold using a composite hydrogel (6% PVA and 0.85% PHY in a 1:1 ratio) [5] (Figure 1a). The skull phantom was 3D printed using multi-material Polyjet technology so that the different skull lobes, fontanelles, and sutures could be printed together in one prototype using three different materials (RGD835, FLX-9870-DM, RGD 8510-DM, Stratasys) with realistic mechanical properties [6]. The skull phantom was printed in two parts, which were assembled by a screwing system (Figure 1b).

Before mounting the brain in the skull, nine 2-mm sonomicrometry crystals (Sonometrics) were manually inserted into the upper part of the brain (Figure 1a), while three crystals were fixed in the lower skull, to assess inter-crystal displacements and estimate brain deformation using trilateration. The fetal head phantom was attached to the bottom of a water tank and a metal Bird cup was placed on the skull using a vacuum pump. A digital force gauge (FH 1K, Sauter) was attached between the cup and the handle of the VAD system to record traction forces (Figure 1c). Sonomicrometry and force data were recorded during simulated VAD with a maximum force of 10-100N with increments of 10N.

RESULTS AND DISCUSSION

The experimental setup allowed simulated VAD testing up to traction forces of 100N. Crystals positioned 5.4 cm and 4.9 cm below the suction point showed a vertical brain tension that increased with the level of traction force, reaching a strain of 3.4% at 100N, 1.7% at 50N, and remaining close to zero at 10N (Figure 1d). The strain behavior varied in different directions, as well as with crystal position and the shape of the traction force curve. The relationship between traction force and fetal brain deformation needs to be further investigated; at higher forces closer to those used in clinical practice and when using a more controlled procedure for positioning the crystals. Further investigation is also needed to relate brain strain and adverse outcomes in VAD.

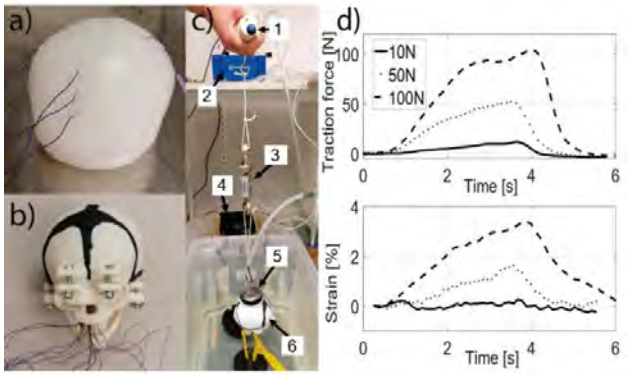

Figure 1 a) Fetal brain phantom (purple sonomicrometry crystal cables), b) Fetal head phantom, c) VAD setup, 1; VAD handle, 2; vacuum pump, 3; force gauge, 4; sonomicrometry, 5; VAD cup, 6; head phantom. d) Sample traction force and vertical strain curves.

CONCLUSIONS

The strain of the brain increased with increasing traction force, and at 100N a vertical strain of 3.4% was obtained. The experimental setup allows further investigation of the relationship between traction force and brain deformation to establish biomechanical evidence for safe VAD.

The BASMI limits patient specific examination compared to motion capture of a four-segment spine

Logan Wade[1], Raj Sengupta[2], James Bilzon[1] and Dario Cazzola [1]
[1]Department for Health, University of Bath, United Kingdom.

INTRODUCTION

Axial Spondyloarthritis (axSpA) is an inflammatory disease that mainly affects the spine, resulting in joint stiffness, entheseal inflammation and bone growth leading to vertebral fusion [1]. The widely used clinical Bath Ankylosing Spondylitis Metrology Index (BASMI) examines spinal mobility and is quick and easy to implement. However, this tool does not correlate well with radiographic disease progression [2], is highly subjective, and crucially, assumes mobility at specific points of the spine are indicitave of mobility across the spine. Each axSpA patient presents with highly variable symptoms, as regions of the spine may be selectively affected in some and not affected at all in others. Therefore, this study aimed to determine the effectiveness of the BASMI to examine whole and within spine mobility.

METHODS

In this ongoing study, fourteen (9M, 5F, 50 ± 9 years, 87 ± 22 kg, 175 ± 10 cm) of forty AS patients have had BASMI and 3D marker-based motion capture assessed. 3D motion capture (Qualisys) used marker clusters placed on six segments, head/neck, upper thoracic, lower thoracic, lumbar and pelvis, to examine an inverse kinematic segment-segment range of motion (RoM) in OpenSim [3]. RoM for each segment was calculated with respect to the inferior segment (e.g. lumbar RoM in respect to the pelvis). RoM is reported for maximal forward flexion, lateral bending, and axial rotation during standing. Movements were performed three times for each participant at their preferred speed and mean values reported. Whole spine RoM was the sum of all segment RoM's. Pearson r correlations are reported to describe the associations between the overall BASMI against overall spine RoM, and three of the five individual BASMI scores against comparable individual segment-segment ROM's. Correlation coefficients were classified as <0.2 (poor), 0.2-0.4 (weak), 0.4-0.6 (moderate), 0.6-0.8 (strong) and >0.8 (very strong).

RESULTS AND DISCUSSION

The overall BASMI score had moderate to strong negative correlations with whole spine RoM in forward flexion (r=-0.61), lateral bending (r=-0.69) and rotation (r=-0.57). Individual BASMI scores had strong negative correlations for forward lumbar flexion (r=-0.65) and lower thoracic lateral bending (r = -0.80), and moderate correlations for lumbar lateral bending (r = -0.42) and head/neck rotation (r = -0.45).

While some BASMI outcomes appeared to have strong negative correlations with patient mobility, other variables were only moderately associated. In addition, Figure 1 demonstrates how mobility at one region of the spine may vary wildly in three patients, while the same patients may be almost identical at another region. Therefore, segment-segment RoM is not indicative of mobility at neighbouring regions in axSpA patients. No BASMI correlations were above 0.8 (very strong) in magnitude, thus while some overall and individual BASMI scores represent strong associations to motion capture of a multi-segmented spine, all BASMI measures will likely be limited in their sensitivity of small changes required to monitor disease progression. As such, the BASMI does not provide sufficient detail to inform personalised treatment approaches and could potentially impede accurate monitoring of disease progression that present at multiple spinal levels.

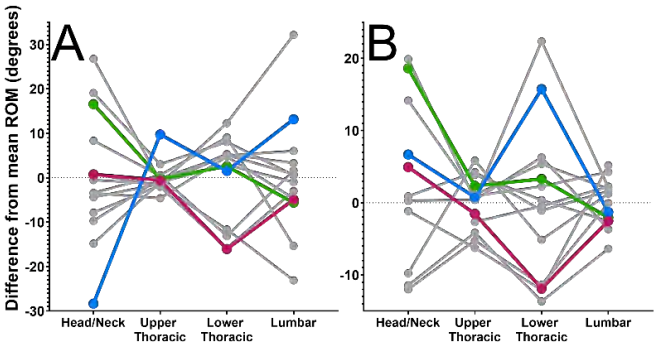

Figure 1: Forward flexion (A) and lateral bending (B), segment-segment ROM, normalised to the mean ROM across all participants. Three patients are highlighted to demonstrate the high variability across the spine.

CONCLUSIONS

To improve monitoring of spinal mobility and disease progression in axSpA, it is essential to focus on individual differences across the whole spine. Future work is needed to develop clinically applicable methods for obtaining reliable and sufficently detailed measures.

THE IMPORTANCE OF REPORTING PERFORMANCE-BASED OUTCOMES FOLLOWING INTRAMEDULLARY NAILING OF TIBIAL SHAFT FRACTURES

Simon Thwaites[1], Mark Rickman[1,2] and Dominic Thewlis[1,2]

INTRODUCTION

No core outcome set exists for intramedullary (IM) nailing of tibial shaft fractures and the optimal nail insertion technique remains inconclusive. Studies commonly describe the presence of anterior knee pain (AKP) with various patient-reported outcome measures (PROMs) for pain and function. However, few studies [1] report objective, performance-based outcomes. This prospective study aimed to investigate differences in PROMs and performance-based outcomes following tibial nailing against a healthy reference group. It was hypothesised there may be differences in time taken for outcomes to reach equivalent levels to the healthy group, but all outcomes would be equivalent to the healthy group after 18 months follow-up.

METHODS

Patients were recruited through an ongoing randomised controlled trial comparing suprapatellar and infrapatellar nailing of extraarticular tibial shaft fractures [2]. Healthy volunteers were case-matched for age, sex, height, and body mass. PROMs included AKP (yes/no), visual analogue scale for knee pain ($VAS_{knee\ pain}{}_0^{10}$), and the Knee Injury and Osteoarthritis Outcome Score – Patellofemoral Subscale ($KOOS\text{-}PF_0^{100}$). Maximum isometric knee extension strength (IKE_{max}) was captured using a MicroFET2 dynamometer. Squatting kinematics were captured using a Vicon motion capture system. A Likert score of knee pain ([0 – 4] scale) was recorded following each activity. Data were processed using Matlab (vR2019b), OpenSim (v4.3), and R (v4.2.2). MAPClient informed scale factors for deep squat OpenSim models [3]. Unpaired Student t-tests or Wilcoxen tests were used for group differences following Shapiro tests for normality.

RESULTS AND DISCUSSION

Table 1 details participant outcomes at each time point grouped by AKP and no pain (NP). $VAS_{knee\ pain}{}_0^{10}$ and $KOOS\text{-}PF_0^{100}$ remained significantly different (p<0.05) to the healthy reference group up to 18 months. Whilst IKE_{max} was equivalent (p>0.05) to the healthy group at 6 months, and max squat hip and knee flexion were equivalent to healthy at 6 and 12 months, respectively (Figure 1). Max ankle dorsiflexion remained below (p=0.02) the healthy group at 18 months (Figure 1). There was no difference (p>0.05) in $VAS_{knee\ pain}{}_0^{10}$ between AKP and NP groups at any time point. Further analyses following increased recruitment and follow-up sessions, and inclusion of additional data is required (additional PROMs, functional tests, and sensor data).

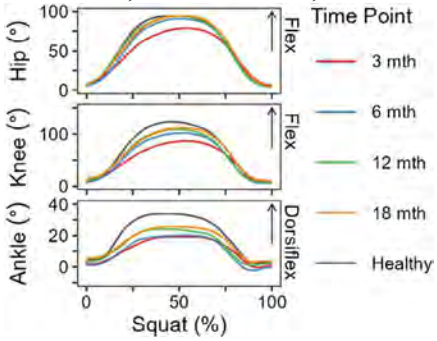

Figure 1 Mean squat flexion angles at the hip, knee, and ankle.

CONCLUSIONS

Performance-based outcomes may enhance reporting following IM nailing of tibial shaft fractures.

INTRODUCTION

Patients with femoroacetabular impingement syndrome (FAIS) suffer from groin pain, functional limitations and an increased risk for early development of hip osteoarthritis [1]. FAIS is induced by an impingement of the femur and acetabulum, provoked by abnormal bone morphology, excessive hip movement or a combination of both [1]. Kinematics of FAIS patients were most often studied during walking, where sagittal hip range of motion (ROM) and peak hip extension were found to be lower than those of healthy controls [2]. In the current study, we investigated more demanding tasks, such as hopping and jumping, that could accentuate the FAIS-induced movement impairments. Thus, time-series 3D hip angles during different tasks were compared between FAIS patients and healthy controls.

METHODS

25 FAIS patients and 25 matched healthy controls of both sexes performed various tasks: walking, running, stepping up a two-step stair, stand up/sit down, single-leg squat, drop jump, lateral hop and pivot turn. For the three latter tasks, participants jumped or stepped down from a box of 30 cm. The loaded phase, from initial foot contact to take-off was considered to define the movement cycle, except for walking and running (heel strike to ipsilateral heel strike). Three-dimensional kinematic data was captured with 13 infrared cameras (Vicon, Oxford Metrics Ltd, UK) using a full-body marker set. Hip joint angles were calculated according to ISB recommendations. Time-series data of hip flexion, adduction and rotation angles of patients and controls were compared using vector-field statistical parametric mapping (SPM) with Hotelling's T2 statistic, followed by scalar post hoc SPM in case of significance.

RESULTS AND DISCUSSION

For walking, no significant differences in hip flexion, adduction and rotation were observed between FAIS patients and healthy controls. This is in contradiction with a recent review which, for continuous kinematic data, qualitatively concluded on reduced hip abduction of FAIS patients during terminal stance [2]. However, four of the 12 included studies did not report any difference for hip kinematics of patients and controls, and four studies reported differences for discrete kinematic variables only (ROM, peak angles).

During stand up/sit down, pivot turn, single-leg squat and running, no impairments in hip kinematics were observed. Also for stair climbing no group differences were observed, which is in agreement with Hammond et al. [3] but contradictory to the findings of Rylander et al. [4], who reported less hip sagittal ROM and peak hip internal rotation in patients.

When hopping laterally with the involved leg, FAIS patients showed more hip flexion at take-off (Figure 1). In contrast, less hip flexion was observed when landing for the drop jump (Figure 1). Reducing hip flexion during the drop jump might represent a strategy to avoid pain and decrease hip joint loading and has been previously observed in women with hip pain [5]. During take-off for the lateral hop, however, hip extensor weakness – which has previously been reported in FAIS patients [6] – might prevent full hip extension. Hip extensor weakness might take effect only during the unilateral hop, as the latter is more demanding than a bilateral drop jump.

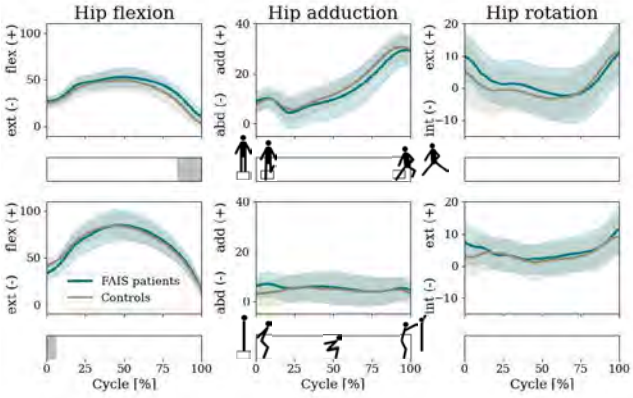

Figure 1 3D hip joint angles during lateral hop (top) and drop jump (bottom) of FAIS patients and healthy controls. Bars depict clusters of SPM significance in post hoc scalar-field t-tests.

CONCLUSIONS

These preliminary results show impaired hip kinematics of FAIS patients during lateral hop and drop jump, but not during walking and other studied tasks. Clinical assessments might therefore need to include demanding tasks, such as a hop, to reveal impairments. Next, musculoskeletal modelling could reveal the effect of altered kinematics on hip joint loading. In addition, patient stratification for different morphologies might improve the understanding of FAIS functional limitations.

POINCARÉ ANALYSIS DETECTS PATHOLOGICAL LOADING RATE VARIABILITY IN POST-ACLR INDIVIDUALS

Noah A. Davidson[1], Yannis K. Halkiadakis[1], Kristin D. Morgan[1]

INTRODUCTION

Post-anterior cruciate ligament reconstruction (ACLR) individuals often suffer from impaired motor control that results in variable limb loading. Variable limb loading can present as loading rate variability (LRV) and can contribute to the development of knee osteoarthritis [1,2]. However, accurately quantifying LRV has proven challenging. Here, Poincaré analysis was used to quantitatively and graphically evaluate differences in short-term stride-to-stride and long-term limb LRV in healthy controls and post-ACLR individuals. We hypothesized that the post-ACLR individuals' overloaded limb would demonstrate greater short- and long-term limb LRV compared to healthy control and underloaded limbs. These findings would reveal how impaired motor control would alter individuals limb loading dynamics.

METHODS

Fourteen post-ACLR individuals and seventeen healthy controls completed a walking protocol on an instrumented treadmill. The post-ACLR participants performed initial walking baseline trials to define their underloaded and overloaded limbs based on their loading rate values. All participants then completed two five-minute walking trials at 1.0 m/s and 1.5 m/s. Poincaré analysis was performed to quantify short-term (SD1) and long-term (SD2) limb LRV in the post-ACLR underloaded and overloaded limbs and the right limb of healthy controls. An ANOVA was performed to compare differences in short-term and long-term LRV amongst the post-ACLR individuals' overloaded and underloaded limbs and the healthy controls right limb.

RESULTS AND DISCUSSION

Poincaré analyses revealed that post-ACLR individuals' overloaded limb exhibited greater short- and long-term limb LRV at the faster walking speed compared to healthy control and underloaded limbs ($p<0.05$) (Table 1). The post-ACLR individuals' overloaded limbs increased LRV was illustrated by a wide dispersion of loading rate values (Fig. 1). No differences were found at the slower walking speed.

These differences in short- and long-term limb LRV suggests that the post-ACLR individuals' overloaded limb suffers from impaired motor control that alters their ability to adopt and maintain healthy limb loading dynamics, which was masked at the slower speed. Thus, it is important for individuals to perform more demanding tasks that will challenge the neuromuscular system and uncover underlying neuromuscular dysfunction.

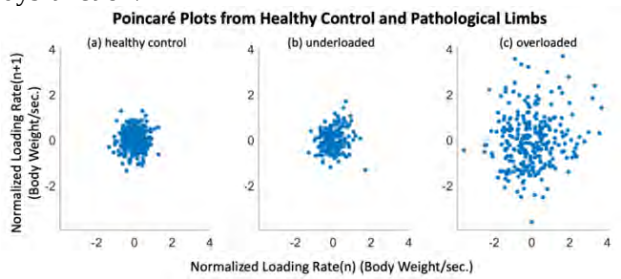

Figure 1 Poincaré plots of loading rate data for a healthy control participant's limb (a) and the underloaded and overloaded limbs for a post-ACLR participant (b, c) during the 1.5 m/s walking trials.

CONCLUSIONS

Poincaré analysis was successful in differentiating multiple facets of LRV between healthy and pathological populations. Furthermore, it revealed that post-ACLR individuals' overloaded limb continues to suffer from impaired motor control. These results suggest that Poincaré analysis could be a useful clinical tool to detect impaired motor control in pathological populations.

INTRODUCTION

In older adults, alterations in biomechanics during common activities can be the early signs of various diseases. However, widespread use of motion analysis has been hampered by time and resource constraints of proven motion capture methods, i.e., marker-based optoelectronic systems. Recently, a method using a deep learning anatomical landmark prediction from video data has become commercially available. Prior studies have evaluated its validity and repeatability to assess gait in healthy young adults [1,2]. Since reliability can be population-specific, the aim of this study was to evaluate test-retest reliability of markerless gait kinematics and kinetics in healthy older adults.

METHODS

An intra-rater test-retest study was conducted, recruiting 11 healthy older adults (81±4 years). Gait analysis was performed twice (9±3 days' interval), using 8 Miqus video cameras (Qualysis, SE) synchronized with 2 force plates (Kistler, Instruments Ltd, SWI; BERTEC, Columbus, USA) at 85Hz and 850Hz, respectively. Participants walked in their everyday clothes and sports shoes at self-selected speed (20 gait cycles). Video data were processed with Theia3D (v2022.1.0.2309, Theia Markerless Inc, CA), using an Inverse Kinematics 3D pose estimation, filtered at 8Hz. The resulting 4x4 pose matrices were analyzed in Visual3D (v2022.03.3, C-Motion, USA). Analog signals were low-pass filtered at 8Hz. Lower limb joint angles (XYZ Cardan sequence) and moments (internal, normalized to subject's body mass) were computed. An integrated pointwise Interclass Correlation Coefficient (ICC) and measurement error (SEM) were computed for curve data (R-code) [3]. Minimal Detectable Change (MDC) was calculated from SEM. An integrated ICC value of 0.70 was considered acceptable.

RESULTS AND DISCUSSION

The average walking speed varied 0.03m/s between sessions. Kinematic ICCs were ≥ 0.70, and quite stable throughout the gait cycle (e.g. Figure 1), except for sagittal and transverse hip joint (Table 1). The SEM were < 2.0º and MDC ≤ 5º, with higher SEM% in the frontal and transverse plane. These SEM values were lower than those reported for discrete points [4]. Reliability for kinetics was similar, with ankle and knee parameters showing an ICC ≥ 0.75. ICCs during the swing phase fluctuated more though (e. g. Figure 1). Hip joint moments ICCs varied between 0.53-0.69; SEM were ≤ 0.05Nm/Kg and MDC ≤ 0.1 Nm/Kg.

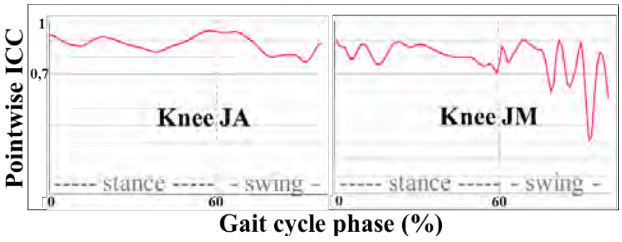

Figure 1 Pointwise ICCs for frontal knee joint angle/joint moment.

CONCLUSIONS

Our study revealed acceptable test-retest reliability for markerless gait kinematics and kinetics for the knee and the ankle, but not for the hip, in healthy older adults.

INTRODUCTION

The emergence of the Markerless motion capture systems (ML) has received increased attention due to its potential in the biomechanics field. Studies have supported the applicability of ML in gait analysis, particularly from the kinematic perspective (e.g., Kanko et al. 2021, [1]). Our previous study has shown the differences in lower extremity sagittal plane joint moments and powers between ML and marker-based (MB) systems during treadmill running [2]. Frontal plane motions are more subtle than those in the sagittal plane and muscles and ligaments that create them function primarily as stabilizers [3], to prevent injury. Therefore, the current study investigated the frontal plane lower extremity joint moments and powers estimated by MB and ML systems during treadmill running.

METHODS

Fifteen healthy, recreationally active young adults were recruited. Participants ran on a treadmill at 3.58 m/s for 2 minutes. The kinematic data were recorded simultaneously by eight infrared and eight high-resolution video cameras. An instrumented treadmill recorded the force data. The last ten strides of frontal plane moments and powers at the right hip, knee, and ankle were calculated from both MB and ML systems using inverse dynamics. The ensemble curves of mean and standard deviations of dependent variables were calculated based on individual measurements of each system. A two-tailed paired t-test was conducted using Spatial Parametric Mapping (SPM) analysis with an alpha level of .05.

RESULTS AND DISCUSSION

Ensembled curves of lower extremity frontal plane moments (left) and powers (right) estimated by MB and ML systems are presented in Figure 1. The SPM results showed significant differences in frontal plane joint kinetics estimated by MB and ML systems. Particular region of interest (ROIs) for ankle moments was between the 3%-30% and 86%-97% of the stride cycle. For ankle joint powers, the ROIs were during 15%-28% and 42%-55%. For the hip joint, the ROIs of the hip moments were during 85%-90%, whereas for the powers, ROIs were during 16%-23% of the stride cycle.

Noticeably, the significance of ankle joint kinetics estimated by MB and ML systems was mainly during the stance phase, where contacting the ground with an increased ankle inversion could indicate higher risks of ankle sprain [4]. Results indicated that ML might underestimate running injury risks. Given that frontal ankle kinetics are often used in investigating shoes and ankle-related injury studies (e.g., Lewinson et al. 2013, [5]), the salient differences from ML may induce more disputes. Additionally, the ML showed smaller magnitudes of hip production power but similar joint moments, which implied the ML might be less sensitive to hip abduction angular velocity during the early stance phase.

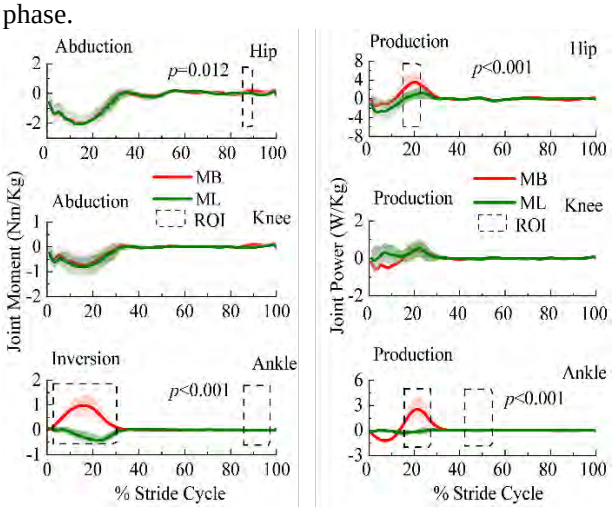

Figure 1. Ensembled curves of lower extremity joint moments (left) and powers (right) in the frontal plane between marker-based (red) and markerless (green) systems. The dotted rectangle regions represented the significant region of interests (ROIs) after Spatial Parameter Mapping (SPM) analysis.

CONCLUSION

Compared to the MB system, the ML demonstrated significant differences in the frontal plane ankle joint moments and powers. Despite the convenience of the ML system in biomechanical applications, the salient distinctions may better inform or complicate injury prevention and rehabilitation.

INTRODUCTION

In the elderly gait, the propulsive force generated by ankle plantar flexion is reduced due to aging, resulting in compensatory movements by the proximal muscles of the lower limb [1]. Specifically, the extension torque of the stance hip joint and flexion torque of the swing hip joint are increased during the push-off phase. Therefore, although reduced propulsive force and its compensations likely make gait unstable, the mechanism is not clear. The purpose of this study is to clarify the mechanisms by which propulsive force reduction and its compensation can make gait unstable using a simple walking model.

METHODS

The simple walking model consists of a point mass M at the hip, point mass m at the foot, massless legs of length l, and a massless trunk. The kinematics of this model are described by the stance leg angle θ relative to the vertical and the swing leg angle ϕ relative to the trunk (Fig. 1A). Note that the trunk was assumed to be always perpendicular to the ground. Therefore, the equations of motion for this model are expressed in dimensionless terms with the overall mass M, leg length l, and time $\sqrt{l/g}$ as the basic units as follows:

$$\begin{bmatrix} 1+\beta & \beta\cos(\theta+\phi) \\ \cos(\theta+\phi) & 1 \end{bmatrix}\begin{bmatrix} \ddot{\theta} \\ \ddot{\phi} \end{bmatrix} + \begin{bmatrix} -\beta\sin(\theta+\phi)\,\dot{\phi}^2 - (1+\beta)\sin\theta \\ -\sin(\theta+\phi)\,\dot{\theta}^2 + \sin\phi \end{bmatrix} = \begin{bmatrix} -k_1\theta \\ -k_2'\phi \end{bmatrix}, (1)$$

where $\beta = m/M$, $k_2' = k_2/\beta$ and k_1 and k_2 are the torque springs between the trunk and stance leg and between the trunk and swing leg, respectively. The step-to-step transition equation is expressed as follows (Fig. 1B):

$$\begin{bmatrix} \theta^+ \\ \dot{\theta}^+ \\ \phi^+ \\ \dot{\phi}^+ \end{bmatrix} + \begin{bmatrix} -\theta^- \\ \frac{\cos 2\theta^-}{B}\dot{\theta}^- \\ -\theta^- \\ -\frac{\cos^2 2\theta^-}{B}\dot{\theta}^- \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{\sin 2\theta^-}{B} \\ 0 \\ -\frac{\sin 4\theta^-}{B} \end{bmatrix} I_{\mathrm{push}}, (2)$$

where $*^-$ and $*^+$ represent the pre- and post-collision states $*$, respectively, I_{push} represents the impulse generated by push-off, and $B = 1 + \beta\sin^2 2\theta^-$. The spring constant of the entire system is $k = k_1 = k_2'$, and the push-off impulse I_{push} was assumed to fully compensate for the energy loss due to the collision (i.e., $\dot{\theta}^- = \dot{\theta}^+$). Therefore, the periodic solution for increasing spring constant k is obtained by the Newton-Raphson method. Note that $\beta = 0.237$ was set with reference to the human body measurement data [2].

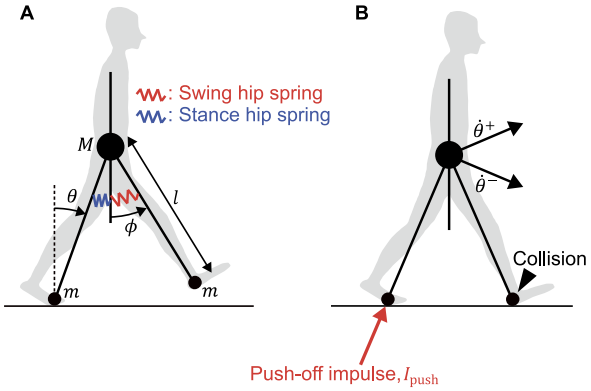

Figure 1 Simple walking model. (**A**) While the swing leg is lifted off the ground, the stance leg and the swing leg are adjusted by the torque springs. (**B**) The moment the swing leg collides with the ground, a push-off impulse is applied.

RESULTS AND DISCUSSION

We obtained a spring constant $k \approx 1.19$ corresponding to one initial condition $[\theta_0 \;\; \dot{\theta}_0] = [-0.4 \;\; 0.4]$. In the future, we aim to elucidate the mechanism of gait instability by calculating the periodic solution and the corresponding push-off impulse I_{push} when the spring constant k is changed.

CONCLUSIONS

We introduced a simple walking model that explains the reduction in propulsive force and its compensation. More detailed analysis to elucidate the mechanism of gait destabilization will be conducted in the future studies.

Relationship between bicycle control and gaze behavior during a narrow-path ride

Takashi Kojima[1], Shunnosuke Anan[1], Katsuki Cho[1], and Masahiro Kokubu[2]

INTRODUCTION

In recent years, bicycle use has been promoted because of its environmental and health benefits. In this context, knowledge that contributes to a stable ride is required. Based on comparisons between competitive cyclists and nonathletes[1], previous studies have demonstrated that small steering and leaning of bikes are important during a straight ride. Also, research has demonstrated that vision is important in bicycling and that competitive cyclists who practice more on road have a visual advantage in maintaining balance[2]. However, these were mostly cross-sectional studies, and longitudinal studies examining intraindividual changes are lacking. Therefore, this study aimed to examine the changes in movement and gaze behavior following two days of riding on straight and narrow paths.

METHODS

Nineteen university students with no previous competitive cycling experience wore an eye-tracking device and helmet and were asked to ride a bicycle motocross (BMX) bicycle on a board 12 cm in width and 30 m in length. The participants returned to the board and rode to the goal even if they deviated from the board. Motion sensors were attached to the helmets, shoulders, bicycle stems, and bicycle forks. Three trials were performed in the pre-test, and two sets of ten trials were performed in practice for two days. Within one week of practice, three trials were performed for the retention test. The following parameters were measured: the percentage of deviation from the lane (deviation rate); bicycle speed; head pitch angle (head pitch); eye position (eye); combined gaze angle (gaze); and optokinetic nystagmus (OKN) parameters (frequency, amplitude, duration, and speed) (Figure 1.a); stem yaw angle (stem); fork roll angle (folk), shoulder roll angle (lean); head roll angle (head roll) (Figure 1.b). The deviation rates obtained through the pre- and retention tests were compared using Wilcoxon's signed-rank test, with each parameter using a paired t-test. Multiple regression analysis was performed with the deviation rate as the objective variable and other parameters as the explanatory variables in the pre- and retention tests.

RESULTS AND DISCUSSION

The results of Wilcoxon's signed-rank sum test indicated that the deviation rate obtained through the retention test (median: 4.73%, IQR: 9.25%) was lower than that obtained through the pre-test (median: 10.97%, IQR: 7.58%). Paired t-tests indicated that the head pitch range, stem variability, range, root mean square (RMS) of velocity, fork variability, and range obtained via the retention test were smaller than those obtained via the pre-test. These results suggest that head stability, small steering, and bike leaning are important for ensuring cycling balance.

The results of the multiple regression analysis of the pre- and retention tests are summarized in Table 1. In the pre-test, three variables (i.e., stem variability, OKN frequency, and amplitude) were included in the regression equation, while in the retention test, seven variables (i.e., head roll range, head pitch range, quartiles, median, fork range, variability, and OKN frequency) were selected. These results suggest that small steering is important in the pre-test, whereas head stability and fine bike leaning are important in the retention test and that high-frequency OKNs is critical for maintaining the stability of the visual field, regardless of skill.

CONCLUSIONS

Through the two days of cycling on straight and narrow paths, the control strategy shifted from operating the steering wheel to stabilizing the head and leaning the bike. These results suggest that high-frequency OKNs, which maintain visual field stability, contribute to bicycle control.

INTRODUCTION

Outdoor running can be perturbed from the slightest change in aerodynamic forces experienced by the body. These forces modify metabolic demand and change the ground reaction force profiles. Wind resistance acts as a resistive force that alters the anterior-posterior forces applied by the runner [1]. As headwind speeds increase, relative to running speed, aerodynamic drag is concomitantly increased. The increase in drag increases the metabolic demand of muscles working to maintain forward momentum and the necessary propulsive forces.

To date, studies investigating the relationship between running mechanics and wind resistance have either solely focused on the physiological changes [2] or used constructed apparatuses [3] to mimic wind resistance in lieu of generating wind. Therefore, the aim of this study was to examine the effect of generated air resistance on GRF profiles. Our secondary aim was to investigate if similar relative air resistances had different effects across running speeds.

METHODS

Twenty-four male subjects (age: 22.0 ± 6.4 years, mass: 65.3 ± 4.9 kg, height: 69 ± 2.1 inches) participated. Subjects ran continuously for five minutes at fast or slow treadmill speeds (4.46 and 3.35 m/s) before an additional 5-minutes at the other treadmill speed. During the five-minute bouts of running, four air resistance conditions, relative to treadmill speed, were applied: 1) Headwind (HW; +0.6m), 2) Tailwind (TW; -0.6 m/s), 3) No wind (NW; 0m/s), 4) No fan (NF; fan off).

A linear regression was used for each treadmill speed correlating horizontal impulse, braking impulse, propulsive impulse, stride rate, and ground time with fan velocity. These variables were measured during the final 30 seconds of each running speed.

RESULTS AND DISCUSSION

As air resistance was increased during fast treadmill running, there was an increase in horizontal impulse ($F=8.847$, $p<.001$, $R^2=0.097$) (Table 1).

Neither propulsive nor braking impulses were significantly different at the fast treadmill speed. It should be mentioned that propulsion during fast treadmill running was trending toward significance ($p=0.08$). Runners choose various approaches in overcoming air resistance in terms of how much braking and propulsion they generate. This is demonstrated by horizontal impulse showing significance, while propulsive and braking impulses did not.

During slow treadmill running, horizontal impulse demonstrated no significant difference across air resistance conditions. Matching with the squared velocity in a drag force equation, the faster the running, the more influential air resistance is upon application of horizontal force.

While horizontal impulse can be increased via an increase in propulsive forces or a decrease in braking forces, the trend of runners in this study opted to increase propulsion.

Ground time and stride rate were also analyzed with no significant differences during fast or slow treadmill conditions across all air resistance conditions.

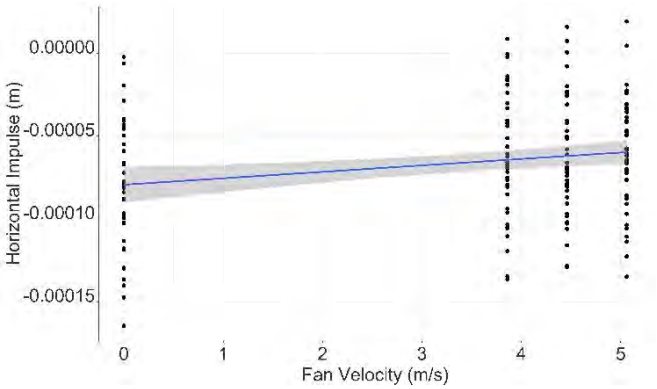

Figure 1 Linear regression of horizontal impulses during fast treadmill speed (4.46 m/s) in NF, TW, NW and HW conditions.

CONCLUSIONS

Horizontal impulse is significantly increased during faster treadmill running in the presence of air resistance. Running on a treadmill with no air resistance leads to differences in running mechanics compared with overground running. Future work will investigate other wind conditions (direction, velocities, and drafting) and its impact on running mechanics and metabolic factors.

INFLUENCE OF NEGLECTING FREE MOMENT AND TRANSVERSE GROUND REACTION FORCES IN THE DETECTION OF THE INSTABILITY OF GAIT

Helene Pillet[1], Xavier Bonnet[1] and Bruno Watier[2,3]
[1] IBHGC, Arts et Metiers Institute of Technology, Paris, France

INTRODUCTION

Monitoring the instability of gait is of great interest to detect and prevent falling risks. State of the art parameters such as the MMA-BCOM index, already evaluated in at risk population [1], basically requires the six components of ground reaction forces and moments or equivalently the position of the center of pressure and four components (i.e. the three components of the force and the vertical free moment). Unfortunatly, it is currently not possible to accuratly estimate the free moment from embedded sensors as well as the antero-posterior and mediolateral component of the force.
The aim of the study was to compare the estimation of the MMA-BCOM index when neglecting the free moment and/or the transverse components of the ground reaction forces with the estimation of the same index including all the components of the ground reaction forces and moments.

METHODS

Two groups of subjects (four with transfemoral amputation (TF) and eight non-amputee (NA)) performed a quantified gait analysis combining full body kinematics capture (200 Hz) with synchronised ground reaction forces and moments recording (1000 Hz). Three force plates were used to measure all the components during at least one entire gait cycle. Position of the center of mass was computed from a geometrical inertial model [2] and forces and moments components were filtered at 10 Hz prior to the computation of the MMA-COM index. This index is the distance between the Minimal Moment Axis and the Center Of Mass of the body and is obtained at each instant of time using:

$$\text{MMA} - \text{COM index} = \frac{\|\boldsymbol{F} \times \boldsymbol{M_{BCOM}}\|}{\|\boldsymbol{F}\|^2}$$

where $\boldsymbol{F} \times \boldsymbol{M_{BCoM}}$ is the cross product between the external forces and the external moment computed at the BCoM, $\boldsymbol{M_{BCoM}}$ [1]. The amplitude of the index was then retrieved and averaged over the gait cycle. Values were compared for the two groups and the three conditions: C1/ complete ground reaction forces and moments; C2/ neglecting the vertical free moment at the center of pressure; C3/ neglecting the free moment and the transverse components of the force.

RESULTS AND DISCUSSION

Average patterns of the MMA-BCOM index for both studied populations show that condition C3 differs from the reference condition C1 contrary to condition C2 which gives very close evolution compared to the reference.

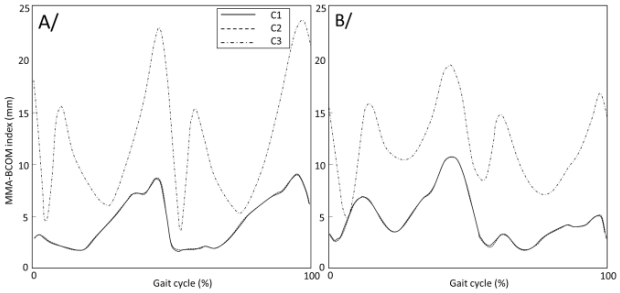

Figure 1 Average patterns of MMA-COM index for A/ NA group, B/ TF group and three conditions

The difference of amplitude of the index between condition C2 and condition C1 is 2 mm (+/-1.2 mm) on average for all the subjects. On the contrary this difference reaches 171 mm (+/-17 mm) between condition C3 and condition C1. In comparison, the difference of amplitude of the index is of in average 36 mm between NA and TF groups. Thus, contrary to condition C1 and C2, condition C3 is not accurate enough to differentiate the groups.

CONCLUSIONS

The results of this study show that the vertical free moment at the center of pressure can be neglected without hindering the capacity of the MMA-BCOM to discriminate the two populations. This conclusion makes realistic the quantification of the parameter by combining transverse forces estimated from inertial measurement units and location of the center of pressure estimated from pressure insoles.

COMPARISON OF TWO HYPOMIMIA INDICATORS IN PARKINSON'S DISEASE

Elena Pegolo[1], Gloria Boldrini[1], Lucia Ricciardi[2] and Zimi Sawacha[1,3]
[1] Department of Information Engineering, University of Padova, Padova, Italy
[2] Molecular and Clinical Sciences Research Institute, St. George's University, London, UK

Email: elena.pegolo@phd.unipd.it

INTRODUCTION

Parkinson's Disease (PD) is the second most prevalent neurodegenerative disorder affecting mostly the motor system. Among other symptoms, hypomimia is considered one of the clinical hallmarks of the disease. This feature causes impairment in face mobility leading to a reduction in patients' quality of life [1]. Even though face expression is one of the most important ways of communication, and this has been widely investigated. No objective measures of hypomimia are currently available. In order to describe face movements in relation to emotions, Ekman and Friesen developed the Facial Action Coding System (FACS) [2]. It encodes facial expressions by means of Action Units (AU) which are described by either single or group of muscles. One of the most used software that embeds AU detection is OpenFace [3].

In this regard, recently, the authors have developed a face mobility index (FMI) [4] with the aim to provide a quantitative measure of the symptom through an easy-to-interpret and intra-subject metric of face mobility applicable to PD.

The aim of this study is to compare the developed FMI against a measure of mobility based on AU with OF (AU_tot) on a cohort of PD and healthy control (HC) subjects. The FMI approach captures face mobility from a physiological point of view since landmarks are detected by muscle insertion points. Whereas AU_tot addresses emotion production from a cognitive point of view, being driven by AU detection. These different approaches could be crucial in understanding PD hypomimia etiology.

METHODS

17 HC (age = 65.8 ± 8.3 years) and 29 PD subjects (age = 68.5 ± 7.8 years) were enrolled in the study. Participants' videos of the basic emotions and the neutral expression were acquired. Frames corresponding to the peak of expressions were extracted and two indexes of face mobility were computed per emotion as follows:

1) FMI: a set of anatomical landmarks determined as the points of insertion of facial muscles was tracked; from these coordinates, 40 distances were calculated. FMI was determined as in [4] normalizing the obtained measures to the neutral expression and computing an overall measure of face mobility.
2) AU_tot: intensities of AUs were extracted through OF. OF is capable of detecting a set of 17 AUs and providing a scale of intensity per each AU from 0 to 5. AU_tot was computed as the summation of all the AUs intensities as a measure of AU-driven face mobility.

Comparison between the two indexes was performed by mean of Pearson correlation at $p<0.05$ significance level.

RESULTS AND DISCUSSION

Table 1 reports the results of the correlation between the two indexes (FMI and AU_tot). Significant correlations were found in the happiness emotion in HC and in the surprise one in PD. Only weak correlations were detected. Furthermore, as expected, values of ρ were lower in the PD population. Results of this study seem to indicate that the two indexes are capturing different facets of face expression. While FMI can be seen as an objective measure of face mobility, AU_tot is related to the cognitive aspects of emotion production.

Table 1: Correlation between the two indexes (FMI and AU_tot) per emotion in the two cohorts. Values in bold obtained a p-value <0.05.

ρ (FMI, AU_tot)	HC	PD
Anger	0.41	0.05
Disgust	0.38	0.19
Fear	0.21	0.19
Happiness	**0.62**	<0.01
Sadness	0.19	0.15
Surprise	0.37	**0.52**

CONCLUSIONS

In conclusion, the two approaches can be considered complementary since they depict different aspects of facial expression. Future developments are needed to validate these methodologies with surface electromyography.

INTRODUCTION

Morphological characteristics and distance running are theoretically well-related; a smaller lower limb moment of inertia around the hip ($I_{LowerLimb}$) can reduce the energy required to swing the lower limb, thereby improving running economy. Human morphology adapts to daily motor tasks, leading to the speculation that distance runners have smaller $I_{LowerLimb}$ than non-runners by smaller fat mass. Meanwhile, the individual variability in morphology is inhomogeneous, being greater in the proximal part [1]. Thus, the fat mass reduction might be limited at the distal part. The moment of inertia is proportional to the square of the radius of gyration ($I = mr^2$), and the relationship between $I_{LowerLimb}$ and lower-limb mass in distance runners may differ from that in normal individuals due to mass distribution. However, the inertial characteristics of long distance runners have not been fully examined.

We investigated the inertial characteristics of distance runners. We hypothesised that the relationship between $I_{LowerLimb}$ and body mass in distance runners differ from that in normal individuals.

METHODS

We analysed fat- and water-weighted MRI of the lower limbs of 20 distance runners and 18 untrained height-matched non-runners (age: 20 ± 1 years and 24 ± 3 years, height: 169.9 ± 5.6 cm and169.7 ± 4.0 m; body mass: 56.20 ± 4.12 kg and 68.93 ± 9.13 kg). We calculated the inertial properties by identifying the tissue (fat, lean or bone) of each voxel and combining the literature values for each tissue density [1]. We used the independent *t*-test and the analysis of covariance (ANCOVA) to compare the distance runners and non-runners.

RESULTS AND DISCUSSION

$I_{LowerLimb}$ was significantly smaller in runners (1.81 ± 0.29 kg.m^2) than in non-runners (2.08 ± 0.30 kg.m^2); however, the slope of the regression line of the relationship between $I_{LowerLimb}$ and lower-limb mass was significantly steeper in runners than in non-runners (Fig. 1). This suggests that the $I_{LowerLimb}$ is more sensitive to lower-limb mass in runners than in non-runners. The centre of mass (CoM) of the lower-limb was significantly more distal in runners than in non-runners (38.1 ± 0.8 vs. 36.8 ± 1.1%Lower limb length). Based on the mechanical relationship of $I = mr^2$, the difference in the slope resulted from the location of the lower-limb CoM.

All tissue masses of the whole lower limb were significantly lower in runners than in non-runners, with the effect size being largest for fat (d = 1.23). This suggests that the difference in lower-limb mass is mainly due to that in fat mass. Fat mass was lower in runners than in non-runners in all segments of the thigh, shank and foot, with the effect size being largest for the thigh (d = 1.07), implying that the difference in fat mass between runners and non-runners is greater proximally than distally. Taken together, we suggest that the fat distribution in runners, with the proximal-specific fat smallness, results in a more distal lower-limb CoM and a longer radius of gyration in runners than in non-runners.

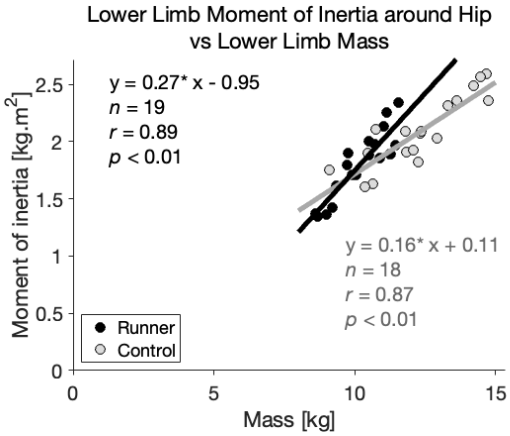

Figure 1 Relationship between lower-limb mass and moment of inertia around the hip.

CONCLUSIONS

We found that $I_{LowerLimb}$ was more sensitive to lower limb mass in runners than in non-runners. This difference was due to a difference in the mass distribution and location of the lower-limb CoM in runners, mainly attributed to a lower fat distribution in the proximal region.

INTRODUCTION

The Achilles tendon (AT) and plantar fascia (PF) are anatomically linked via the calcaneus in humans [1]. This indicates that the PF can serve as a pathway for transmitting passive tension of the AT to the forefoot. In an active state, AT compliance has been shown to modulate the operating length of the triceps surae muscle, thereby affecting its force-producing capacity [2]. Recently, we found that the AT and PF exhibit a balanced mechanical interaction upon passive ankle–foot dorsiflexion that modulates the passive range of motion of the human ankle-foot complex [3]. However, it remains unknown if the PF behaves as a simple in-series spring with the AT during muscle contraction, and its compliance influences preceding muscle–tendon behavior. Addressing this question will provide novel *in vivo* evidence for the muscle–tendon–fascia interaction that utilizes human-specific anatomical features in the ankle-foot complex. The purpose of this study was to investigate the interaction between the AT and PF during triceps surae muscle contraction and its impact on the force-producing capacity.

METHODS

Twenty-one healthy adults (12 males and 9 females, 23.0 ± 2.9 years) participated. Participants were reclined on the bed of a 3T magnetic resonance (MR) scanner (GE Healthcare, USA) with their dominant foot secured to a custom-made fixture (VINE, Japan) at the neutral position. Participants were requested to perform ramp isometric ankle plantar flexion (approx. 8 s to voluntary maximum, 5 s hold, 8 s to full relaxation; Figure 1A). During ramp contraction, oblique sagittal dynamic MR images were obtained with a 3D, fast gradient-recalled acquisition in the steady state sequence (TE: 3.0 ms, TR: 6.5 ms, FOV: 280 × 280 mm, matrix: 256 × 128, time resolution: 0.40 s [2.50 Hz], total phases: 70). A custom-built optical strain gauge (Shinko electric wire, Japan) was attached to the footplate of the fixture to obtain the strain data of footplate at a sampling rate of 100 Hz. The ankle plantar flexion torque was calculated by the strain and lever arm of the footplate.

At the time of submission, the length changes (ΔL) in AT and PF during ramp contraction have been measured with OsiriX MD software (Pixmeo, Switzerland) based on our previous study [3]. The onset of contraction was determined as the frame just before the beginning of action from the resting state. Due to the ongoing nature of this work, no statistical tests have been performed.

RESULTS AND DISCUSSION

Upon increasing and decreasing ankle plantar flexion torque during ramp contraction, the AT and PF were lengthened and shortened with their maximal elongation reaching up to 4.4 ± 2.5 mm and 3.0 ± 1.5 mm, respectively. The data confirm that the magnitude of AT and PF elongation is decoupled (Figure 1B) while showing individual variability. The results indicate that the PF is not a simple in-series spring with the AT.

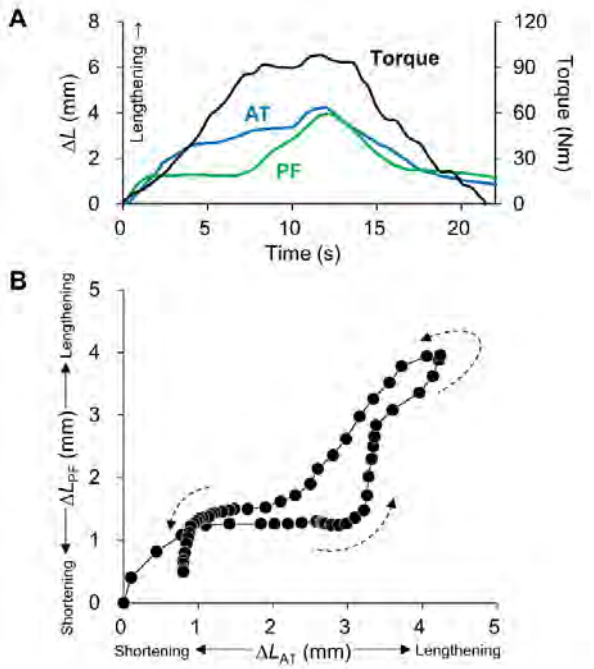

Figure 1 Exemplar of ΔL in AT and PF and joint torque (A), and relationship between ΔL in AT and PF for one participant (B).

CONCLUSIONS

Preliminary data provide novel evidence for the mechanical interaction between the AT and PF during fixed-end contraction of the triceps surae muscle in humans *in vivo*. Further data analyses will provide to examine its impact on the muscle operating length and force-producing capacity.

MARKERLESS SAGITTAL PLANE KINEMATIC ANALYSIS OF SPRINT RUNNING: COMPARISON BETWEEN A DEEP LEARNING ANALYSIS AND MANUAL DIGITIZATION

Hiroaki Noro[1], Shota Akahoshi[2], Keiichiro Hata[2,3], Yohei Yamazaki[2,3], Misato Ishikawa[2], Shuta Matsui[2], Lee Rou You[2], Kazuhiko Yamazaki[2], Toshio Yanagiya[1,2,3]

INTRODUCTION

In sprint running, kinematic analysis is valuable in research and the sports biomechanics field. In recent years, markerless motion capture tools have been used to measure kinematic data because of several practical benefits. Most previous studies tested the markerless motion capture in indoor laboratory settings [1,2,3] and sprint competitions often held outdoors. Therefore, the test of the accuracy of the markerless motion capture system in the outdoor condition is needed to evaluate the motion of sprinters. Besides, DeepLabCut (DLC) is a markerless motion capture tool that utilizes deep learning. Therefore, this study aimed to examine the agreement of joint angles using markerless motion capture tools with manual digitization.

METHODS

To make trained data set in DLC, 159 sagittal plane view videos were used in which subjects performed 100-m or 400-m sprint running. In the DLC analysis, 18-20 pictures were selected automatically in each video. Then the shoulder, knee, ankle, and tip of the shoe were digitized manually on the DLC platform. In manual digitization analysis, a person who had experienced over a year digitized the same point. After that, six videos (these videos did not include the trained data set) were automatically digitized by the DLC with the trained data set.

The coordination data was smoothed in each analysis by a fourth-order Butterworth lowpass filter at 15 Hz, referencing Van Hooren et al. (2023) [4]. The hip, knee, and ankle joint angles were calculated, and the difference between DLC and manual digitization method was observed using one-dimensional statistical parametric mapping. All of the analysis was conducted using Python 3.8.

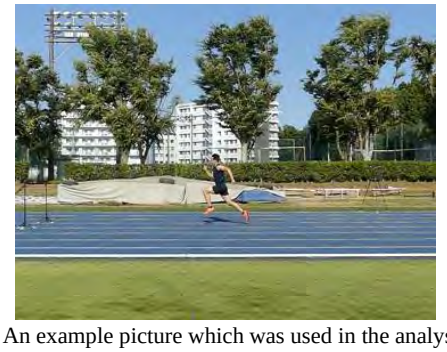

Fig1. An example picture which was used in the analysis.

RESULTS

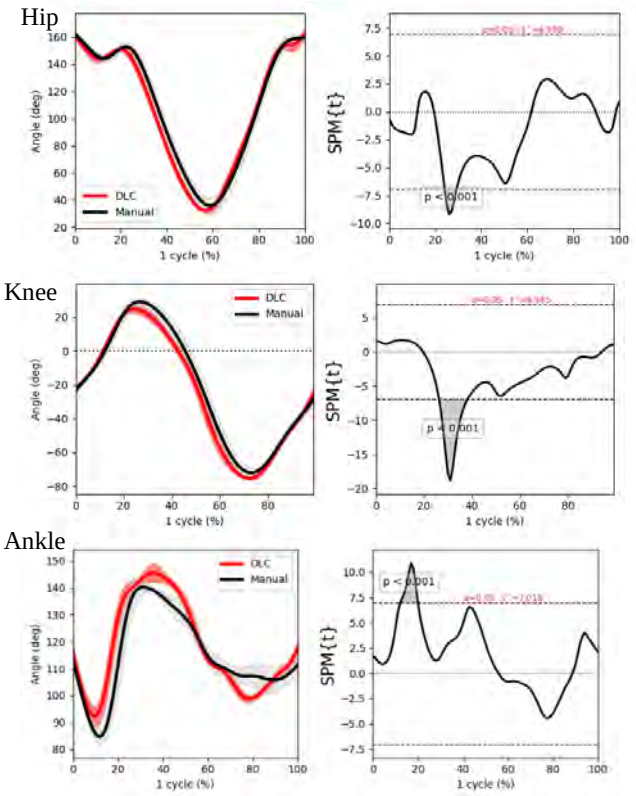

Fig2. Comparison between DeepLabCut (DLC) and Manual digitalization with statistical parametric mapping (paired t-test, $p < 0.05$).

The analysis was conducted in each hip, knee, and ankle joint angle, and significant differences were observed in the early stance phase (hip: 28%-39%, knee: 25%-29%, ankle: 13%-19%).

CONCLUSIONS

In outdoor sprint running, although Joint angles in the lower extremity in the DeepLabCut and manual digitization showed similar trends, a few differences were observed.

INTRODUCTION

The stretch-shortening cycle (SSC) is known as the dynamic movement using muscle-tendon interactions. The SSC is the phenomenon in which the force exerted by the concentric contraction following the preceding eccentric contraction is enhancedcompared with the force exerted by the solely performed concentric contraction. Generally, tendon elongation is considered the primary mechanism of this force enhancement [1]. On the other hand, the recent study [2] reported that the magnitude of the SSC effect was not different between with and without the tendon. The fundamental reasons for this inconsistency across previous studies are thought to be attributable to the methods of data collections as follows; 1) direct or indirect determinations of the elongation of tissues, 2) number of muscles contracted during the SSC, 3) magnitude of the elongation of the muscle-tendon unit (MTU) during the preceding eccentric contraction. To resolve these discrepancies, this study aimed to determine the elongations of the rat triceps surae muscle and the Achilles tendon directly during extreme elongation of the MTU.

METHODS

Three male Sprague-Dawley rats were used in this study. The triceps surae MTU was surgically exposed, and then the surrounding tissues were carefully removed. The blood and nerve supplies were kept as intact. The distal end of the Achilles tendon was cut with a remnant piece of the calcaneus. The Achilles tendon with calcaneus was rigidly attached to a force transducer with a motor (Figure 1-A). The isometric tetanic contraction of the triceps surae muscle was evoked by electrical stimulation of the tibial nerve at the optimal length, and the triceps surae MTU was then elongated until the MTU was ruptured. During the above trial, the triceps surae MTU was imaged by using the high-spatial resolution camera. The pixel resolution of this system was approximately 0.015 mm.

RESULTS AND DISCUSSION

The ultimate elongation of the triceps surae MTU was 10.5 ± 0.4 mm. The elongations of the triceps surae muscle and the Achilles tendon were determined for each 10% of the ultimate elongation of the MTU (Figure 1-B). The elongation of the triceps surae muscle gradually increased from 0% to 90%, but not from 90% (8.4 ± 0.3 mm) to 100% (8.3 ± 0.4 mm). The elongation of the Achilles tendon slightly increased from 0% to 90%, whereas the corresponding elongation markedly increased 1.5 times from 90% (1.4 ± 0.1 mm) to 100% (2.2 ± 0.2 mm).

The current results revealed that the magnitude of elongation was markedly greater for the triceps surae muscle than for the Achilles tendon at each percentage of the ultimate elongation of the MTU. Further, the elongation of the Achilles tendon was seemed to be small despite the experimental conditions (the magnitude of stretch and the magnitude of force) of this study was far beyond the physiological range. These indicate that while the tendon elongation may contribute to the force enhancement during the SSC to some extent, this effect may not be the primary contributor.

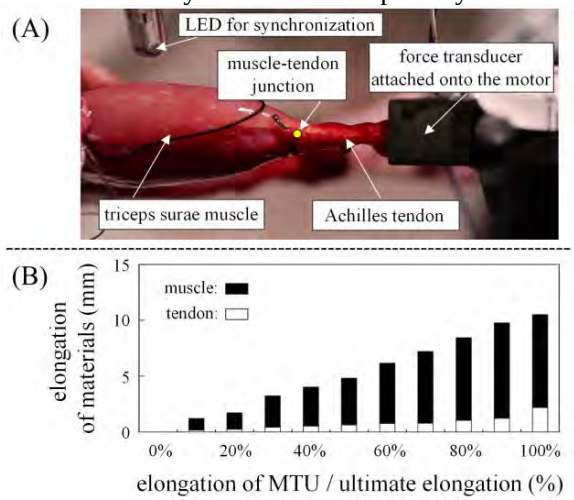

Figure 1 Experimental setting (A), the elongations of the triceps surae muscle and the Achilles tendon during the elongation of the corresponding MTU with tetanic contraction (B).

CONCLUSIONS

In conclusion, this study determine the elongations of triceps surae muscle and the Achilles tendon directly during extreme elongation of the correspoding MTU. As the results, the magnitude of elongation was markedly greater for the triceps surae muscle than for the Achilles tendon.

Switch point of impact height of adjusting segments to reach ball heights during a two-handed backhand stroke at various impact heights

Sichao Zhang[1], Natsuki Sado[2], and Norihisa Fujii[2]
[1] Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Japan.
[2] Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan.
Email: s2030468@s.tsukuba.ac.jp

INTRODUCTION

The two-handed backhand stroke has been most widely adopted by professional and amateur players but is less researched than the forehand strokes [1]. During a baseline rally, players have to hit the ball at various heights. A number of different patterns exist for reaching the ball height, such as adjustment of the lower/upper limb or trunk segment alone or in their combinations. However, it is unclear what solution that skilled tennis players use to adjust the lower and upper limbs and trunk to reach the various ball heights. Thus, we aimed to investigate the adjustment of segmental height according to the impact heights in highly skilled tennis players during a two-handed backhand stroke.

METHODS

Fifteen male university tennis players (right-handed) hit the incoming ball at various impact heights (72 ± 6 in total) to a 3 × 2 m target area cross-court with a two-handed backhand stroke behind the baseline. The impact height was presented in the ratio % of participant height. Segmental components that made up the racket height (segmental heights) were defined as the difference between the proximate joint and distal joint centers for the trunk and lower limbs, and as the difference between the distal joint and proximate joint centers for the racket and upper limbs (Figure 1). We used the piecewise linear regression method to determine the switch point of impact height at maximum R^2 for each segment.

RESULTS AND DISCUSSION

The switch point of impact height was found in right foot, right thigh, left shank, trunk, upper limbs from the distribution of segmental heights against impact height (Figure 1). The switch points of impact height [range of mean of each segment; 52.1−57.1%)] were around the ratio of leg length of the participants (50.9 ± 1.3%). This result indicates that tennis players switch the adjustment of the segments around the height of the pelvis. When impact height was lower than pelvis, the players mainly adjusted right thigh, left shank and trunk, which may facilitate keeping racket face angle by a similar posture of upper limbs. When the impact height was higher than pelvis, the players mainly adjusted right foot and both upper limbs. Before or when the supporting leg reaches its limited height, the players obtained the height from the ankle plantar flexion. Producing greater racket speed requires trunk rotation velocity. During the late forward swing, the extension of the frontal leg contributes to rotating the pelvis [2]. These findings suggest that players obtain the height by ankle plantar flexion to maintain the knee and hip in flexion that may facilitate rotating trunk at higher heights. Redundant degrees of freedom provide many solutions of combinations to reach the same racket outcomes. However, players consistently adopted a set of limited solutions that change the adjustment around an impact height. Players with higher accuracy also adopted a consistent adjustment of the velocity and angle of the racket according to the impact heights [3]. The present results suggest that a consistent strategy according to the ball conditions may facilitate controlling the velocity and angle of the racket.

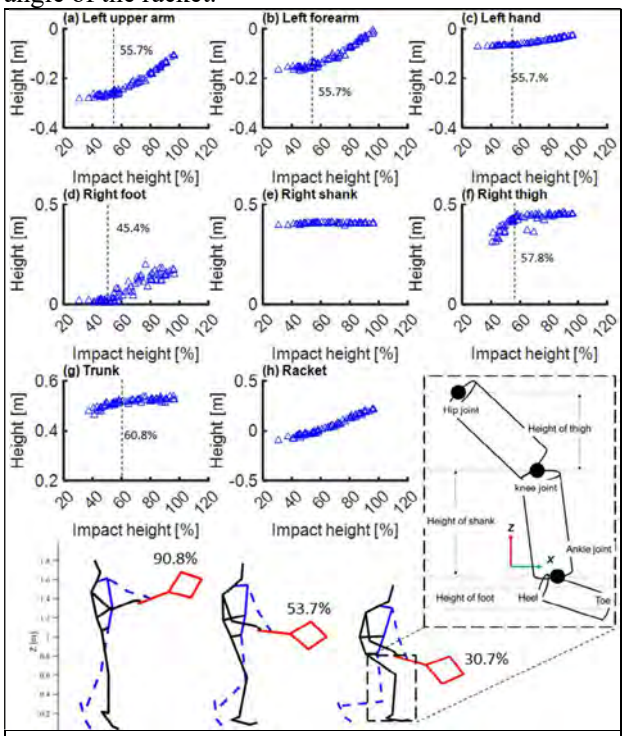

Figure 1 Relationships between impact heights and segmental heights. The switch point of this participant was 45.4−60.8%. Vertical dash lines represent the switch point for each segment.

CONCLUSIONS

Tennis players switch to using the upper and lower limbs to reach the impact heights around the pelvis. This suggests that beginners can refer to the pelvic height to determine the impact height. Below the pelvis, beginners can lower the body by the leg with same posture of upper limbs to hit the ball, while above the pelvis adjust upper limbs to obtain height.

INTRODUCTION

Muscle cross-sectional area (CSA) is an important and suitable parameter for estimating muscle function (e.g., strength and power) [1]. Since CSA is used for training or health monitoring, its reproducibility and validity are crucial issues. CSA assessment using ultrasonography (US) is considered as a convenient method, which is not time-consuming, expensive and not limited by location or target population, such as sports fields or children. In addition, the extended-field-of-view (EFOV or panoramic imaging) technique is a convenient technique for producing large cross-sectional images of the whole muscle that cannot be obtained with a single conventional US image [2]. However, the capture of some muscles may be difficult due to their specific size and shape [3]. This holds for large or curved muscles. Therefore, the purpose of this study was to quantify the reproducibility and validity of US-based CSA measurements of different lower limb muscles as compared to the "gold standard" MRI.

METHODS

Twenty-four healthy participants (12 men: 26.3 yr, 176.8 cm, 69.6 kg; 12 women: 24.8 yr, 165.8 cm, 59.7 kg) volunteered for the present study. The CSA of nine muscles of the dominant lower-limb was measured at the same location using ultrasonography (US) (MACH 30, SuperSonic Imagine, France) and MRI (3-T Vida, Siemens, Germany). During all measurements, the ankle and knee joints were positioned at 15-20° plantar flexion and 175-180° extension respectively. US measurements were performed in prone position for the calf and hamstrings, and in the supine position for the quadriceps and tibialis anterior muscles; MR acquisitions were performed in the supine position. Daily reproducibility of US and MRI measurements (n=16) was assessed using the intraclass correlation coefficient ($ICC_{1,1}$). Pearson product moment correlation and Bland-Altman analysis were used to analyze the relative and absolute validity, respectively, between US and MRI. Data are presented as mean ± SD with significance set at $p<0.05$.

RESULTS AND DISCUSSION

Reproducibility of CSA measurements was similar for US (0.994-0.999) and MRI (0.978-0.998) measurements.

The bias, lower and upper limits of agreement (LoA) and r^2 values are gathered in Table 1. The US-based CSA measurements were significantly and positively correlated with the corresponding MRI values with r^2 ranging from 0.54 to 0.90. The weakest correlation was found for the semimembranosus and the strongest for the rectus femoris muscle suggesting that the relative validity of US-based CSA versus MR-based CSA cannot be accepted equally for all muscles.

Bland-Altman analysis illustrated that US-based CSA measurements were systematically smaller than the corresponding MRI values for the whole set of muscles except tibialis anterior, for which US-based values were larger. Furthermore, larger muscles had larger absolute differences between US and MRI assessments, but curved muscles (e.g., gastrocnemius medialis) had unexpectedly similar absolute and relative errors to less-curved muscles (e.g., rectus femoris).

Table 1: Bias, lower and upper limits of agreement (LoA), and r^2 values by correlation analysis between US and MRI CSA.

Muscle	Bias (cm^2)	Upper LoA (cm^2)	Lower LoA (cm^2)	r^2
Biceps femoris long head	-2.01	0.29	-4.31	0.87***
Semitendinous	-1.18	1.14	-3.50	0.80***
Semimembranosus	-1.30	1.85	-4.46	0.54***
Rectus femoris	-2.06	-0.04	-4.08	0.90***
Vastus lateralis	-5.49	-0.74	-10.24	0.83***
Vastus medialis	-5.55	-0.86	-10.25	0.87***
Gastrocnemius medialis	-2.14	0.29	-4.57	0.89***
Gastrocnemius lateralis	-1.81	-0.40	-3.22	0.89***
Tibialis anterior	1.63	3.05	0.20	0.78***

Negative numbers indicate US values lower than MRI. ***$p<0.001$

CONCLUSIONS

The present comparative analysis indicates that using the EFOV algorithm, which may increase the risk of errors due to overlapping of successive images, the absolute error may be affected more by muscle size than by muscle curvature.

INTRODUCTION

Poor neurocognitive function, including slow reaction time (RT), has been suggested as a potential risk factor for noncontact anterior cruciate ligament (ACL) injury by impacting judgment accuracy or movement coordination [1]. Improper sagittal plane lower extremity biomechanics, such as landing with greater kinetics while the knee is in near full extension, are associated with elevated ACL tension [2]. Understanding the relationship between neurocognitive performance and landing mechanics may provide insight into ACL injury prevention and return-to-play following ACL injury and reconstruction. However, limited study has examined this notion. Therefore, this study aimed to investigate the relationship between RT and sagittal plane landing mechanics associated with ACL injuries in healthy individuals during a single-leg task.

METHODS

Eight healthy participants (6 females, 2 males; age = 18.3±0.5 years, height=175.0±11.9 cm, mass = 65.9±10.7kg) participated in this study. Participants performed two touchscreen-based eye–hand coordination tasks, including direct and cognitive–motor integration (CMI) conditions [3]. RT in each condition was calculated as the time (in seconds) between the disappearance of the central target and movement onset. Additionally, participants completed three successful single-leg drop landing (SLJL) trials with their dominant limb. A 30 cm height box was placed at a distance equal to 25% of participants' height from the force plate. Lower extremity kinematics in sagittal plane and kinetics, including knee flexion angle (KFA) and internal knee extension moment (KEM) at initial contact (IC), peak KFA of the entire landing and peak KEM, peak vertical and posterior ground reaction forces (GRFs) between the initial 100 milliseconds after IC, during SLJL trials were calculated using data collected via an optical motion capture system interfaced with one force plate. GRFs and joint moments, were normalized by body weight and body weight*height, respectively. Pearson correlation coefficient (r) was used to examine the relationship between RT in direct and CMI conditions and sagittal plane landing mechanics ($\alpha<0.05$.) and were accordingly interpreted as negligible (<0.30), low (0.31-0.50), moderate (0.51-0.70), high (0.71-0.90), and strong (>0.90) correlation.

RESULTS AND DISCUSSION

Results of the correlational analyses are presented in Table 1., indicated that faster CMI RT, but not direct RT, was significantly correlated with less KEM at IC (greater knee flexion moment). The remaining landing mechanical variables were not correlated with RT under the direct and CMI conditions. Individuals who have faster CMI RT may engage hamstring pre-activation landing strategies to increase internal knee flexion moment at IC, thus co-contract with the quadriceps to stabilize the knee joint and potentially reduce the risk of ACL injury [4].

CONCLUSIONS

Faster RT during CMI condition explained 54.6% of variance in less KEM (greater knee flexion moment) at IC in healthy individuals. Our findings suggest that individuals with a better neurocognitive RT can utilize safer landing mechanics with respect to ACL injury risk potentially by engaging greater hamstring co-contraction, resulting in a decreased KEM during landing.

INTRODUCTION

The lateral ground reaction force (GRF) toward the centripetal direction acts on a runner who runs in a curved path. Previous research reported that the inward GRF impulse of the left foot contact phase was larger than that of the right foot contact phase in the curved path [1]. However, the lateral GRF acting on the runner during the approach phase into the curved path is unknown. Thus, this research aims to investigate the difference in the lateral velocity change between the right and left contact phases caused by the lateral GRF impulse in terms of participant variability.

METHODS

The authors conducted an experiment on a 50 m straight all-weather track with 50 force platforms (TF-90100, Tec Gihan, Uji, Japan; 500 Hz) embedded. We made a curved path (radius: 38.2 m) after 40 m of the straight path. Ten male collegiate sprinters performed five runs from straight into curved paths with their own 90-95% effort with their spiked shoes. We analyzed 18 trials (three trials of six participants) in which the ground reaction force could be measured for six steps (five steps on the straight path and one step on the curved path, Figure 1). The impulse of the lateral ground reaction force during each step was calculated and normalized by the participant's mass. The mean and standard deviation of three trials for each participant were calculated (Table 1).

RESULTS AND DISCUSSION

Only participant A had a larger lateral velocity change by the right foot contact phase than that by the left foot contact phase in the first, second, and third cycles. On the other hand, the other participants had a larger lateral velocity change by the left foot contact phase than that by the right foot contact phase in their second (except for participant F) and third cycles. Moreover, for participants B, D, and H, the difference in the lateral velocity change between the right and left foot contact phases was larger than those of participants F and G in their third running cycle. Therefore, these results suggested that the kinetics of the approach phase into the curved path can vary between individuals.

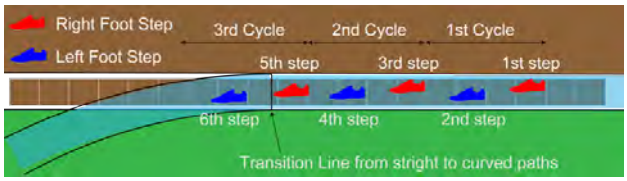

Figure 1 Definition of running cycles

CONCLUSIONS

This research suggests that the lateral velocity varied by the lateral GRF impulse on the left foot contact phase could be larger than that on the right foot contact phase during the approach phase into the curved path in sprint running. In addition, there was a variation between individuals in the difference of their lateral velocity change between the right and left foot contact phases.

INTRODUCTION

Jumping is the most power-demanding tasks, of which the high jump is the extreme mode of jumping high for humans. Higher jumping can be translated as the acquisition of mechanical energy directly contributing to the raising of centre of body mass upwards (E_{vert}). In jumping modes from static conditions (e.g., squat and counter movement jump), since E_{vert} is mainly acquired by the lower-limb extensor work/power; the ability of mechanical work/power exertion is the major determinant of its performance. Meanwhile, in the jumping from a running approach, E_{vert} is also acuired by converting the energy due to the approach horizontal velocity into E_{vert} with non-extension movement [1].
In the high jump, athletes theoretically can increase the jump height either by increasing the effective work/power exertion and/or by increasing the converted energy; however, it is unclear which component determines performance. Inter-individual variance exists in the lower-limb joint movements during the take-off in the high jump even at similar levels of performance [2]. We hypothesised that jumpers may achieve their jump height from different E_{vert} acquisition components between individuals.

METHODS

Sixteen male high jumpers (22.6 ± 3.2 years, 1.80 ± 0.06 m, 68.2 ± 5.8 kg personal and season best record [PB and SB]: 1.90–2.35 m and 1.80–2.30 m) performed high jump trials with maximal effort with the bar setting to 90% of their SB. We analysed the kinematic and ground reaction force data. E_{vert} components during the take-off phase were decomposed into a component acquired via conversion from horizontal velocity ($E_{vert\_converted}$) and a component acquired via system work ($E_{vert\_syswork}$: net of effective joint work for moving the centre of mass). The mean of three trials was used as the representative value of the participant. Pearson's correlation coefficients were calculated to examine the relationship between the variables.

RESULTS AND DISCUSSION

$E_{vert\_converted}$ was 60.3 ± 3.9% (range 53.3–66.9%) of the total increase in E_{vert} during the take-off. Although both $E_{vert\_converted}$ and $E_{vert\_syswork}$ were significantly correlated with the total increase in E_{vert} (Figure1A-B), $E_{vert\_converted}$ and $E_{vert\_syswork}$ was not significantly correlated (Figure1D). Furthermore, the percentage of $E_{vert\_converted}$ in E_{vert} was not significantly correlated with the total increase in E_{vert} (Figure1C). These results indicate that the rate of E_{vert} acquisition components differs between individuals and is independent of the performance, supporting the hypotheses. This suggests that although jumping is the most power-demanding motor tasks, higher performance can be achieved not only by increasing the power/work exertion ability but also by improving $E_{vert\_converted}$ due to the non-extension movement in the high jump.

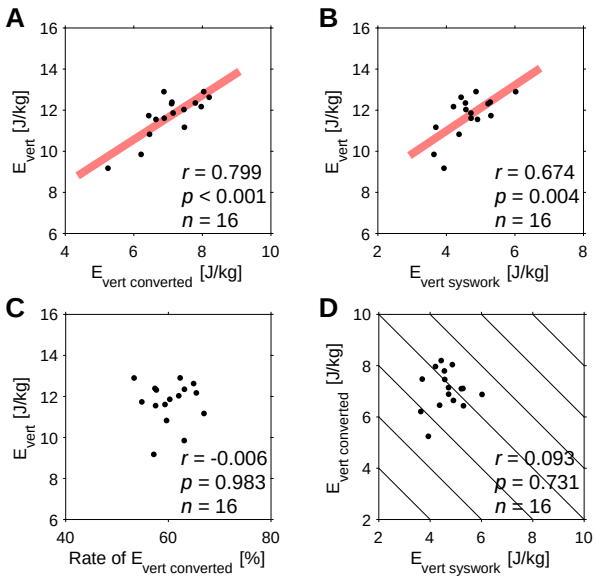

Figure 1 Correlations between E_{vert} and components of E_{vert}.

CONCLUSIONS

We found that performance is independent of whether greater lower-limb work exertion or greater conversion of the energy due to the approach horizontal velocity with non-extension movement. This suggests that to achieve higher performance in the high jump, athletes have the option of increasing either or both.

WHY ARE FORCE-VELOCITY PROFILES DETERMINED IN DYNAMOMETER EXPERIMENTS DIFFERENT FROM THOSE DETERMINED IN JUMPING EXPERIMENTS?

INTRODUCTION

Force-velocity profiling has been proposed in the literature as a method to identify the overall mechanical characteristics of lower extremities [1]. A force-velocity profile is obtained by plotting for vertical jumps with different added loads the average push-off force as a function of the average push off velocity, fitting a straight line to the results, and extrapolating this line to find a theoretical maximum isometric force (F_0) and unloaded shortening velocity (v_0). Force-velocity profiles have also been determined using experiments with leg-press dynamometers, and these yielded values for F_0 and v_0 that were different from those obtained using loaded jumps [2, 3]. The purpose of the present study was to explain these differences by simulating loaded maximal squat jumps and leg extensions on an isokinetic leg press dynamometer over the same range of motion.

METHODS

Squat jumps with added loads of 0, 20, 40, 60 and 80% of body mass, as well as isokinetic leg extensions at velocities of 0.1 to 4 m/s, were simulated using a planar forward dynamic model of the musculoskeletal system [4]. The model had foot, shank and thigh segments and a head-arms-trunk segment, and was actuated by muscle-tendon complexes of SOLeus, GAStrocnemius, VASti, RECtus femoris, GLUtei and HAMstrings (Fig. 1). Each muscle-tendon complex was modeled as a Hill-type unit. The model calculated the segmental motions resulting from stimulation (STIM) input to the muscles. Initial STIM-levels were chosen such that equilibrium initial conditions were achieved. Subsequently, STIM of each muscle was allowed to switch 'on', and switching times were optimized using a parallel genetic algorithm to find maximum height for the loaded jumps, and maximum work on the leg press dynamometer for the different isokinetic velocities. Following [1], for each squat jump the gain in potential energy after take-off was divided by leg extension distance (formally, this yields the force averaged over distance, $\bar{F}^d$) and plotted as a function of half the take-off velocity to obtain the force-velocity profile. For each extension on the leg press, the work done on the dynamometer was divided by leg extension distance and plotted as a function of the isokinetic velocity.

RESULTS AND DISCUSSION

The force-velocity profiles for the two tasks were quite different (Fig. 1). The isokinetic leg press results demonstrate that the force-velocity relationship of the leg as a whole is nonlinear; it obviously depends on factors such as hip angle and preload. It is clearly not represented by the force-velocity relationship determined using loaded jumps, and the associated variables F_0 and v_0 have no physiological meaning. The reason is that the average push-off force is not determined by the average leg extension velocity; we should not be relating the average force during each jump to the average leg extension velocity during that jump, but to a higher velocity. The problem is, however, that this higher velocity is different for each loaded jump (see arrows for two jumps in Fig. 1) and it cannot be determined from measurements during a jump which velocity should be used. Hence, the force-velocity profile determined using loaded jumps does not represent the intrinsic force-velocity relationship of the leg as a whole. It is nothing other than what it is: a relationship between effective work per distance and half the take-off velocity in vertical jumps.

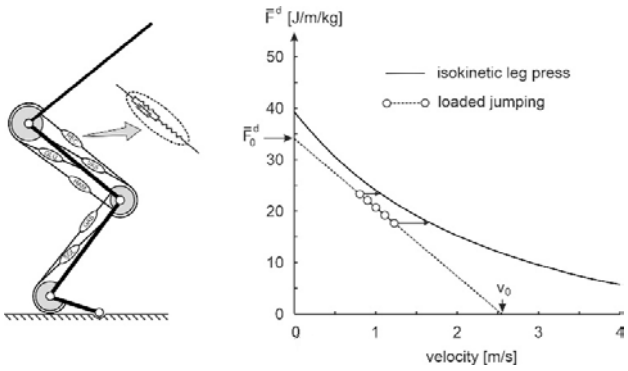

Figure 1 *Left*: Forward simulation model used in this study. *Right*: Force-velocity profiles determined for the model by simulating five squat jumps with added loads, and leg extensions on an isokinetic leg press dynamometer at different velocities.

CONCLUSIONS

To determine the intrinsic force-velocity relationship of the leg as a whole, different constant leg extension velocities should be imposed and the force or work done should be measured. This can only be achieved using isokinetic leg-press dynamometers; the force-velocity profiling approach based on loaded jumps is unsuitable for this purpose.

ARE LOWER EXTREMITY JOINT KINETICS INFLUENCED BY SHOE COLLAR HEIGHT IN COLLEGIATE FEMALE VOLLEYBALL PLAYERS?

Tanner A. Thorsen[1], Lindsey G. Legg[1]
[1] School of Kinesiology and Nutrition, The University of Southern Mississippi
Email: tanner.thorsen@usm.edu

INTRODUCTION

Collegiate volleyball players commonly wear mid-cut (MC) shoes, with a collar height that rises just superior to the talocrual joint. Previous research has demonstrated that prophylactic restriction of ankle dorsiflexion range of motion (e.g., brace, tape, collar height) can alter lower extremity joint kinetics in both the sagittal and frontal planes. Increased joint moments have been linked with ankle and knee joint injury [1]. With the jumping and landing demands inherent in volleyball, risk for injuries such as ankle sprains and anterior cruciate ligamet rupture is increased, yet the effect of MC on lowe extremity jiont moments is unclear [2]. It is also unclear if collar height affects dominant (DL) and non-dominant limb (NDL) kinetics differently during unilateral landings. Thus, the purpose of this research was to elucidate the effects of a MC volleyball shoe compared to a standard low-top (LT) volleyball shoe on sagittal and frontal plane lower extremity joint moments, and between dominant and non-dominant limbs, during a landing task in collegiate female volleyball players.

METHODS

Seventeen female collegiate volleyball players (20.12 ± 1.32 years) performed unilateral forward drop landings on each limb in both MC and LT versions of the same shoe (Crazyflight, Adidas AG, Herzogenaurach, Germany). Participants landed from a 30 cm high box placed 40% of their height from the leading edge of a force plate. Limb dominance was defined as the limb used to kick a ball. GRF and lower extremity joint kinematics were collected using AMTI force plates (2400 Hz) and a 10-camera motion capture system (240 Hz), repectively. Sagittal and frontal plane internal joint moments were then computed using inverse dynamics for DL and NDL during each shoe conditon. A two-way repeated measures ANOVA was performed to compare shoe and limb conditions. Effect size was calculated as partial eta squared (n_p^2).

RESULTS AND DISCUSSION

Smaller peak plantarflexion moments were found with MC (Table 1). Greater peak knee abduction moments were found in DL (Table 1, Figure 1). At the hip, greater peak extension moment was observed in the DL, and greater hip abduction moment was observed in the dominant LT condition and in the NDL MC condition compared to the DL MC condition (Table 1).

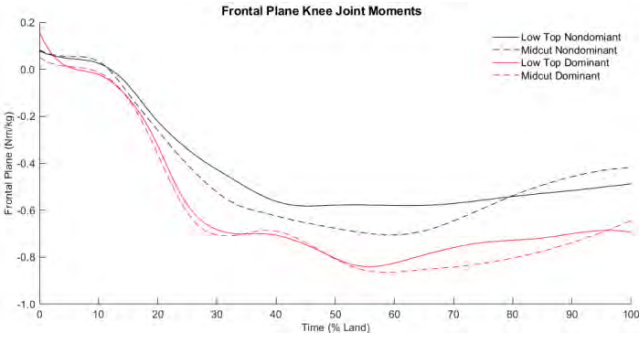

Figure 1 Frontal plane knee joint moments during the landing phase of a unilateral forward drop landing.

CONCLUSIONS

MC shoes promoted a reduced plantarflexion moment; however, this reduction was not sufficient to affect knee joint moments between shoes. Greater knee abduction moment was observed in the DL indicating players may have adopted more neutral landing mechanics on their NDL. This suggests that player preference may guide choice of shoe (MC vs. LT) and not prophylactic concern. Between limbs, however, improving landing mechanics on the DL may reduce knee injury risk (i.e., decreasing frontal plane joint moments) while playing volleyball, regardless of shoe [3].

PECTRORALIS MAJOR AND DELTOID MUSCULARITY IN SHOT PUTTERS: REVERSAL OF WHETHER CROSS-SECTIONAL AREA OR VOLUME IS RELATED TO PERFORMANCE.

Shogo Hashimoto [1], Toshihide Fujimori [1], Takeshi Edagawa [1], Keigo Ohyama-Byun [2], Yoshikazu Okamoto [3], Takahito Nakajima [3], and Natsuki Sado [2]

INTRODUCTION

A shot put is an event in which a heavy shot is 'put' forward and upwards. The muscles that cross the shoulder joint, which connects the trunk to the upper limb, are expected to be highly stressed during the shot put. It was suggested that maximal force and mechanical work/power exertion abilities of the shoulder muscles are important for performance [1]

The prime movers of the diagonal shoulder movement would be the pectoralis major (PM) and deltoid (DELT) muscles. The directions of action of these muscles are anatomically different and may have different effects on performance; however, to the best of our knowledge, shoulder muscularity in shot putters has not been examined. We assessed the PM and DELT morphology in shot putters using two indices: muscle cross-sectional area (CSA) and muscle volume, which reflect the potential for maximal force and mechanical work/power, respectively. We hypothesised that PM and DELT would be differentially related to shot put performance on the two measures.

METHODS

We collected the transverse water-weighted magnetic resonance images (MRIs) from the upper limbs (2 mm interval) and the trunk (5 mm interval) of 11 male shot-putters and 14 untrained males. From the MRIs, we calculated the maximum transverse CSAs and the volumes of PM and DELT. When calculating the volume of the DELT, one participant in both groups had missing MRI images and were excluded from this analysis. Welch's *t*-test was used for intergroup comparisons. Cohen's d was used for the effect size of each *t*-test. The relationship between each muscle index and the season's best were tested using Pearson product-moment correlation coefficient.

RESULTS AND DISCUSSION

CSA and volume in both muscles were significantly greater in shot putters than in untrained men ($p < 0.01$, $d > 1.40$), with the effect size in PM being larger for CSA and that in DELT being larger for volume, respectively. Season's best was strongly correlated with CSA and volume for both PM and DELT, with a stronger correlation in PM for CSA and that in DELT for volume, respectively (Figure 1). This inversion of volume and CSA supported our hypothesis. Athletes put a shot diagonally upward with the trunk almost vertical during the shot-put motion. Therefore, the mechanical demand of each muscle during the motion is considered as the large force exertion in PM to inhibit horizontal shoulder abduction due to the reaction force of the shot, and as the mechanical work/power exertion in DELT to increase the gravitational-potential energy of the upper limb and the shot. This study suggests that the morphology of the PM and DELT in shot putters and its relationship to performance are consistent with the mechanical demands of each muscle in the shot-put motion.

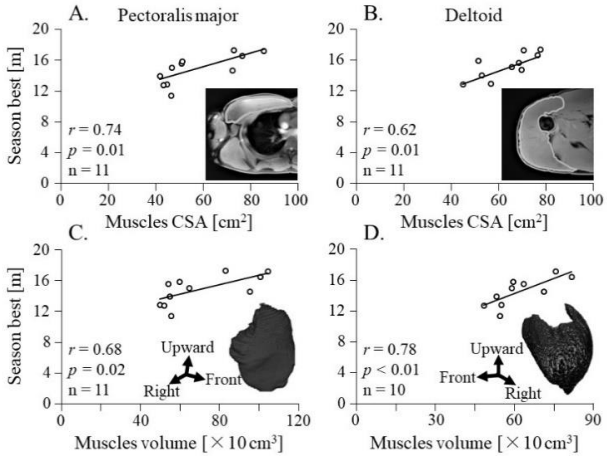

Figure 1 Relationship between muscle cross-sectional area (A, B) and muscle volume (C, D) of pectoralis major and deltoid muscles and season's best.

CONCLUSIONS

We find that CSA is more related to shot put performance in PM, whereas volume is more related to performance in DELT. The reversal of the relationship between these indices and performance is suggested to be consistent with the mechanical demands of the shot-put motion.

INTRODUCTION

Fast bowling is heavily reliant on the mechanics of the front leg, which acts as a quasi-rigid lever connecting the ground to the pelvis. There are four broad categories of front-leg technique: flexor, extender, flexor-extender, and constant brace [1]. However, coaches, tend to instruct fast bowlers to extend their front knee during delivery, claiming that this technique not only increases release height, but also generates faster ball speeds. A direct coaching intervention requires the bowler to actively engage the knee extensors during front foot contact, working on the premise that an independent increase in the knee extension angle will enhance the bowler's performance. This practice would conflict with research showing that joint angle is subject to non-local cumulative effects arising from distant parts of the kinetic link chain [2].

One method to determine the magnitude and type of knee muscle contribution to knee joint rotation is to calculate the angular work about the knee. Hence, the aim of this study was to analyse the knee angular work of a sample of young high performance fast bowlers during the arm-acceleration phase. We hypothesised that changes in knee extension-flexion angle are dependent on the effect of body segment motions occurring at locations in the kinetics link chain that are remote from the knee.

METHODS

A Cortex Motion Analysis System (Version 1.0, Motion Analysis Corporation Ltd., USA) was used to record three-dimensional (3D) motion and force plate data for 18 young fast bowlers during six bowling trials. Each bowler wore a full body marker set comprising fifty-one 25-mm spherical markers, which were attached to bony landmarks [3]. A recursive fourth-order low-pass Butterworth filter was sed to smooth the *xyz*-coordinates of the marker data. The smoothed motion analysis data of the markers were imported into a four-segment rigid-body 3D kinematics and kinetics model of the front leg designed using Visual3D software (Version 5, C-Motion, Germantown, MD). Local segment coordinate systems of the rigid-body model were defined for the pelvis and front leg. The normalised knee torque versus angular displacement data was interpolated by B-splines and then numerically integrated with the trapezoidal rule to calculate the normalised angular work at the knee using Mathematica (Wolfram Research, Inc., Version 12.0). Positive work indicates that the joint torque actively contributed to knee flexion-extension, whereas negative work indicates that knee flexion-extension was controlled.

RESULTS AND DISCUSSION

Most bowlers were flexors (61%), followed by flexor-extenders (28%), and then extenders (11%). Interestingly, the knee angular work for most of the arm-acceleration phase was negative, indicating the torque at the knee acted to control or resist the rate of knee flexion-extension. For instance, from 40-100% of the phase, the mean knee angular work for the bowlers in the knee flexor-extender group was negative, suggesting that the knee flexors were contracting to control the rate of knee extension from 60-100% of the phase (Figure 1). Similarly, negative knee angular work operated from 36-100% of the phase for the bowlers in the flexor group, and from 0-100% for the bowlers in the extender group.

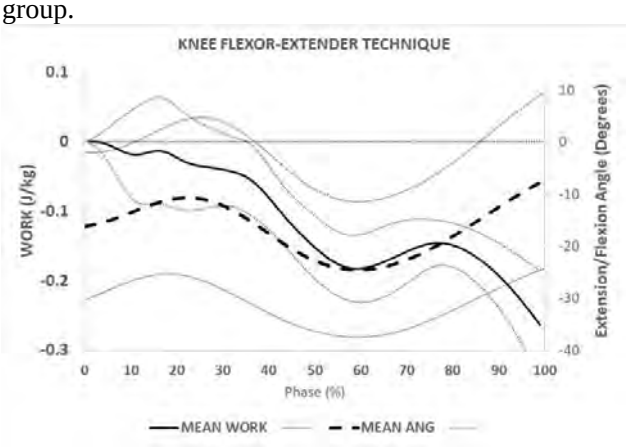

Figure 1 Mean normalised work at the knee and knee flexion-extension angle during the arm-acceleration phase for the flexor-extender technique.

CONCLUSIONS

The knee angular work at the front knee during the arm-acceleration phase of the fast-bowling action tended to be mostly negative for all front-leg techniques. Both knee flexion and extension were mostly controlled, suggesting that knee motion is influenced by non-local effects in the kinetic link chain. Coaching interventions that focus on increasing knee extension angle should consider the whole-body segment interactions on the knee.

INTRODUCTION

Tendons play a major role in normal musculoskeletal functioning. Injury, pathology or disease of tendons can impair function and may require surgical repair or reconstruction. Characterisation of "normal" tendon structure and biomechanical properties is important for understanding mechanisms and progression of pathology and healing, and for understanding native properties to develop biomimetic grafts. This study aims to compare structural and functional characteristics of a range of different human tendons.

METHODS

Nine different tendons were retrieved from 39 fresh-frozen human cadaveric lower-limbs (35 donors; 22 male, 13 female; aged 49-99 years) including: Achilles tendon (AT), tibialis posterior and anterior (TP, TA), fibularis longus and brevis (FL, FB), flexor and extensor hallucis longus (FHL, EHL), plantaris (Plt) and flexor digitorum longus (FDL). The central length underwent tensile testing to failure, measuring maximum load at failure and ultimate tensile strength (UTS). Proximal and distal samples (1-3 sections per region) from the same 9 tendons were collected from a subset of 11 donors (5 male, 6 female; 68-99 years) for histological assessment using Haematoxylin and Eosin (HE), Toluidine Blue (TB) and Picrosirius Red (PSR) staining. A total of 936 region-matched images (312 per stain; 200x magnification) were included for analysis. Cell characteristics (cell density, and nuclear circularity and size) were quantified from HE images. A scoring system was developed assessing fibre architecture (HE, PSR), crimp wavelength (PSR), and proteoglycan content (TB). Biomechanics and cell characteristics were analysed using multivariate, mixed-effects linear regression, controlling for donor sex, age, height, weight, and tendon region. Semi-quantitative histology scores were analysed using Kruskal-Wallis and Dunn's test with proximal/distal regions analysed separately. Sidak's correction was used for multiple comparisons.

RESULTS AND DISCUSSION

There were no significant tendon-specific differences for UTS (Figure 1i) or maximum load when controlling for donor characteristics. Different tendons and tendon-regions exhibited different histological properties. Structural differences between tendons were more common in the distal versus proximal regions (Figure 1iii, iv). Distally, there were tendon-specific differences in crimp wavelength, and proteoglycan staining area and intensity, while only crimp wavelength varied between tendons in the proximal region. Regional variations in cell characteristics, crimp characteristics and proteoglycan content reflect different attributes associated with bone vs muscle ends of the tendon and different loading environments of the tendon/region.

Cell density was significantly influenced by the type of tendon ($p=0.0040$), with TA exhibiting significantly greater cell density compared to AT, TP, FB, Plt, and FDL; all $p<0.05$; Figure 1ii). Furthermore, the region of tendon (proximal/distal) was significantly related to cell density (distal = greater density; $p<0.0001$) as well as nuclear morphology (distal = more round; $p=0.0001$) and size (distal = smaller; $p=0.0007$). While greater cell density and morphology are often indicative of pathology [1,2], such variations may reflect different physiological or functional characteristics of the regional tissue. Interestingly, there were significant correlations between UTS of the central tendon and distal tendon cell characteristics: UTS decreased with increasing density ($p=0.0328$) and cirularity ($p=0.0009$), suggesting an overall altered structural capacity of tendons with greater cell numbers and rounding.

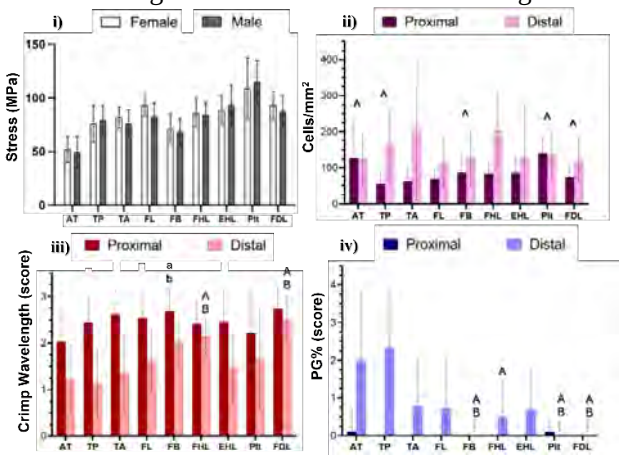

Figure 1. **i)** Ultimate tensile strength, **ii)** cell density, **iii)** crimp wavelength, and **iv)** proteoglycan staining area of nine different human lower leg tendons (see *methods* for abbreviations). Data as mean ± standard deviation, $p<0.05$ represented by symbols where applicable: ii) tendon different to TA (^); iii and iv) proximally different to AT(*a*) or TP (*b*); distally different to AT (*A*) or TP (*B*).

CONCLUSIONS

This study identifies unique histological properties of different tendons and variations associated with their mechanical properties. These relationships improve our understanding of tendon structure and function which has important clinical implications, particularly for the selection of grafts or the design of biomimetic materials based on specific native tissue properties.

INTRODUCTION

Tendon rupture leads to long-term functional, structural, and mechanical changes in the Achilles tendon (AT) and triceps surae (TS) muscles [1]. Despite many studies investigating the recovery of the AT after rupture, factors that are associated with good recovery are still poorly known. Thus, we aimed to explore interconnections between structural, mechanical, and neuromuscular parameters and their associations with markers of good recovery.

METHODS

A total of 35 patients with unilateral rupture (6 females) participated in this study. Muscle-tendon structural, mechanical, and neuromuscular parameters were measured 1-year after rupture. Mechanichal and structural parameteres were measured using ultrasonography. For detailed information on the measurements and calculations please refer to [2,3]. Surface electromyography (EMG) signals of soleus (SOL), MG, lateral gastrocnemius (LG) and flexor hallucis longus (FHL) were collected during 30% of maximal isometric ramp plantar flexion and normalized to root mean square (RMS) from a 1-sec window during maximum voluntary contraction. Total EMG activity of all plantarflexor muscles was also computed by summing the normalized SOL, MG, LG and FHL EMG activity. This cumulative value denoted 100% and was used to evaluate the relative contribution of each muscle to total plantarflexor activity.

Interconnections between the inter-limb differences (Δ) were explored using partial correlations controlled for age and sex, followed by multivariable linear regression to find associations between the measured factors and the following markers that indicate good recovery: 1) tendon length, 2) tendon non-uniform displacement, and 3) FHL normalized EMG amplitude difference between limbs. Covariates inclusion in the models was based on previous knowledge, considering the associations detected in the exploratory correlations. We also investigated the relative contribution of FHL to total triceps surae EMG activity during submaximal contraction between limbs.

RESULTS AND DISCUSSION

ΔMG (β=-0.12, [95%CI -0.20 – -0.03]) and ΔLG (β=-0.086, [95%CI -0.16 – -0.006]) subtendon lengths were associated with MG tendon Δstiffness. MG (β=11.56, [95%CI 4.22 – 18.90]) and soleus (β=2.18, [95%CI 0.10 – 4.05]) Δsubtendon lengths explained 48% of variance in FHL EMG amplitude (Figure 1). Regression models for tendon length and non-uniform displacement were not significant.

The relative contribution of MG on total plantarflexor EMG activity was lower in the injured limb with a mean difference of 0.061 (95%CI 0.02-1.0) and was accompanied by an increased FHL contribution to total EMG in the injured limb, with a mean inter-limb difference of -0.061 (95%CI -1.06 - -0.016).

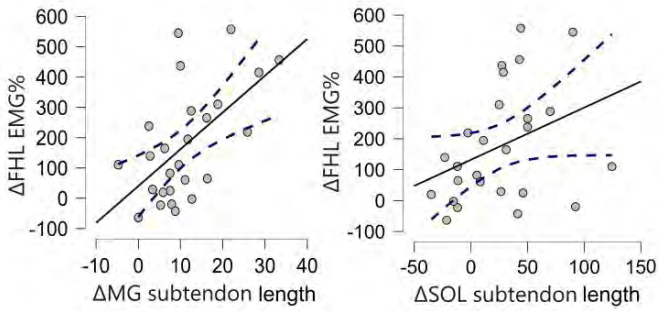

Figure 1 Scatter plots showing bivariate associations between the identified independent predictors of ΔFHL EMG% in the multivariate regression model.

CONCLUSIONS

Higher tendon stiffness may ameliorate the effects of tendon lengthening, so rehabilitative measures that promote MG muscle activation, and increase muscle strength along with tendon stiffness could improve functional outcomes. It is true that TS muscle weakness is partially compensated by FHL but FHL capacity to compensate for the loss of strength in the injured limb is limited due to relatively short plantarflexion moment arm. Thus, treatments and rehabilitation should not emphasize the role of FHL to allow recovery of the TS.

In-Vivo Patellar Tendon Strain Measured using Ultrasound Differs by Sex and Region of the Tendon

Naoaki Ito[1], Rodrigo Scattone Silva[2], and Karin Grävare Silbernagel[1]

INTRODUCTION

Patellar tendinopathy is a prevalent condition in young active individuals and is most common in males and in the medial region of the tendon [1,2]. In vitro tendon stiffness is known to differ by region (medial, lateral, central) [3], however studies in vivo are lacking. Males typically have stiffer tendons than females [4] and the variability in stiffness by region and sex may result in unbalanced loads within the patellar tendon during quadriceps contraction. Such unbalanced loads through the tendon may further explain the etiology of injury. The purpose of study was to investigate the differences in patellar tendon strain between regions and sex in healthy individuals.

METHODS

Healthy participants (10 male | 10 female, age: 26±4 years, body mass index: 25±3 kg/m^2) performed unilateral isometric knee extensions on a dynamometer at 60% of their maximal voluntary isometric contraction (MVIC) in 90° of knee flexion. Concurrent extended field of view ultrasound images of the patellar tendon were collected. Images were collected in the medial, lateral, and central regions of the patellar tendon. Resting images were also collected for each region. Patellar tendon strain was calculated by dividing the change in length at 60% MVIC by the resting length [5]. Linear mixed effects model using Satterthwaite's method was used to determine the fixed effects of region (medial, lateral, central), sex, and the interaction between sex and region on patellar tendon strain. Participants were included in the model as random effects. Pairwise comparisons were performed for significant findings (α=0.05).

RESULTS AND DISCUSSION

Main effects of sex ($p < 0.01$) and region ($p < 0.01$) were observed; however, no interaction effect ($p = 0.477$) was seen. Males had less strain than females (mean [95% confidence interval]: male strain = 8.3 [6.4 – 10.2] %, female strain = 13.8 [11.9 – 15.7] %). The central region (central strain = 6.9 [4.9 – 9.0] %) had less strain compared to both medial ($p < 0.01$, medial strain = 11.7 [9.7 – 13.7] %), and lateral ($p < 0.01$, lateral strain = 14.6 [12.6 – 16.6] %) regions. No statistically significant differences were observed between the medial and lateral regions ($p = 0.08$) (**Figure 1**).

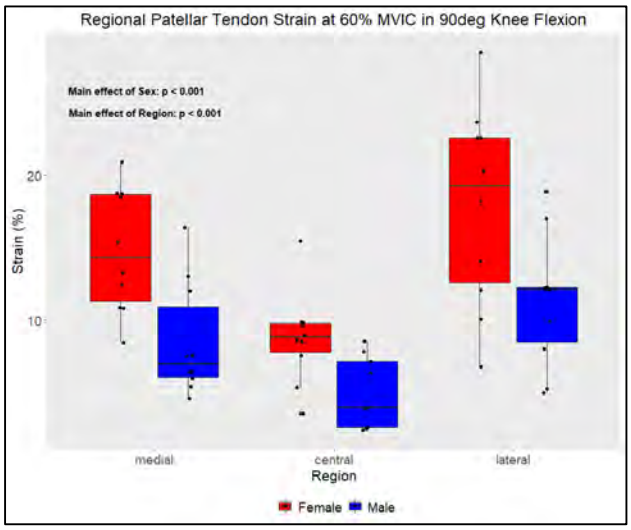

Figure 1. *Regional patellar tendon strain by sex. MVIC, maximal voluntary isometric contraction.*

Consistent with our previous knowledge about stiffer tendons in males compared to females [4], the patellar tendon in females experienced higher levels of strain at the same effort level compared to males. The medial and lateral regions of the tendon also experienced higher levels of strain compared to the central region. The high prevalence of patellar tendinopathy in the medial region [1] may be due to the medial region undergoing higher levels of strain at the same effort levels compared to the central region.

CONCLUSIONS

Patellar tendon strain differs by sex and region. The varying prevalence in sex and in location of patellar tendinopathy may in part be explained by the unbalanced loads observed. Tendon strain levels by sex and region may have to be considered as risk factors for injury and may guide interventions in rehabilitation when treating patellar tendon injuries.

INTRODUCTION

Near-infrared spectroscopy (NIRS) is a powerful bioanalytical technique that enables rapid, invasive but non-destructive assessment of human bone, cartilage, and meniscus properties [1]. NIRS has demonstrated great potential for estimating mechanical and compositional properties of bovine knee ligaments and patellar tendon (PT) when near-infrared spectra have been obtained from prepared testing samples [2,3]. However, estimating tendon properties with NIRS has not been performed with near-infrared spectra acquired with the tendon intact. Further, the viability of NIRS for characterizing human tendon material properties has yet to be assessed. Thus, the aim of this study was to investigate whether near-infrared spectra obtained from intact cadaveric PT can estimate its material properties.

METHODS

Eight fresh-frozen cadaver (5F; 65±8 yr; 1.72±0.15 m; 83±23 kg) knees were used. Near-infrared spectra were obtained from medial, central, and lateral PT regions via small incisions through the skin (Figure 1) using a Stellarnet spectrometer (DS-InGaAs-512). Each PT was harvested and split into three mediolateral pieces further divided at their approximate center width into anterior and posterior parts. Using a custom-made tool, each of the six pieces were cut into dumbbell-shaped samples at their approximate longitudinal center. Micro-computed tomography (SkyScan 1172, Bruker) was used to obtain sample cross-sectional area. After preconditioning, stress relaxation (one-step, 30 minutes at 8% strain) and sinusoidal (20 cycles of 0.5% strain amplitude from 8% strain at 0.1, 0.5, 1.0, 2.0, and 5.0 Hz) tests were performed in a mechanical testing device (Mach-1 v500css, Biomomentum; Figure 1). Then, samples were pulled to mechanical failure at 0.05%/s. Phase angle and dynamic modulus were obtained from the sinusoidal data, and parameters relating to toe and linear regions and yield and failure points were analyzed from stress-strain curves. Individual NIRS prediction models were constructed for each biomechanical variable and evaluated with five-fold cross validation. Depending on the output of the optimization process, regression was implemented as partial least squares or support vector machine [1–3]. As no systematic region-specific differences in PT material properties were found [4], data from each mediolateral region's anterior testing piece were used for the reference biomechanical data.

RESULTS AND DISCUSSION

Many biomechanical parameters obtained here could be predicted with reasonable error (i.e., $r_{CV} \geq 0.5$; $RMSE_{CV} \leq 20\%$) by NIRS spectra obtained directly on the patellar tendon. Model predictions of viscoelastic properties, which are important for the efficiency of movement, performed best.

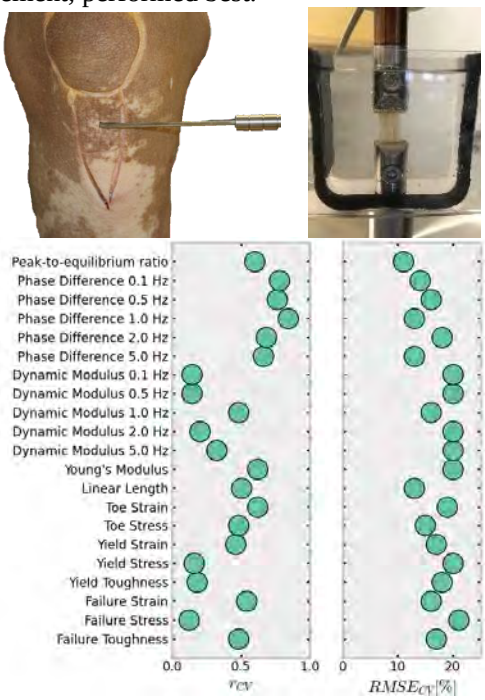

Figure 1. *Top*: *In situ* acquisition of near-infrared spectra (left) and *in vitro* mechanical testing (right). *Bottom*: Calibrated (r_{CV}) and cross-validated ($RMSE_{CV}$) comparisons between measured and predicted human patellar tendon material properties.

CONCLUSIONS

Further development of the NIRS probe and models of light-tendon and light-skin interactions may lead to the development of NIRS as a tool for non-invasive *in vivo* characterization of human tendon mechanics.

EFFECT OF MINIMALIST SCHOOL SHOES ON INTRINSIC FOOT MUSCLE SIZE

Roy T.H. Cheung[1], Shayan Quinlan[2], Alycia Fong-Yan[2] and Irene S. Davis[3]

INTRODUCTION

Walking in minimalist shoes has been reported to promote intrinsic foot muscle size and strength in active adults [1]. A recent investigation by our team, however found that minimalists did not result in larger or stronger intrinsic foot muscle among school aged children [2], which can be explained by the low minimalist index (46%) of their test shoes. Hence, we investigated the effect of true minimalist shoes on intrinsic foot muscle sizes and strength in school children.

METHODS

We recruited 28 healthy participants who aged between 9 to 12 from the same primary school which participated in our previous study [2]. Participants were excluded if they had any injury three months prior to recruitment, wore orthotics, or had general ligament laxity. After the baseline assessment, all participants were given a pair of minimalists (94% minimalist index, Softstar, OR, USA) as their regular school shoes for two school terms (i.e., February to September), followed by a re-assessment. The shoes were worn during school hours in accordance with strict uniform policy (6 hours/day, 3 days/week). The cross-sectional area (CSA) of abductor hallucis (AH) and flexor digitorum brevis (FDB) were measured by a portable ultrasound machine (VINNO Technology, Suzhou, China). The toe flexor strength (TFS) of the hallux and the lesser toes were measured by a customised dynamometer which demonstrated excellent reliability [3]. One-way ANCOVA were used to test differences in the dependent variables between minimalist and control groups (collected in [2]), using the pre-intervention measure as the covariate for the post-intervention measure analysed.

RESULTS AND DISCUSSION

Of 28 participants in the minimalist group, only 17 participants completed the study (attrition rate 39%). The demographics, including age, height, weight, and BMI between the two groups were comparable ($p>0.591$).

Significant greater CSA of FDB was found in the minimalist group ($p=0.026$, Figure 1), but not for other variables. When compared to moderate minimalist shoes [2], true minimalists resulted in a larger effect (Table 1). The absence of changes in the CSA of AH and TFS may be partly explained by the relatively short exposure (i.e., 3 days/week x 6 hours/day).

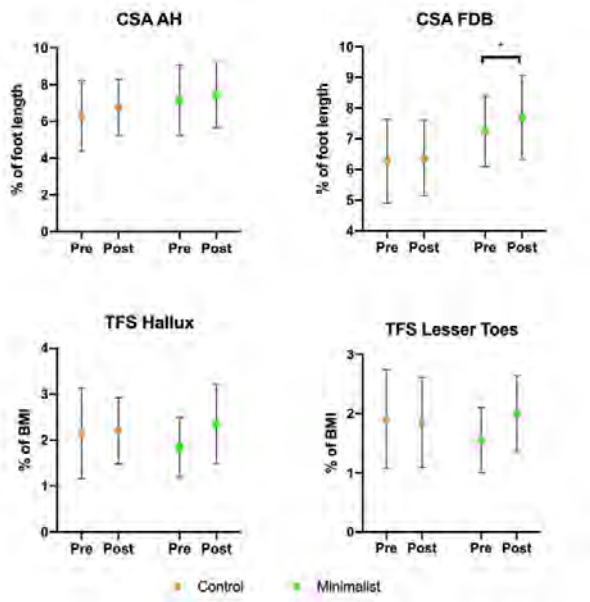

Figure 1 Cross-sectional area (CSA) and toe flexor strength (TFS) of selected intrinsic foot muscles before and after intervention.

CONCLUSIONS

Minimalist school shoes result in a greater FDB muscle size, but not AH. TFS was also unchanged over this 8-month period.

Investigation of optimal perceived comfort in sports shoes with plantar pressure distribution

Wei-Ting Tu, Kuangyou B. Cheng
Institute of Physical Education, Health, and Leisure Studies, National Cheng Kung University, Tainan, Taiwan
Email: rb6101049@gs.ncku.edu.tw

INTRODUCTION

The comfort filter paradigm, allowing an athlete to select comfortable running shoes using his/her own comfort filter, has been proposed[1]. While adopting this paradigm would possibly reduce the injury risk and oxygen consumption, the perceived footware comfort may be influenced by multiple factors including anthropometry, skeletal alignment, foot sensitivity, and plantar pressure patterns. Footwear design features such as fit, torsional stiffness, cushioning, support, and stability have also been suggested to influence comfort[2].

Since the magnitude and distribution diagram of plantar pressure reveal force interaction between the foot and the ground, it might be reasonable to predict perceived comfort in shoes using the information of plantar pressure. For instance, compared with the least comfortable insole, significantly higher pressure and force magnitude in the midfoot area was found when wearing the most comfortable insole[3]. On the contrary, another study concluded that the perception of comfort of a running shoe cannot be predicted through impact and plantar pressure[4].

One possible reason for these contradictory results might be that while the plantar pressure data were under specific control in most studies, the perceived comfort varied with lots of physical and psychological characteristics. For example, individuals with a high foot arch prefer soft insert material. In contrast, those with a low foot arch favour hard insert material[5]. The perceived comfort might be different for each person, which explains the varied correspondence between plantar pressure and perceived comfort.

The purpose of this study was, (i) to demonstrate that similar individual comfort ratings in Visual Analogue Scale may result from two different kinds of plantar pressure distribution, and (ii) to identify the corresponding between plantar pressure and perceived comfort.

METHODS

Three heel-toe recreational runners with the foot size of US 7-9 were recruited in this study. The participants passed intra-rater reliability assessment with respect to the VAS (ICC $\geq$ 0.7)[2]. They were tested on 10 days with one session per day, only sessions four to six were used[5]. They performed 200m of walking on a treadmill at the speeds which they felt comfortable with, which was followed by indicating their comfort rating on the Visual Analogue Scale (0–150mm; '150' indicates the highest comfort level) in four different running shoes. An in-shoe plantar pressure measuring system (Industrial Technology Research Institute, Taiwan, sampling at 30 Hz, 89 sensors) was inserted to the shoe.

RESULTS AND DISCUSSION

Subject1 rated shoeA 120mm (Comfortable) and shoeB 113mm (Comfortable) in VAS, indicating two similar rating scores with different magnitude and distribution of plantar pressure. Around 20% more (Value of sensor: 0-255) pressure in the midfoot and heel regions was found (Table1). This may provide the reason for the previous contradictory results. It was also found that while some sensors showed positive correlation with comfort rating, some others did not.

CONCLUSIONS

Positive correlation in some sensors seemed to provide supporting evidence for the studies with consistent results. However, identifying relationship between plantar pressure and perceived comfort may in general be impractical due to the difficulty in finding a certain correlation which fits everyone. Furthermore, perceived comfort may vary with individual physical and psychological characteristics. With the plantar pressure data collected for the shoes regarded as comfortable in this study, a greater number of shoes tested in future research might provide data for optimal plantar pressure prediction based on machine learning algorithms.

Rate of knee flexion at the instant of landing during running can influence initial knee joint stiffness estimates due to running shoe cushioning.

Zhenyuan Zhang and Mark Lake
School of Sport and Exercise Science, Liverpool John Moores University, Liverpool, UK
Email: M.J.Lake@ljmu.ac.uk

INTRODUCTION

The setting of lower limb joint stiffness during running reflects the impact-moderating behaviour of the human neuromuscular system that is associated with both performance and injury risk. A joint torsional spring model is typically used to quantify stiffness by examining the initial slope of the joint moment-angle relationship. However, this approach may not be sensitive enough to reflect adaptations in the dynamics of landing that are linked with impact attenuation between different running shoe conditions [1]. An alternative joint stiffness calculation places more emphasis on the initial kinematic conditions of ground contact (kinematic-only method) [2], as the stiffness setting during early stance could elucidate the mechanics of impact attenuation which might contribute to reduced injury risk [3]. Therefore, this study aims to compare knee joint stiffness during the early impact phase of running with thin- and thick-cushioned shoes using the traditional moment-angle and the kinematic-only methods.

METHODS

Twelve experienced runners ran at 4.5 m/s on a runway with a force plate surrounded by an 8-camera motion capture system in the middle to record ground reaction force and marker trajectory data, respectively. They wore two pairs of running shoes constructed with either a thin (30mm) or thick (54mm) midsole. For the traditional calculation, knee joint stiffness at the early impact phase was represented as the slope of a regression line fitted to the knee joint moment-angle curve from initial contact (IC) to peak knee flexion velocity. The kinematic-only method for knee joint stiffness calculation (as detailed in Verheul et al. [2]) was determined over the same time period. A 2 x 2 repeated-measures ANOVA was performed to assess the influence of calculation methods on initial knee joint stiffness between shoe conditions.

RESULTS AND DISCUSSION

There was a significant interaction between calculation methods and shoe conditions ($F_{1,11}$=86.4, p=0.001). Figure 1 shows no significant difference in knee joint stiffness between the two shoe conditions using the traditional calculation method (p=0.774) which is in accordance with the literature [4]. When using the kinematic-only method, the thick shoe resulted in ~34% increase (p=0.001) in initial knee joint stiffness compared to that of the thinner midsole condition. The kinematic-only approach can be more influenced by the initial dynamics of landing, particularly the rate of knee flexion at the instant of ground contact. At this instant the knee was similarly flexed for the two shoe conditions, but the rate of knee flexion was significantly higher for the thinner midsole shoes (Table 1). This likely contributes to the lower initial knee stiffness during the impact phase for that shoe and can be partly explained by the notion of maintaining system stiffness. Adapting to more cushioning provided by a thick midsole, the body may increase initial knee joint stiffness to maintain the shod lower limb combined system stiffness. If the knee joint does not become stiffer with more cushioned shoes, the whole system will be less stiff and potentially detrimental to running economy [5].

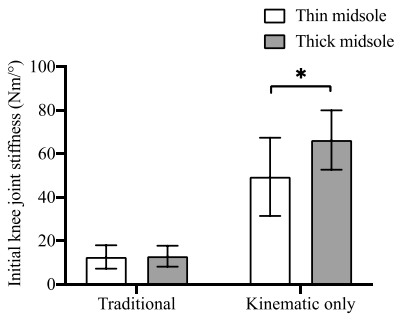

Figure 1 Initial knee joint stiffness in the two shoe conditions using the two calculation methods. * Significant at p<0.001.

Table 1 Knee flexion angle and angular velocity at initial contact (IC) during running in the two shoe conditions, * significant at p<0.001.

	Thin	Thick
Knee flexion angle at IC (°)	17.8 ± 5.9	18.6 ± 5.4
Knee flexion velocity at IC (°/s)	**241.1 ± 77.4***	201.4 ± 81.7

CONCLUSIONS

The moment-angle relationship for determining initial knee joint stiffness might be less sensitive to elicit the effect of different cushioned running shoes compared to kinematic-derived stiffness estimates that emphasise the initial dynamic conditions of foot strike during running.

INTRODUCTION

The Nike Vaporfly 4% (VP4) running shoe is often referred to as a game changer in improving running economy and performance. The substantial 4% energy savings observed have been attributed to a compliant and resilient midsole foam, curved carbon-fibre plate, and the shoe geometry [1]. Studies have tried to explain the observed results by comparing running mechanics in the VP4 shoe to previously established running shoes. One variable that is unexplored thus far, is the muscle activity while running in the VP4 shoes, even though muscle contractions are known to affect whole-body aerobic energy expenditure during locomotion [2]. Furthermore, almost all studies to date have compared the VP4 shoe to other running shoes (e.g., adidas Boost), which are substantially different in their construction This makes it challenging to explain the source of the observed improvements. Therefore, the purpose of this study was to investigate the effects of the VP4 shoe features on lower-limb muscle activity during running for three systematically changed construction features, the carbon fiber plate, the midsole material and the toe spring.

METHODS

Twelve healthy adult males participated in this study. All participants performed overground running at a constant speed of 3.9 m/s in four shoe conditions. The three test conditions were a prototype version of the VP4 shoe. These included “No Plate”, in which the carbon fibre plate had been removed from the midsole, “EVA”, in which the Nike PEBAX foam was replaced with a low-density EVA, and “Toe Wedge”, in which the toe spring was blocked by a foam wedge. The control condition was the original VP4. Muscle activity data were collected using a surface electromyography (EMG) system from four lower-leg muscles (tibialis anterior (TA), gastrocnemius medialis (GM), peroneus longus (PL), and the soleus (SOL)) at a sampling frequency of 2000 Hz. The overall EMG intensity was determined for each muscle in the four shoe conditions for each subject. Finally, the percent change in the overall EMG intensity was summarized (Fig. 1) to present the number of subjects that showed a higher versus lower intensity while running in the test shoes compared to the control shoe. A subject was considered to have a higher or lower intensity in the test shoe if they showed a change in intensity greater than ±5%.

RESULTS AND DISCUSSION

All three features (carbon plate, midsole material, and toe spring) tested in this study affected EMG intensity during running. Changes in EMG intensity were subject-specific, such that some subjects showed higher intensity, while some showed lower intensity in the test shoes compared to the control. Overall, subjects showed a relatively larger change of up to 100% when increasing the intensity, compared to a smaller change of up to 25% when decreasing the EMG intensity.

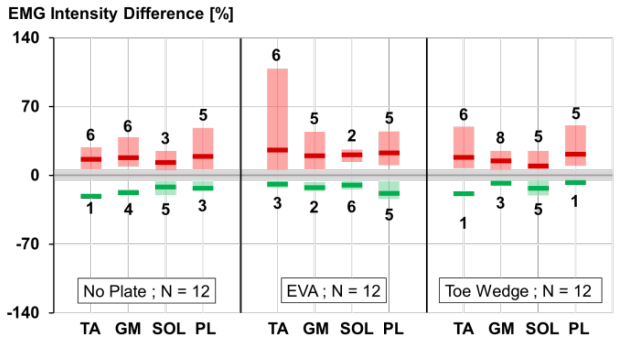

Figure 1. Changes in EMG intensity in the three test shoes (No Plate, EVA, and Toe Wedge) relative to the original Nike Vaporfly 4% (control) shoe in the four muscles (TA: Tibialis Anterior, GM: Gastrocnemius Medialis, SOL: Soleus, PL: Peroneus Longus). Positive values represent a higher EMG intensity, while negative values represented a lower EMG intensity in the test shoe compared to the control. The red and green shaded bars represent the percent change range observed in each test condition and each muscle, with the average presented by a solid red/green line within the shaded area. The numbers above and below the bars represent the number of subjects that showed an increase or decrease in the EMG intensity in the respective test shoes and muscles.

CONCLUSIONS

The Nike Vaporfly 4% shoe features such as the curved carbon fibre plate, PEBAX foam, and the forefoot geometry affect muscle activity during running. Differences in muscle activity adaptations in runners may help explain the large inter-runner variability in performance benefits achieved with advanced running shoes like the Nike Vaporfly 4%.

INTRODUCTION

Minimalist shoes (MIN) have been known to induce barefoot running and enable runners to take more mechanical advantage than conventional cushioned running shoes (CON) [1] . Recently, racing shoes that boost the performance of long-distance runners with thick curved outsole and carbon-fiber plates (e.g. Alphafly; AF, Nike) have been additionally developed [2]. Multiple studies addressed the effects of MIN and CON on the running style [1], but they analyzed only the resultant pattern without considering the runner's original habitual pattern. Recent studies also compared the effects of AF and conventional shoes on running economy (RE) [2, 3], but there is still a lack of comprehensive understanding of the effect of shoe type on running pattern and RE. This study aims to investigate the hitherto unknown interaction between the habitual foot strike angle (FSA) and shoe conditions, and their effects on RE.

METHODS

Nine male recreational runners (Mean ± SD: age 29.0 ± 3.8 years; height 1.75 ± 0.04 m; body mass 73.7 ± 4.8 k) visited the laboratory on two separate days at least 48 hours apart and within a 2 week period. On the first visit, the participants performed an incremental test so that we could select the intensity of running on the next visit and measure their preferred FSA. Participants were divided into three groups based on their FSA: forefoot, midfoot and rearfoot strike runners. On the second visit, we provided the participants with 3 pairs of shoes: MIN (Asics SORTIEMAGIC RP5, average shoe mass: 160 g, offset: 0 mm), CON (Adidas UltraBoost 20, average shoe mass: 310 g, offset: 10 mm) and AF (Nike Air zoom α-fly next%, average shoe mass: 210 g, offset: 4 mm). The participants completed 3 sets of 7 min running (1 min at 70%, 1 min at 80%, and 5 min at 90% of maximal velocity) on a treadmill wearing one of the 3 different footwear during each set. The order of shoe conditions was randomized. We measured FSA and $\dot{V}O_2$ values at velocities below the ventilation threshold. We then performed multiple factor (3 shoe conditions × 3 habitual FSA groups) repeated measures ANOVA to identify their effects on FSA and RE.

RESULTS AND DISCUSSION

Depending on habitual FSA measured on the first visit, 3, 5, and 1 participants were categorized as rearfoot, midfoot, and forefoot group, respectively. The two- way ANOVA shows significant main effects of the group and significant interaction (group × shoe condition) on FSA. Additionally, we observed significant main effects of the group and shoe condition on RE. Compared with CON, AF and MIN improved RE by 4.96% and 3.08%, respectively with statistical significance. Post-hoc multiple comparisons additionally show that 1) FSA significantly decreased under AF and MIN conditions compared to CON condition for rearfoot group; 2) RE was significantly improved in midfoot and forefoot groups compared to rearfoot group; and 3) RE was significantly improved under AF condition compared to CON in midfoot and rearfoot groups (Figure 1). These findings demonstrate that AF with thick outsole saves metabolic cost by returning the energy effectively, but this merit is more noticeable in runners with habitual patterns of rearfoot and midfoot strike.

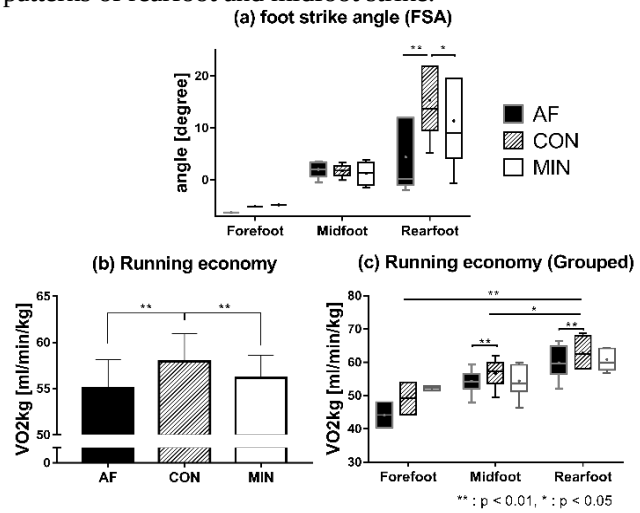

Figure 1. The outcome values for each group (forefoot, midfoot or rearfoot) and shoe condition (AF, CON or MIN). Dots and lines in the box indicate mean and median values, respectively.

CONCLUSIONS

Studies analysing the effect of footwear or other interventions should consider the habitual pattern of the runners as well as the designed intervention.

USING GAZE-TRACKING TO ASSESS COGNITIVE LOAD IN LOWER LIMB PROSTHETIC USERS

Sabina Manz[1,2], Michael Ernst[1], Thomas Schmalz[1], Strahinja Dosen[2] and Jose Gonzalez-Vargas[1]

INTRODUCTION

Clinical assessments of lower limb prosthetic users primarily focus on performance and psychological outcome measures [1]. The assessment of cognitive load, however, is often neglected.

It is known that lower limb prosthetic users have to deal with an increase in cognitive load (e.g., by focusing on the device during walking) [2,3], and research has shown that their gaze behavior, which indicates the focus of attention [4], indeed differs from the able-bodied population [5].

Therefore, gaze tracking might be an instrument to measure cognitive load while using a lower limb prosthesis, but this has not been investigated before. The aim of the present study was to test the feasibility of using gaze tracking for the assessment of cognitive load in lower limb prosthesis users.

METHODS

Two participants (P01 and P02) with unilateral transfemoral amputation (mobility level K3) participated in this pilot study. During the study, the participants wore a microprocessor-controlled prosthetic knee joint (GeniumX3, Ottobock). The participants were asked to perform a battery of tasks, including level walking (LW), walking on uneven ground (UW), obstacle avoidance (OB), a combination of stair ascent and ramp descent (SURD), as well as ramp ascent and stair descent (RUSD), in addition to a task outside of the laboratory (staircase climbing, SCUp/SCDown). For each task, the participants were asked to focus their visual attention on a target at the end of the walkway, unless they felt the need to look somewhere else (i.e., down on the pathway).

A mobile eye tracker (Tobii Pro Glasses 3) measured gaze location (i.e., focus of attention) during all tasks, and target fixation time expressed in % relative to total trial time was calculated. In addition, the participants were asked to rate the perceived cognitive demand of each task on an interval scale from 1 (very, very low) to 9 (very, very high).

Kinematic data were recorded from all laboratory-based tasks using an optical motion capture system.

Spearman's rank correlation coefficients were determined to describe the relationship between gaze data and perceived cognitive load.

RESULTS AND DISCUSSION

Figure 1 shows a significant negative correlation between target fixation time and subjective rating of cognitive load for P01 ($r = -0.91$, $p < 0.01$). Contrarily, P02 perceived all tasks as very easy (rated as 1) and the target fixation times did not decrease substantially (no correlation coefficients could be determined).

The results of P01 highlight the potential of a mobile eye tracker to measure cognitive load representative of perception.

Furthermore, the target fixation time was able to show that the tasks were not difficult enough for P02 to have an effect on cognitive load, leading to inconclusive results in this case (Figure 1).

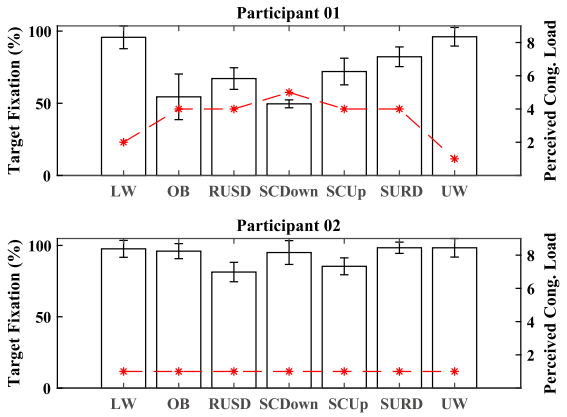

Figure 1 Target fixation times (in %, mean ± standard deviation) and perception of cognitive load (red dashed lines and asterisks) of all tasks for P01 and P02.

CONCLUSIONS

This pilot study has shown that using a mobile eye tracker could be an easy, objective measure for assessing the cognitive load of lower limb prosthetic users. Importantly, the approach of measuring cognitive load with a mobile eye tracker could be used outside of a laboratory environment, in the everyday lives of the users.

Future analyses of the kinematic data including more participants will be conducted to investigate if and how an increase in cognitive load affects performance.

INTRODUCTION

Individuals with transhumeral (TH) limb loss have the highest rate of prosthesis abandonment, up to 60%, often citing limited motion as the cause [1,2]. The conventional TH socket restricts movement, but there is a lack of literature regarding how TH prostheses impact kinematics during activities of daily living (ADLs). The present study aims to investigate the impact conventional socket-suspension systems have on a simple proprioceptive targeting motion in a cohort of individuals with TH amputation, specifically understanding how the use of a prosthesis affects body movement and positioning while reaching.

METHODS

Eight male subjects with TH limb loss and socket-suspended prostheses participated in the study (median age: 58 years (range 29-77). Four subjects used a body-powered hook, one a myoelectric hook, and three a myoelectric hand. The subjects had used their devices for a median of 5 years (range 2-12). Subjects completed a proprioceptive targeting task with their intact and prosthetic limb [3] under a 24-camera VICON Motion Analysis motion capture system (Vicon Motion Systems Ltd., Oxford, UK) at the Veterans Affairs Salt Lake City Gait Lab. A modified Plug-In Gait marker set was used to track the trunk, head, arms, forearms, and hands. The marker trajectory data were filtered in Visual3D (v6, C-Motion; Germantown, MD) with a fourth-order, low-pass Butterworth filter with a cut-off frequency of 6 Hz. Horizontal and vertical areas between the path of the targeting hand and the direct line between the start and end points of each trial were calculated. Motion smoothness was calculated from the number of velocity peaks, where an inverse relationship exists between motion smoothness and the number of velocity peaks [4]. Glenohumeral (GH) and trunk angular displacement were defined as the difference in joint angles at the start and end of each trial. Paired-Sample Wilcoxon Signed Ranks tests were used to compare the targeting conditions – intact versus prosthetic limb. Results are reported as mean (95% CI), $p \leq 0.05$ was significant.

RESULTS AND DISCUSSION

No significant difference was measurable in horizontal area when targeting with the intact limb v. the prosthesis, 14.56 cm^2 (0.60-28.52) vs. 15.32 cm^2 (7.99-22.64), respectively. No significant difference was measurable in vertical area when targeting with the intact limb v. the prosthetic limb, 25.37 cm^2 (3.27-47.47) vs. 63.83 cm^2 (0-127.69), respectively. The reaching motion was significantly more smooth when targeting with the intact limb compared to the prosthetic limb, 3.13 velocity peaks (1.78-4.47) vs. 2.25 velocity peaks (1.48-3.01), respectively, $p = 0.04$. This finding is consistent with the way distal joints are used for corrective movements in proprioceptive positioning, joints which are not actively repositioned when targeting with the prosthesis. GH flexion was significantly greater when subjects targeted with their intact limb than when they targeted with their prosthesis. In the three axes of trunk angular motion – flexion, lateral flexion, and rotation – there was significantly less angular displacement when targeting with the intact limb than the prosthesis (Table 1).

Table 1. Joint angular displacement during targeting. *p≤0.05

	Intact Limb	Prosthetic Limb
GH Flexion, mean (95% CI)	21°(16-26)	9°(2-15)*
Trunk Flexion, mean (95% CI)	1°(0-2)	12°(6-17)*
Trunk Lateral Flexion, mean (95% CI)	1°(0-2)	5°(3-6)*
Trunk Rotation, mean (95% CI)	3°(1-4)	9°(4-14)*

Our results identified significant impacts on kinematics when reaching with the prosthesis, as quantified by the differences in motion smoothness and joint angular displacements. These differences may effect how individuals use their prostheses: compensatory motions may impact neck and back pain and differences in smoothness could result in less reliable fine movements. Future studies will investigate the impact of TH prosthetics on body positioning and movement during a broader range of ADLs and other complex tasks.

CONCLUSIONS

This study aimed to quantify differences in kinematics between the intact limb and prosthetic limb in individuals using socket-suspended TH prostheses. Significant differences during a simple reaching task were identified. Understanding these impacts will enable future studies comparing socket-suspended systems to osseointegrated endoprosthetic systems for functional changes related to the suspension method.

INTRODUCTION

Cross-slope walking is recognized as a daily encountered task and a greater biomechanical challenge than level walking in transfemoral prosthesis users (TFPUs) [1,2]. When walking on an inclined surface, the component of gravity along the slope always acts to pull the individual toward the bottom of the slope. To achieve the stable straight-line walking on the cross-slope, the individual is required to generate an equal amount of upward mediolateral ground reaction force (GRF) impulse to counteract this downward gravitational impulse. In particular, unilateral TFPUs have two different conditions; the prosthetic limb is either on the lower side or on the upper side. Thus, compared to able-bodied controls, they would have more difficulty in achieving the similar amount of mediolateral GRF impulse as gravitational impulse for both conditions. Therefore, the aim of this study was to compare the mediolateral GRF impulse and the gravitational impulse during cross-slope walking in unilateral TFPUs and able-bodied controls.

METHODS

Twelve unilateral TFPUs and fourteen able-bodied controls were asked to perform straight-line walking on a 6° (10%) inclined cross-slope surface at their self-selected walking speed. We recorded the GRF using two force platforms integrated in the cross slope for both limbs. At least four successful trials were selected for both the lower and upper prosthetic conditions. The upward mediolateral GRF impulse was calculated as the sum of the upward GRF impulses of the lower and upper side limbs. Further, the downward gravitational impulse during the gait cycle was calculated as the product of body weight, $\sin 6°$, and gait cycle time. All variables were normalized to the body weight of each participant. Finally, paired *t*-tests were performed to check the statistical differences in the upward ML GRF impulse and downward gravitational impulse for all conditions. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Fig.1A&B shows the averaged mediolateral GRF for unilateral TFPUs and able-bodied controls during the stance phase of cross-slope walking. For the unilateral TFPUs, the upward mediolateral GRF impulse was significantly greater than that of the downward gravitational impulse for both the lower ($p < 0.001$) and the upper ($p < 0.001$) prosthetic conditions (Fig. 1C).

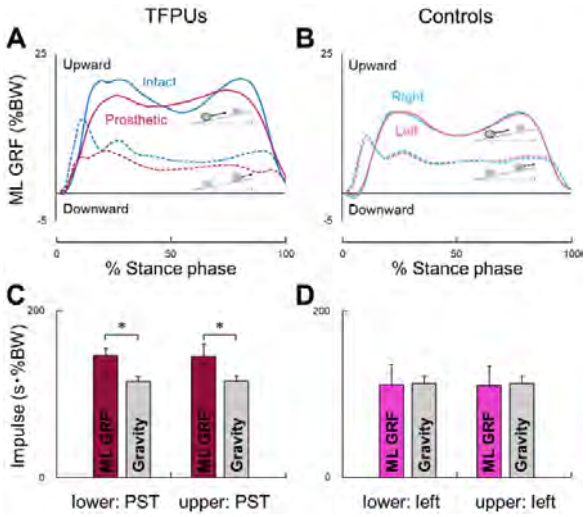

Figure 1 A, B) Averaged waveform of mediolateral (ML) GRF for TFPUs and able-bodied controls during the stance time of cross-slope walking. Positive GRF indicates the upward direction (from bottom to top side) along the cross-slope. Bold and dashed lines indicate lower and upper side conditions, respectively. **C, D)** Comparison between upward ML GRF impulse and downward gravitational impulse for TFPUs and able-bodied controls in both conditions: the prosthetic limb is on the lower side (lower: PST) and on the upper side (upper: PST). An asterisk (*) indicates a significant difference between ML GRF impulse and gravitational impulse.

However, no significant differences were observed between the two impulses for the able-bodied controls in either the lower and top left condition (Fig. 1D). These results suggest that the unilateral TFPUs in both conditions move upward rather than in a completely straight direction. This extra upward impulse could provide a margin of safety if the TFPUs encounter a disturbance that pushes them downward and causes them to fall.

CONCLUSIONS

TFPUs showed larger upward mediolateral GRF impulses than downward gravitational impulses during cross-slope walking, whereas able-bodied controls showed no significant differences between the two impulses. These results suggest that unilateral TFPUs have the specific mediolateral GRF control strategies compared to the able-bodied controls.

Unilateral transfemoral amputees might be at risk of lateral compartment degeneration of the knee joint

Diana Toderita[1], Clement D. Favier[1], David P. Henson[1], Vasiliki Vardakastani[1], and Anthony M.J. Bull[1]
[1] Department of Bioengineering / Imperial College, London, United Kingdom.
Email: diana.toderita15@imperial.ac.uk

INTRODUCTION

High-functioning unilateral transfemoral amputees (UTF) are susceptible to intact knee osteoarthritis (OA) [1], which is a mechanically-mediated condition. Unilateral transtibial amputees (UTT) are known to show medial intact knee compartment overload, which might explain the risk of OA for UTT [2], but little is known for UTF. This study aims to understand the mechanical indicators of the development and progression of knee OA in the UTF population.

METHODS

Gait motion capture and force plate data were collected from seven UTF with no known secondary conditions. All participants were fitted with microprocessor-controlled prosthetic knees and dynamic response feet and have been prosthesis users for a minimum of two years. Seven able-bodied people (AB) were group matched to the UTF cohort by sex, age, height, and mass. The control dataset is a subgroup of a previous dataset [3]. Musculoskeletal modelling was performed using Freebody to compute joint contact forces [4].

RESULTS AND DISCUSSION

Figure 1 and Table 1 present the knee loading characteristics for UTF and AB. Whilst the UTF lateral compartment of the knee presented higher loading rates, peaks, and impulse (area under the force curve) than AB, there were no significant differences in the medial knee loading between UTF and AB. These findings show that the higher knee loading for UTF is localized to the lateral compartment. As high and repetitive loading might lead to joint degeneration [5], the higher knee loading rate, lateral knee contact forces and impulse observed in this study indicate that UTF might be more susceptible to lateral knee OA as opposed to medial knee OA, as is the case for UTT [2].

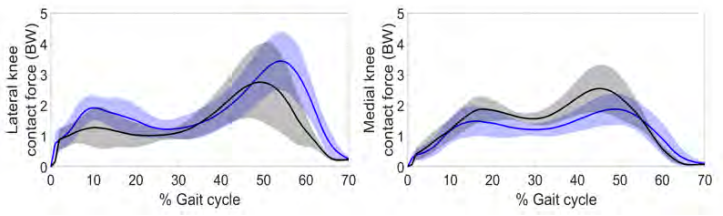

Figure 1. Lateral and medial intact knee joint contact forces. UTF – blue. AB - black.

CONCLUSIONS

Unexpectedly, this study's results indicate that the higher functional demand of the intact limb compared to AB may increase the risk of lateral knee OA in the UTF population, as opposed to UTT who might be more susceptible to medial knee OA [2]. Mitigation strategies could be explored through prosthesis adjustments, including alignment to shift the ground reaction force vector, or muscle strengthening to ensure optimal long-term musculoskeletal health.

A non inferiority approach to investigate the influence of stem fixation and stem type on revision rates in elective THA procedures depending on patient age

Michael Morlock[1], Oliver Melsheimer[2]

[1] Institute of Biomechanics, Hamburg University of Technology (TUHH), Hamburg, Germany.
[2] German Arthroplasty Registry (EPRD Deutsches Endoprothesenregister gGmbH), Berlin, Germany.
Email: morlock@tuhh.de

INTRODUCTION

The overall early revision rate in elective Total Hip Arthroplasty (THA) three years after surgery is lower for cemented stems in the German Arthroplasty Register (EPRD): cemented 2.9% (2.8 - 3.0) vs. uncemented 3.4% (3.3 - 3.5). In elderly patients, however, the mortality rate is elevated for cemented fixation [1]. Consequently the outcome of uncemented stem fixation with increasing patient age has to be analysed in more detail to understand, how stem type and fixation affect the revision rate with increasing patient age.

METHODS

Elective primary THA cases for primary Coxarthrosis using uncemented cups without reconstruction shells were selected from the EPRD data base (n_0= 294,442). Five stem types were defined: cementless, cementless with collar, cementless short, cemented, and cemented with collar. Stems with at least 300 cases at risk three years after surgery were analysed individually. Revision rates of stem types were analysed in 4 age cohorts: below 60 years (“young”), between 60-70 (“mid-1”), between 70-80 (“mid-2”) and above 80 (“old”). The reference stem [2] for each cohort was determined as the stem with the lowest revision rate and at least 1000 cases under surveillance 3 years after surgery (n_3 = 151,035).

RESULTS AND DISCUSSION

No significant differences in revision rates between stem types and fixation were found for the “young” cohort (not shown). In the “mid-1” cohort, the revision rate for “cementless” stems was higher than for “cementless short” (p<0.001) and “cementless collared” stems (p< 0.001) (Table 1). In the “mid-2” cohort, “cementless stems” showed a higher revision rate as all other stem types (p<0.001; Table 1). “Cemented” and “uncemented collared” stems performed best in the “old” group with uncemented stems being inferior by 20% (Figure 1).

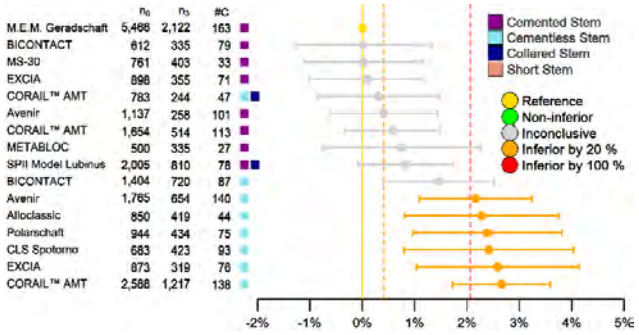

Figure 1: Non-inferiority plot for the investigated hip stems (type, fixation, design) in the “old” patient group.

CONCLUSIONS

“Cementless” and “cementless short” stems should not be used in patients older 80 years due to the higher risk of revision due to peri-prosthetic fracture [3]. The use of “cementless” stems in 70-80-year-old patients should be considered very carefully due to the increased revision risk shown in the EPRD. If cementing should be avoided, “cementless collared” stems seem to be a good alternative.

CENTER OF MASS KINEMATICS ROBUSTLY PREDICT REACTIVE JOINT TORQUES AT THE ANKLE, KNEE, AND HIP DURING PERTURBED STANDING

Kristen Jakubowski[1*], Giovanni Martino[1], Gregory Sawicki[2], Lena Ting[1]

[1] Wallace H. Coulter Department of Biomedical Engineering, Emory University & Georgia Institute of Technology, Atlanta, USA [2] George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, USA *Email: kjakubo@emory.edu

INTRODUCTION

Mimicking the healthy physiological response to postural perturbations may aid in developing robotic devices that augment human balance. Additionally, a *global* control scheme, where one control signal can be used for multiple joints, greatly simplifies the control of robotic devices compared to relying on an independent signal for each individual joint. Interestingly, the reactive muscle activity elicited in multiple leg muscles in response to postural perturbations is driven by *global* feedback of center of mass (CoM) kinematics [1]. Inspired by this physiological principle, Afschrift et al. [2] recently demonstrated that *global* feedback also drives the reactive torque at the ankle during standing and walking. However, it remains to be seen if this *global* feedback principle underlies the multi-joint torque response. Accordingly, we tested the feasibility of using *global* feedback of CoM kinematics to predict the reactive multi-joint torque response at the ankle, knee, and hip to perturbations during standing.

METHODS

We assessed reactive leg joint torques to backward support surface perturbations in 7 healthy young adults (25 ± 4 years). Participants maintained standing balance during randomized ramp and hold perturbations at 12 cm or 75%, 85%, and 95% of their step threshold, each tested four times. Whole-body kinetics and kinematics were used to estimate ankle, knee, and hip torques using the OpenSim Inverse Dynamics (ID) tool [3].

We used a modified version of the previously developed sensorimotor response model (SRM) [1] to estimate the reactive joint torques as a time-delayed linear combination of CoM kinematics. The previous SRM could only fit non-negative signals, such as electromyography (EMG). Thus, we modified it to predict negative signals, like joint torques (Fig 1A). Additionally, the previous SRM captured the direction-specific muscle-level responses (e.g., agonist muscles activated in response to CoM acceleration while antagonist muscles responded to CoM deceleration). Since we are examining the joint-level response, which is the net effect of the activation of individual muscles, we modified the model to predict the joint torque response to both CoM acceleration and deceleration. The goodness of fit between the ID and CoM estimated ankle, knee, and hip torques were assessed using R^2 (similarity in shape), and variability accounted for (VAF; similarity in magnitude). One-tailed t-tests were performed evaluating $R^2 \geq 0.75$ and VAF $\geq$ 75%.

RESULTS

For all joints and all perturbation magnitudes, the SRM reconstructed the ID torques well. The ID joint torques (Fig 1A, black) were similar in shape and magnitude to the CoM-derived joint torque (Fig 1A, green & yellow). Hip torque increased immediately following the perturbation, while ankle torque was delayed, which may be due to differences in tendon compliance between hip and ankle musculature that impact how muscle short-range stiffness is transferred to the joint. Across all participants, ankle (yellow), knee (blue), and hip (green) torque were reconstructed well for all perturbation magnitudes (all $p > 0.05$; Figure 1 B & C).

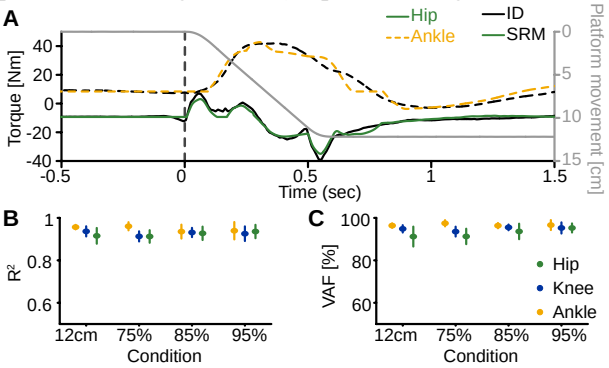

Figure 1 (A) Representative ID (black) and SRM-based reactive hip (solid, green) and ankle (dotted, yellow) torque to a 12 cm perturbation. The dotted grey line indicates the start of the perturbation, while the solid grey line is the movement of the platform. Positive torque indicates plantarflexion and hip flexion. (B & C) The R^2 and VAF across all participants during each perturbation condition (12 cm to 75%, 85%, and 95% of step threshold) for the ankle (yellow), knee (blue), and hip (green).

DISCUSSION & CONCLUSION

We found that a single control signal (CoM kinematics) can accurately predict the multi-joint torque response to standing perturbations of varying magnitude. These results provide important insights into the joint-level neuromechanical control of balance. Additionally, a physiologically-inspired *global* control scheme, with a one-to-many rather than one-to-one mapping, may simplify the control of lower-limb exoskeletons, prostheses, and bipedal robots.

INTRODUCTION

Wheelchairs are crucial mobility devices for people with impairments in the trunk and lower limbs. However, when using a wheelchair, users are forced to maintain a prolonged sitting position. As a result, eye height differences, accessibility issues and complications related to sitting occur. We are developing Qolo, a mobility device that enables people with lower limb impairments to stand on their own and move in a standing position. When users bend their trunk forward, knee extension and standing motions are assisted by its gas springs (Fig 1). This device does not require any electricity during the sit-to-stand and stand-to-sit transitions [1]. Even people with lower limb disabilities can stand up in a few seconds, just as quickly as healthy people can. A powered wheelchair unit is attached to the device, enabling Qolo to move around. We performed a feasibility study of Qolo in people with spinal cord injuries (SCIs).

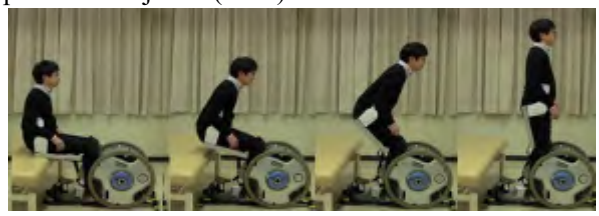

Fig.1

METHODS

In the first prototype, the participants were four SCI patients whose neurological levels of injury (NLI) ranged from T10 to L3, and the American Spinal Injury Association (ASIA) Impairment Scale (AIS) ranged from A to C. While the two individuals (L3C and T10C), whose Manual Muscle Test (MMT) for hip flexor was over one and knee extensor was over three, were able to perform both sit-to-stand and stand-to-sit transitions, the remaining two individuals (T10A and T11A) could only conduct stand-to-sit transitions. Thus, we modified Qolo to increase the spring tension. In the second prototype, we did experiments with 13 participants (ranging from C5 to L3, AIS A-C, Table 1).

RESULTS AND DISCUSSION

All 13 subjects were able to perform sit-to-stand and stand-to-sit transitions (Table 1). In addition, even a T4 SCI patient was able to conduct both movements using a hard trunk orthosis. As SCI patients higher than T6 level have a higher risk of autonomic disorders such as orthostatic hypotension and autonomic hyperreflexia, we think that the practical application of Qolo would be for SCI patients lower than T6 level. The advantages of being in a standing position are as follows: reduction of hip and knee joint contractures, prevention of pressure ulcers, alleviation of spasticity, as well as activation of the cardiovascular and digestive systems [2].

Moreover, using Qolo, people with SCIs may recreate their daily activities in a standing position; to enhance their quality of life (QOL).

Table 1

ID	Gender	Neurological Level	MMT Hip Ext.	MMT Knee Ext.	Qolo Stand-up	Qolo Sit-down
1	M	L3 C	1	3	✓	✓
2	M	T10 C	2/1	5/2	✓	✓
3	M	T12 A (acute)	0	0	✓	✓
4	F	T12 A	0	0	✓	✓
5	M	T11 A	0	1	✓	✓
6	F	T10 A	0	1	✓	✓
7	M	T9 A	0	0	✓	✓
8	M	T7 A	0	0	✓	✓
9	F	T6 A	0	0	✓	✓
10	M	T6 A	0	0	✓	✓
11	F	T4 A	0	0	✓	✓
12	M	C5 C	2/1	4/2	✓	✓
13	M	C6 C	1/2	2/4	✓	✓

CONCLUSIONS

Personal standing mobility Qolo enables people with lower limb impairments due to spinal cord injuries to stand up by themselves. Using Qolo has the potential to improve their trunk function and boost their QOL.

Effect of an Assistive Robotic System's Compliance on Subject's Muscular Activation and Comfort

Maximilian Siebert[1], Anna Wankum[1], and Catherine Disselhorst-Klug[1]

INTRODUCTION

In robotics, compliance refers to the amount a subject can move the end effector of a robot. Previous work showed a significant change in patients' muscular activation with different levels of robotic compliance during rehabilitation tasks, in which the patient actively supports the movement. In this application, a level of compliance similar to human therapist is suggested. [1]
To relieve the physical stress of caregivers during physical demanding tasks, assistive robotic systems are developed, which lift and hold patient's legs. In contrast to rehabilitation, patients do not perform active movements during these caregiving tasks. Even if there is no need to activate the muscles during such tasks, the degree of robotic compliance might affect the muscular activation, which, in turn, can influence the patient's comfort.
The objective of this work is to examine an appropriate level of compliance for assistive robotic systems in caregiving to ensure patients' comfort.

METHODS

In this study, a lightweight robotic arm (KUKA lbr med) held 30 healthy subject's (15 female, 15 male) legs for 60 seconds while a caregiver applied a decubitus bandage to the subject's foot. The task was performed in four different modes: 1) with low compliance of the robot (LC), 2) with medium compliance (MC), 3) with high compliance (HC), 4) with a second caregiver holding the leg without any influence of the robot (NR). The order of the different modes was randomized. After each mode subjects had a break for 60 seconds.
The amount of muscular activation of vastus lateralis, rectus femoris and gastrocnemius was recorded with surface electromyography (sEMG) according to SENIAM recommendations. The resulting sEMG envelope was calculated and the average of the envelope was used to characterize the amount of muscular activation. The average of the muscular activation was normalized to the corresponding human assisted mode (NR) of each subject.
Additionally, subjects made pair-by-pair comparisons of all four modes regarding their comfort and preference. The comparisons resulted in a score between -6 (preferred the human caregiver in all trials) and 6 (preferred the robotic assistance in all trials).

RESULTS AND DISCUSSION

The normalized muscular activation of vastus lateralis and rectus femoris did not show a significant change between the different levels of compliance. However, the sEMG was significantly lower compared to the human assisted mode (NR).
The normalized muscular activation of gastrocnemius showed a significant decrease from 1.12 (HC) to 1.05 (MC) and 0.91 (LC). However, in contrast to the knee extensors, no decrease in muscular activation compared to NR was found.
With an average score of 2.13, subjects showed a preference for the robotic assisted modes over the human assisted mode and mostly preferred LC.
Furthermore, the average muscular activation of all three muscles decreased for subjects with higher preference of robotic assistance (Fig. 1).

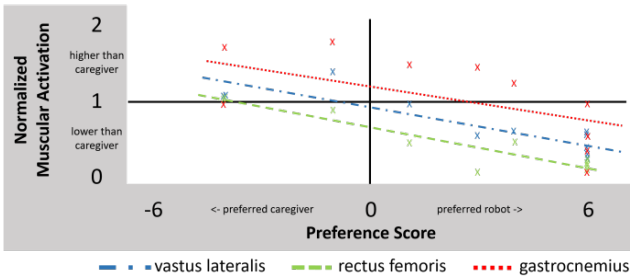

Figure 1: Comparison of robotic and human caregiver preference to muscular activation

It can be assumed, that the subjects higher preference of the LC mode led to higher trust and therefore to a general lower muscular activation compared to HC and MC modes. Additionally, the usage of an assistive robotic system seems to improve comfort in comparison to assistance of a second caregiver during the considered task.

CONCLUSIONS

These results confirm that, opposite to rehabilitation applications, a high, human-like amount of compliance of an assistive robotic system in caregiving seems not to be favorable and leads to higher muscular activation and lower acceptance of subjects than lower compliance.
While the study can prove the importance of robotic compliance on the subjects comfort and acceptance, the ideal amount depends on the use-case, in which the assistive system is used. It is highly recommended to consider compliance when designing assistive systems.

FINDING ASSISTANCE STRATEGIES BASED ON MUSCULOSKELETAL SIMULATION AND MACHINE LEARNING

Xianyu Zhang, Shihao Li, Zhenzhi Ying, and Naohiko Sugita

Email: lsh@mfg.t.u-tokyo.ac.jp

INTRODUCTION

In recent years, many lower limb exoskeletons and other wearable assistive devices have been developed to assist human walking, particularly to reduce the metabolic cost of walking. However, this goal is difficult to achieve owing to the complexity of the human body and significant individual differences. To date, there is no consensus on the assistance strategy and no clear method to obtain a personalized assistance strategy. This has hindered the development and application of exoskeleton technology. In this study, we proposed an approach that combines musculoskeletal simulation (MS) with machine learning to obtain personalized effective and feasible assistance strategies for ankle-joint walking-assist exoskeletons (AWAEs) in real-time.

METHODS

The purpose of this study was to identify personalized assistance strategies applied to the ankle joint that could effectively and feasibly reduce the metabolic cost of walking at various speeds. To achieve this, the open-source software OpenSim was employed to conduct forward muscle-driven simulations. A publicly available gait dataset containing 22 subjects as reported by Camargo [1] was considered. Based on the approach of Uchida [2], an ideal actuator was added at the ankle joint of the musculoskeletal model. With MS, an ideal assistance (IA) strategy which could theoretically minimize the metabolic cost was obtained. To save simulation time and improve the feasibility and timeliness of the IA strategy, we modified its shape so that it provides assistance only in the plantarflexion direction and parameterized it with four features. Then a back propagation neural network was applied to predict the personalized assistance strategy in real-time by inputting physiological information that can reflect individual differences and real-time walking speed information. Finally, the prediction performance of our proposed approach was evaluated, and the performances of the IA and predicted assistance (PA) strategies in reducing metabolic costs were also evaluated through simulations.

RESULTS AND DISCUSSION

Through simulation verification, we found that our proposed method can predict personalized assistance strategies in real-time, and the obtained strategy has approximately 85% similarity in shape to the unilateral IA strategy. In terms of metabolic cost reduction, we found that the IA strategy reduced the total metabolic cost of calf muscles by 0.74 ± 0.18 w/kg (slow), 1.10 ± 0.25 w/kg (normal), and 1.37 ± 0.15 w/kg (fast) compared to the unassisted case, a relative reduction of approximately 60%. While the PA strategy effectively reduced the metabolic cost of calf muscles by 0.21 ± 0.11 w/kg (slow), 0.30 ± 0.12 w/kg (normal), and 0.50 ± 0.08 w/kg (fast), a relative reduction of approximately 20%. Although the PA strategy only achieves approximately 1/3 of the assistance effect of the IA strategy, our proposed method does not require laborious simulations and allows obtaining personalized assistance strategies for various speeds in real-time. Meanwhile, our approach yields a more feasible and practical strategy while maintaining the efficiency of reducing metabolic costs.

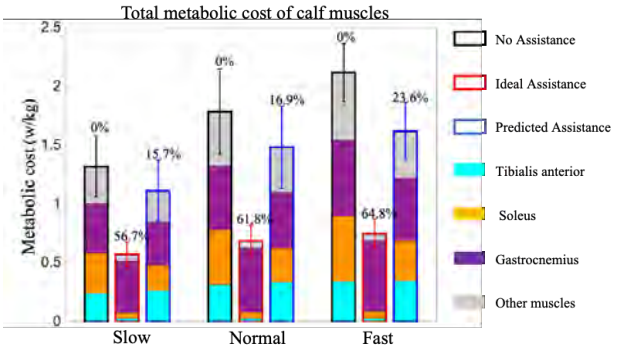

Figure 1 Metabolic costs of calf muscles with different strategies. The black, red, and blue borders indicate the three different strategies of no assistance, IA, and PA, respectively. And in each bar, different coloured areas represent the metabolic cost of different individual muscles: tibialis anterior (cyan), soleus (orange), gastrocnemius (purple), and others (gray).

CONCLUSIONS

In this study, we proposed a novel approach that combines musculoskeletal simulation with machine learning to obtain personalized effective and feasible assistance strategies for AWAEs in real-time. The obtained personalized assistance strategies are feasible and practical while maintaining efficiency in reducing metabolic costs. We expect our results to promote some consensus on assistance strategies for AWAEs. Further, we hope that this work can be used to guide the design of exoskeletons in the future.

SUMMARY

In this study, an adaptive control framework was developed for a knee exoskeleton based on an EMG-driven neuromusculoskeletal (NMS) solver-informed Bayesian neural network (BNN) with uncertainty quantification. Knee flex/extension torque with uncertainty quantification was analysed. The assistance level of the knee torque determined by the uncertainty quantification was also investigated.

INTRODUCTION

Research interest in exoskeleton assistance strategies that integrate the user's torque capacity continues to grow exponentially. However, the predicted torque capacity from the users generally includes uncertainty from different sources, which may influence the next step of exoskeleton control where safety is a vital factor in the user-interface. The objective of this study is to develop an adaptive control framework for a knee exoskeleton based on an EMG-driven NMS solver-informed BNN. We aim to provide different assistance levels based on the uncertainty quantification of the user's estimated physiological torque.

METHODS

An adaptive control framework was developed for a knee exoskeleton based on an EMG-driven NMS solver-informed BNN model. The inputs of the NMS solver-informed BNN were two kinds of features: (1) experimental measurements -- muscle signals and joint angles, and (2) informative physical features extracted from the underlying NMS solver, such as individual muscle force and joint torque. The outputs were knee joint torque with uncertainty quantification represented by confidence bounds. The predicted knee torque with uncertainty confidence levels was then used to determine the assistance level of the knee exoskeleton through a TCP/IP data stream.

The input and output data for the EMG-driven NMS solver-informed BNN model was adopted from a previous study [1]. Eight able-bodied subjects performed ten types of daily activities, including fast walking, normal walking, slow walking, jump down from a stair, jump up to a stair, jump up, land, squat, sit to stand and stand to sit. Surface EMGs (Myon nano) of gastrocnemius medialis, gastrocnemius lateralis, rectus femoris, vastus medialis, vastus lateralis, biceps femoris, semitendinosus of one leg were recorded. Marker trajectories were recorded (Vicon V16, AMTI force plates), and kinematics and kinetics were computed based on the CGM2.3 model [2].

Knee flex/extension torque with uncertainty quantification was analysed. The assistance level of the knee torque determined by the uncertainty quantification was also investigated.

RESULTS AND DISCUSSION

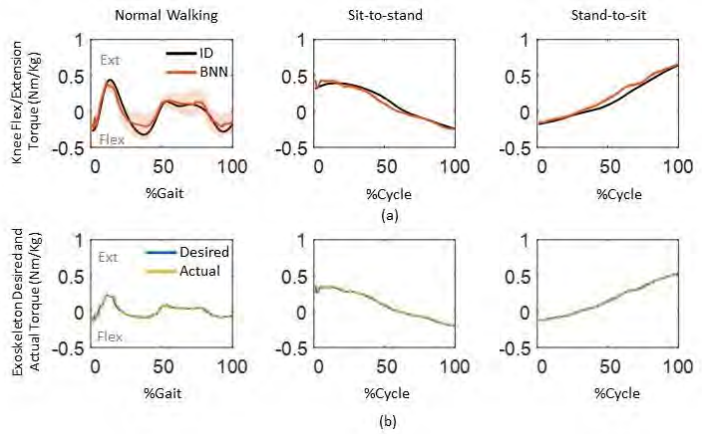

Figure 1: (a) One example of measured (by inverse dynamics (ID)) and predicted knee flex/extension torques (Nm/kg) by Bayesian neural networks (BNN, shown as mean ± std (uncertainty)) during normal walking, sit-to-stand and stand-to-sit. (b) One example of the desired and actual assistive torque from the knee exoskeleton.

BNN predicted knee torque accurately during sit-to-stand and stand-to-sit; however, slightly higher uncertainties of the predicted torque were observed around terminal stance and terminal swing (Fig. 1 (a)). This may be due to the transition between the stance and swing phases of gait. The adaptive control framework for the knee exoskeleton provided desired assistive torque with low error (Fig. 1 (b)). However, low assistive torques could be found during terminal stance and terminal swing because of the higher uncertainties.

CONCLUSIONS

The proposed BNN model was able to predict knee flex/extension torque with uncertainty quantification and transmit the prediction to the adaptive control framework to provide corresponding assistive torque. Further investigation is underway to develop an advanced assistive scheme based on the predicted torque and uncertainties using wearable sensors.

EVALUATION OF A PASSIVE UPPER-LIMB EXOSKELETON DURING A SIMULATED DYNAMIC WORK TASK OVER A LARGE SHOULDER WORKSPACE

Leon Lauret[1], Brent J. Raiteri[1,2], Paolo Tecchio[1] and Daniel Hahn [1,2]

[1] Human Movement Science, Faculty of Sport Science, Ruhr University Bochum, Bochum, Germany

INTRODUCTION

Musculoskeletal disorders (MSDs) are a leading cause of work-related injuries in the industrial field and greatly affect worker well-being. Assistive devices, so-called exoskeletons, pose a promising solution for companies to reduce potential risk factors that lead to MSDs [1]. However, most upper limb exoskeleton studies [2,3] only examined exoskeleton support in overhead arm positions, which does not represent a realistic shoulder workspace [4]. Therefore, the aims of this study were to evaluate a passive exoskeleton over a large shoulder workspace and to construct an arm position-specific support profile to help inform how exoskeleton support should be adapted for different work tasks [4].

METHODS

Surface EMG recordings (1000 Hz) of the upper trapezius, anterior and middle deltoid, and biceps and triceps brachii were recorded from four participants (all male) and their upper body kinematics were captured using an eight-camera Vicon motion capture system. Data were recorded during three exoskeleton conditions: No support (NoExo), when the passive exoskeleton (Ottobock Paexo Shoulder) was not worn; optimal support (Exo_{opt}), which supported the participant's 90° abducted arm against gravity, and; maximal support (Exo_{max}), which applied double the support of Exo_{opt}. During these conditions, participants were required to complete two tasks with their right hand using a 1.5 kg cordless drill and their sternum aligned with the left column of screws: A pattern-task (PAT) that consisted of driving each screw of a 6x6 matrix for 10 s in a predefined pattern without a break in between screws, and; a mapping-task (MAP) that consisted of driving each screw of a 3x3 matrix for 10 s with a 30 s break in between screws. Mean EMG amplitudes (moving 500 ms root-mean-square amplitude) and shoulder and elbow angles were calculated post-processing. For PAT, the first and last 10 s from Exo_{opt} and Exo_{max} were compared with NoExo to investigate (1) immediate and (2) fatigue-dependent and/or learning-dependent effects of the exoskeleton, respectively. The MAP recordings were used to construct a heatmap to visualize differences in exoskeleton muscle support for different screw locations and arm positions. Differences were calculated as symmetrized percent differences.

RESULTS AND DISCUSSION

A reduction in mean (±SD) summed activity of the upper limb muscles was observed during the first 10 s of PAT (Exo_{opt}: -6.9±3.4%; Exo_{max}: -13.8±8.4%) that persisted until the end of PAT (Exo_{opt}: -6.0±3.1%; Exo_{max}: -12.3±12.8%). The heatmaps generated from MAP (Fig. 1) indicate that the reductions in mean summed muscle activity occurred in the overhead arm positions with either an abducted shoulder or an extended elbow. Conversely, the exoskeleton appeared to have a limited effect or even interfered with working positions close to the body.

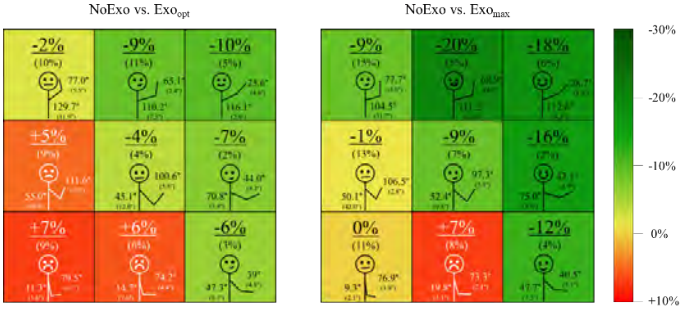

Figure 1. Heatmaps (n=4) of Exo_{opt} and Exo_{max} showing the mean (SD) shoulder abduction and elbow flexion angles and the mean (SD) differences in summed muscle activity at different screw locations with exoskeleton support.

CONCLUSIONS

The exoskeleton reduced overall upper limb muscle activity throughout the dynamic work task, with Exo_{opt} showing a more consistent effect than Exo_{max}, while Exo_{max} showed greater support. However, the mean reduction in muscle activity was not as large compared with previous studies that assessed a smaller shoulder workspace [2,3]. The heatmaps indicate that the system is only likely to be effective when working with an abducted shoulder and/or extended elbow.

LEG JOINT KINETIC DETERMINANTS OF SPRINT ACCELERATION RUNNING

Ryu Nagahara[1]
[1] National Institute of Fitness and Sports in Kanoya, Kanoya, Japan.
Email: nagahara@nifs-k.ac.jp

INTRODUCTION

Sprint acceleration ability is of great importance for many sports, particularly for 100-m races. Joint work and power are useful for understanding energy generation and absorption at joints during sprinting. Changes in joint work have been documented as the net work done at all three major leg joints linearly decreased with decreasing acceleration magnitude during sprint acceleration [1]. Although macroscopic changes in work done at each joint during sprint acceleration have been revealed, there is a lack of knowledge regarding the determinants of sprint performance in terms of waveform analysis using leg joint kinetic variables. Therefore, the purpose of this study was to demonstrate determinants of sprint performance during sprint acceleration in terms of step-to-step joint power waveform analysis.

METHODS

Sixteen male sprinters (mean ± SD: age, 20.4 ± 1.2 years; stature, 1.73 ± 0.04 m; body mass, 65.1 ± 3.7 kg; personal best 100-m time, 11.34 ± 0.41 s) participated in this study. Participants performed maximal effort 35- and 60-m sprints two or three times for each. A long (50 m) force platform system which was consisted of 54 force platforms (1000 Hz; TF-90100, TF-3055, TF-32120, Tec Gihan, Kyoto, Japan) measured GRF during sprinting from the start to the 27-m mark for the 35-m trials and from the start to 50-m mark for the 60-m trials. A motion capture system, which consisted of thirty-nine infrared cameras (250 Hz; Motion Analysis Corporation, Santa Rosa, CA, US), was used to measure three-dimensional coordinates of 47 retro-reflective markers affixed to the participant's body with a volume of approximately 30 m × 1.5 m × 2 m (length × width × height), covering the later 30-m of the force platform system. The participants started from the 23-m mark on the force platform system for 35-m trials and from the start (at the edge of the force platform system) for 60-m trials.

The thresholds to detect foot strike and toe-off were set at 20 N of vertical force. From the marker coordinate data, the endpoints of 15 segments of the whole body were determined [2]. The endpoint coordinates were smoothed with a fourth-order Butterworth low-pass digital filter with a cut-off frequency of 15 Hz. Joint moments at the hip, knee and ankle were calculated using a standard inverse dynamics analysis for both legs. Joint power was calculated by the dot product of the joint moment and angular velocity at each joint. Then, one-dimension statistical parametric mapping for correlation analysis was used to examine relationships between running speed and joint power signals during the support phase at each step.

RESULTS AND DISCUSSION

Statistical parametric mapping for correlation analysis revealed that mean running speed at each step was positively correlated with positive hip joint power at the 1st (45 to 61% of the support phase), 4th (26 to 32% of the support phase), 8th (15 to 41% of the support phase), 10th (23 to 37% of the support phase), and 12th step (25 to 30% of the support phase). Moreover, mean running speed was negatively correlated with positive hip joint power at the 4th (0 to 9% of the support phase) and 6th step (0 to 2% of the support phase). In addition, mean running speed was negatively correlated with negative hip joint power at the 15th (66 to 86% of the support phase) and 16th step (59 to 65% of the support phase). In terms of the knee joint, mean running speed was positively correlated with positive knee joint power at the 16th (66 to 78% of the support phase), 20th (61 to 72% of the support phase), and 22nd step (72 to 81% of the support phase). For the ankle joint, mean running speed was positively correlated with positive ankle joint power at the 4th (59 to 85% of the support phase), 6th (77 to 91% of the support phase), 8th (73 to 97% of the support phase), 16th (74 to 90% of the support phase), and 18th step (71 to 94% of the support phase). Moreover, mean running speed was negatively correlated with negative ankle joint power at the 4th (21 to 40% of the support phase) and 8th step (31 to 44% of the support phase).

CONCLUSIONS

The current results demonstrate that important joint kinetic variables could change during sprint acceleration. Particularly, positive power productions during the first half of the support phase were related to running speed in the early acceleration section, while negative power production (mainly produced by hip extension angular velocity and hip flexion moment) during the second half of the support phase could affect running speed during the later acceleration section. These findings can be useful for considering sprinting techniques and training programs for improving sprint performance.

INTRODUCTION

Running Prosthetic Feet (RPF) enable athletes with lower limb amputations to compete in high level track competitions [1]. However, their sprinting biomechanics is not fully understood [2]. Studying running kinematics (joint angles) and kinetics (Ground Reaction Forces-GRFs) aims to prevent injuries and enhance performance outcomes [1]. The aim of this work is to study kinematics and kinetics of an elite Paralympic sprinter in steady state running on both treadmill and track.

METHODS

A female gold medallist, unilateral transfemoral amputee Paralympic sprinter participated in this study. The athlete (55 kg, 1.60 m) used 1E91 standard RPF Cat. 3.5 and mono-axial 3S80 knee (Ottobock, Germany) with a specific alignment of the socket and the foot, equal to 15° [3]. Two sessions were performed: treadmill and indoor track (Palaindoor, Padova, Italy). During the treadmill session a SkillRun treadmill (Technogym, Italy) was placed on four P6000 force platforms (BTS, Italy; 1 kHz) and integrated with a DX-6000 motion capture system (BTS, Italy; 250 Hz). The athlete performed a steady state running test at 5 m/s for 7 s [4]. During the track session the athlete ran on a 60 m indoor athletic track and was captured by 28 infrared cameras (Vicon, UK; 300 Hz) covering the central 20 m of the track. RPF was instrumented with a 6-axis load cell mounted between the prosthetic knee and the clamp [5]. The load cell, whose pose was tracked via retro-reflective markers, was connected to a SLICE NANO compact acquisition system (DTS, USA; 2 kHz) placed in a running backpack. The athlete performed a sprint reaching an average steady state speed of 6.5 m/s. Kinematics and GRFs analyses of the Affected Limb (AL) were performed in both sessions. Cardan 'ZXY' angles of hip and knee joints and trunk were calculated, with Z being the medial-lateral axis. GRFs collected in the clamp Coordinate System (CS) were transformed into the ground CS after being low-pass filtered (4^{th} order Butterworth filter, cut-off: 15 Hz in treadmill and 52 Hz in track). Signals were segmented based on foot strike and foot off detection and averaged over 5 steps. Peak values and impulses of anterior-posterior (GRF_X) and vertical (GRF_Y) GRFs were calculated and normalized for the athlete's body weight (BW).

RESULTS AND DISCUSSION

Kinematics and GRFs analyses are reported in Figure 1. AL knee behaved similarly in both tests: fully extended during stance, while flexed during swing. AL hip ranges of motion were 60° and 89°, and average values were 30° and 49° for treadmill and track, respectively. These variations could be attributed to different test speeds (5 vs 6.5 m/s) and trunk inclination (0-10° vs 5-15°). Vertical GRF peaks were 2.61 N/BW in treadmill and 3.39 N/BW in track. Horizontal force had minima (braking) of -0.22 and -0.60 N/BW and maxima (propulsion) of 0.44 and 0.57 N/BW for treadmill and track, respectively. Net horizontal impulses were $9 \cdot 10^{-3}$ N·s/BW for treadmill (propulsion: $20 \cdot 10^{-3}$ N·s/BW, braking: $-11 \cdot 10^{-3}$ N·s/BW) and $5 \cdot 10^{-3}$ N·s/BW for track (propulsion: $26 \cdot 10^{-3}$ N·s/BW, braking: $-21 \cdot 10^{-3}$ N·s/BW). Differences could be related to athlete's speed [6] or confidence levels: further tests on an instrumented track would validate the wearable system.

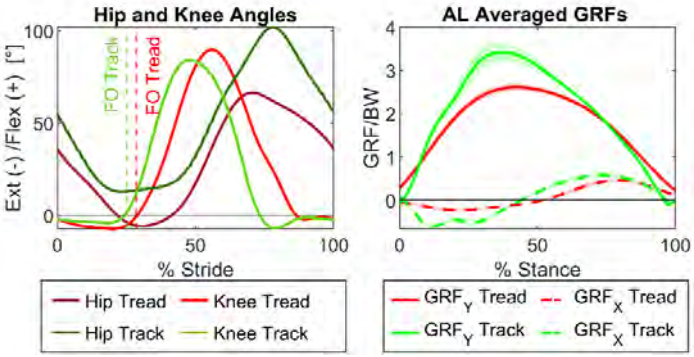

Figure 1 AL Hip and Knee joint angles in the sagittal plane (left) and AL averaged GRFs (right) for treadmill and track sessions

CONCLUSIONS

The aim of the present work was to report kinematic and kinetic data of an elite Paralympic sprinter running both on treadmill and on track. Results proved the feasibility of both test configurations and showed kinematic and kinetic differences, which open to further investigations.

INTRODUCTION

In many sports, it is imperative to have the ability to quickly change directions, which can be facilitated through greater horizontal ground reaction forces (GRF) and greater ankle plantarflexor moments [1,2]. Research has shown that greater horizontal GRF and ankle moments during rapid change of direction movements have been achieved using a laterally banked surface [1]. During a lateral movement, the banked surface elicits a re-orientation of the GRF vector, and a frontal plane re-alignment of the ankle joint. Research suggests that as the ankle moves away from a neutral orientation, into greater ankle inversion, there is a decreased ability to produce sagittal plane ankle moments, that are key to sport performance [3]. To incorporate a laterally banked surface into a sport setting, lateral wedged insoles can be placed inside footwear, to mimic the structure of the banked surface. Therefore, the purpose of this study was to determine the influence of lateral wedged insoles on athletic performance during a shuffle movement.

METHODS

Eleven female (age: 21.9 ± 2.7 years, height: 1.71 ± 0.07 m, body mass: 65.3 ± 5.5 kg) and seven male (age: 22.7 ± 2.4 years, height: 1.83 ± 0.08 m, body mass: 83.6 ± 5.9 kg) collegiate basketball players participated in the study. The participants performed five successful trials of a shuffle drill in two shoe conditions. The conditions consisted of a Control condition, and a Lateral Wedge (LW) insole condition. The 3D printed insoles had a 5-degree incline on the lateral edge and tapered past the metatarsophalangeal joint for comfort. All participants wore Nike Kyrie Flytrap 5 basketball shoes, with both the natural insole (Control condition), and with the natural insole replaced with lateral wedged insoles (LW condition). During data collection, each participant performed maximal effort basketball-style shuffle movements where each trial consisted of shuffling between two endpoints that were 5 m apart on a straight line. The participants went between the endpoints twice while kinetic and kinematic data were collected during the stance phase of two changes of direction using a motion capture system (240Hz) and force platform (2400Hz). Timed athletic performance was measured with photocells. Statistical comparisons were made between the footwear conditions using a paired t-test at a significance level of $\alpha = 0.05$. The primary variables of interest were the timed performance, peak GRF in the direction of movement (horizontal GRF), GRF vector orientation, and ankle sagittal plane moment and power.

RESULTS AND DISCUSSION

Performance and biomechanical results of interest are shown in Table 1. While no difference in overall drill performance, there was a significant decrease in the change of direction stance time with the LW condition ($p=0.03$). A significantly greater horizontal GRF was observed with the LW condition ($p=0.02$), which led to a more horizontally oriented GRF vector ($p=0.03$). There were no differences observed at the ankle between the Control and Lateral Wedge conditions.

CONCLUSIONS

The use of lateral wedged insoles resulted in greater horizontal GRFs and a re-orientated GRF vector to a more favourable position for performance. These results led to a decrease in stance time, effectively reducing the amount of time needed for the participants to change direction.

ACKNOWLEDGEMENTS

This study was funded by the Natural Sciences and Engineering Research Council and We-TRAC (University of Calgary). Footwear was provided by Nike.

EFFECT OF CLEAT AND RIDER POSITIONING ON LEG JOINT FUNCTION

Colin R. Firminger[1], Michael J. Asmussen[1]
[1]Department of Biology, Mount Royal University, Calgary, Canada.
Email: cfirming@gmail.com

INTRODUCTION

Lower-limb joint torques and powers have been widely studied during cycling [1,2], yet the mechanical function of these joints remains unknown. Previous research has offered insight into how lower-limb joints function during walking and running by characterizing their behaviour relative to four basic mechanical components (i.e., strut, spring, motor, damper) [3]. Insight into the mechanical function of these joints could help elucidate how muscles function during cycling and inform how muscle tissue loading is affected by rider posture (i.e., seated versus standing) and foot placement (i.e., cleat positioning). We hypothesized that a standing posture would change the mechanical function of the joints such that strut function at the ankle would increase as it becomes more weightbearing and required to transfer energy, while a more posterior cleat positioning would decrease the motor function at the ankle as its external moment arm would decrease.

METHODS

Ten participants cycled on a stationary ergometer at 250W and at three cleat positions (neutral position, 2cm anterior, 2cm posterior). Centre of pressure and pedal reaction force data were collected with pressure insoles, while an 8-camera motion capture system collected marker data from the participant's right leg. Inverse kinematics and dynamics were performed in OpenSim to determine joint moments and powers. Previously-published equations [3] were modified to calculate normalized joint functional indices for the four aforementioned mechanical components during the entire pedal stroke. Changes in joint function with cleat and/or rider position were examined using a two-factor repeated measures ANOVA.

RESULTS AND DISCUSSION

During all forms of cycling, the hip and ankle functioned as motors while the knee functioned as a damper (Figure 1). The hip was significantly more of a damper when standing compared to seated ($p<0.001$). Descriptively, the ankle appeared to function more as a strut when in a standing position, although this difference was not significant. Cleat position did not significantly affect the mechanical function of the joints.

This study was the first to characterize the mechanical function of the lower-limb joints during seated and standing cycling. As motors, the hip and ankle tend to predominantly generate positive power throughout the majority of the pedal stroke. As a damper, the knee tends to absorb energy (negative work) throughout the majority of pedal stroke. Previous research from our group has noted changes to Achilles tendon strain with posterior cleat positioning, however it is interesting that the joint continues to function nearly identically regardless of cleat position. Similarly, while joint moment magnitudes have been shown to differ greatly between seated and standing postures [2], our research illustrates that joint function is relatively unchanged. This research points to a consistent function of the lower-limb joints during cycling, regardless of rider posture or cleat positioning. Future research should explore how the muscles crossing these joints enable this behaviour.

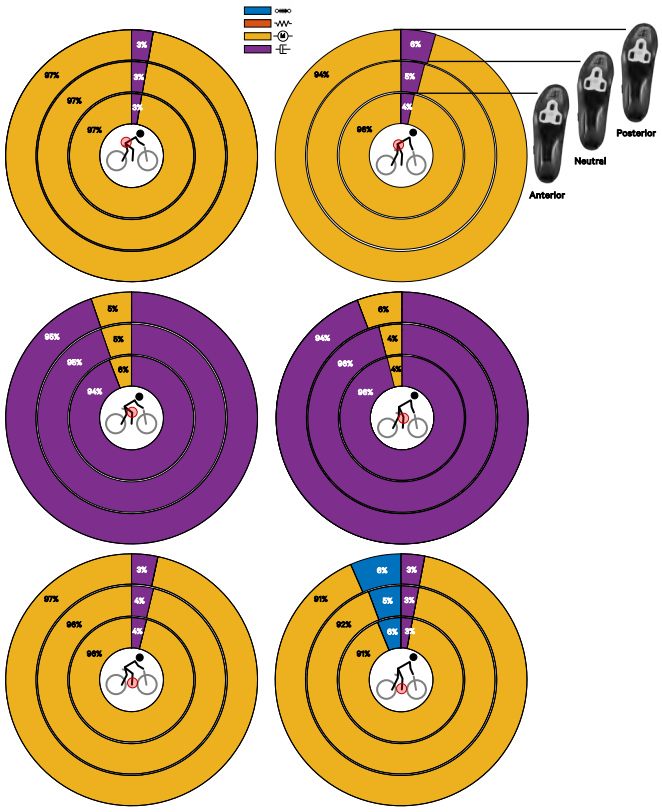

Figure 1 Normalized joint functional indices at the hip (top), knee (middle), and ankle (bottom) during seated (left) and standing (right) cycling at 250W. Inner to outer rings represent anterior, neutral, and posterior cleat position, respectively. Joint functions: blue = strut, red = spring, yellow = motor, purple = damper.

CONCLUSIONS

Cycling cleat and rider position appear to have little effect on lower-limb mechanical joint function during cycling, with the ankle and hip primarily functioning as motors and the knee largely functioning as a damper.

IMPULSE GENERATION AND INITIAL VELOCITIES IN BASKETBALL TWO-FOOT RUNNING JUMPS

Jun Ming Liu[1], Antonia Zaferiou[1]
[1] Musculoskeletal Control and Dynamics Lab, Stevens Institute of Technology, Hoboken, NJ, USA
Email: jliu130@stevens.edu

INTRODUCTION

Jump height has performance implications for basketball [1]. However, two-foot running jumps (TFRJs) have not yet been studied in basketball. TFRJs involve the redirection of the body's momentum through application of linear impulse by each leg. In volleyball TFRJs, the first leg generated more vertical and less backward impulse than the second leg [2]. This study describes impulse generation by each leg in basketball TFRJs. Additionally, the initial velocities of the COM provide context for the impulse generated during the jump. In volleyball TFRJs, initial forward velocity correlated with jump height [2] and in stationary jumps, initial downward velocity correlated with jump height [3]. Thus, this study investigates if initial velocities and net impulse generated correlate with jump height. We hypothesize (1) that the first leg generates more vertical and less backward impulse than the second leg, (2) jump height correlates with initial forward velocity, initial downward velocity, and net vertical impulse.

METHODS

Nine male recreational to college-level basketball players volunteered for the study in accordance with the IRB. They performed five to ten TFRJs from NBA combine test distance (4.57m) to a basketball hoop while kinematic and kinetic data were collected (Bertec Force Plates 1000 Hz, Optitrack Motion Capture 250 fps). They performed self-selected warm up and were instructed to tap their preferred arm on the hoop as high as they could. Hoop height was selected during warm up for each participant to ensure max jump intent. The data were processed in MATLAB (Mathworks, MA). The forward axis was the average horizontal forward trajectory of the COM during flight, vertical axis was global vertical, and leftward axis is cross product of vertical and forward. The phase of interest starts from ground contact of first leg until final toe off (**Figure 1A**). Initial velocities of the COM were computed the frame before ground contact. Jump height is calculated from COM velocity at take-off. Linear impulse is the time integral of ground reaction force (GRF) of each leg through the phase of interest. Net vertical impulse is total vertical impulse from both legs minus downward impulse from bodyweight. Signed rank tests were used to compare impulse between legs ($p<0.05$). Pearson's correlation was calculated between jump height and initial velocities or impulses using the trial with median jump height for each participant ($p<0.05$).

RESULTS AND DISCUSSION

Compared to the second leg, the first leg generated more vertical impulse in all participants and more backward impulse in seven out of nine participants (**Figure 1**). There were non-significant positive correlations between jump height and initial forward velocity ($r=0.45$, $p=0.23$), initial downward velocity ($r = 0.18$, $p=0.63$), and net backward impulse ($r=-0.10$, $p = 0.79$). There was a significant positive correlation between jump height and net vertical impulse ($r=0.7$, $p=0.03$).

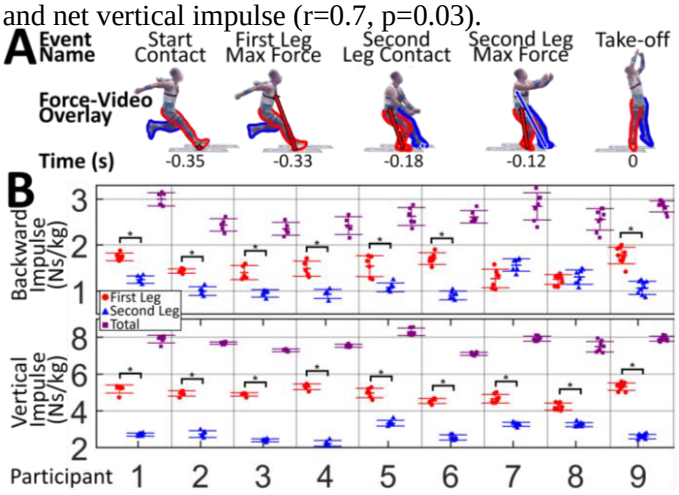

Figure 1: (A) Exemplar timeline and events in a jump (B) Backward (top) and vertical (bottom) impulse generated by the first (red) and second (blue) legs and total impulse from both legs (purple). *$p<0.05$

Compared to volleyball spike jumps, differences in impulse generation strategies may be due to greater initial forward velocity [2]. The non-significant correlations between jump height and initial velocities may indicate initial conditions play a small role in jump height, but more data are needed. The differences between basketball TFRJs and prior studies highlight importance for sports-specific jumping research. Differences in impulse may have performance and injury implications due to different movement strategies.

CONCLUSIONS

This study found that the first leg generated more backward and vertical impulse than the second leg in most participants. Jump height was only correlated with net vertical impulse. The findings differ from prior studies on volleyball spike jumps and stationary jumps, further encouraging sports-specific jumping research.

CENTRE OF PRESSURE AND ROLL OVER SHAPE FROM WEARABLE SENSORS DURING OVERGROUND RUNNING OF AN ELITE PARALYMPIC AMPUTEE SPRINTER

INTRODUCTION

A comprehensive assessment of running performance of amputee sprinters requires the measurement of Ground Reaction Forces (GRFs) [1] and the estimation of joint moments [2]. An additional important parameter is the description of the trajectory of the Centre of Pressure (COP), which is usually expressed in the ground Coordinate System (CS). The projection of this trajectory onto a body-based CS is known as Roll Over Shape (ROS) [3]. ROS was introduced for walking, thus knowledge is limited in running and even more in amputee running. Aim of the work is to present a method to calculate the ROS of the affected limb in amputee sprinters using Running Prosthetic Foot (RPF).

METHODS

One elite Paralympic female sprinter (mass: 55 kg, height: 1.60 m) with unilateral transfemoral amputation participated in this study. She wore Runner 1E91 Cat. 3.5 RPF and 3S80 mono-axial prosthetic knee (Ottobock, Germany). She performed a series of sprints at a mean top speed of 6.5 m/s on a 60 m runway in an indoor athletic track (Palaindoor, Padova, Italy). Forces and torques were collected through a 6-axis load cell positioned at the RPF clamp and connected to a lightweight acquisition system (SLICE NANO, DTS, USA; 2 kHz). An inertial sensor (6DX, DTS, USA; 2 kHz) was used to measure the 3D acceleration and angular velocity of the RPF [4], while 28 infrared cameras (Vicon, UK; 300 Hz) captured the 65 retroreflective markers attached to the athlete's body and prosthesis. The trajectory of the COP was obtained combining the measured forces and torques with the absolute position and the sagittal inclination of the RPF. Load components were resolved in the ground CS, then the instantaneous horizontal anterior-posterior coordinate of the COP was calculated as the lever arm necessary to produce the torque measured at the clamp ($M_{z_{CL}}$). By analogy with a sound limb, where ROS describes the evolution of COP in a shank-based CS [3], ROS was here obtained by projecting the COP onto a clamp-based CS.

RESULTS AND DISCUSSION

The COP in Ground CS (Figure 1a) moves back from Foot Contact (FC) to Midstance (MS, i.e. hip joint centre vertically aligned with knee joint centre), due to the large deformation of the blade, then it moves again forward towards the foot tip up to its extremity at Foot Off (FO). In Clamp CS (Figure 1b), during the first phase of stance, large deflection of the RPF and the forward rotation of the proximal segments (clamp and pylon), causes the ROS to come quickly closer to the Clamp, reaching its maximum height at MS. In the second part of the stance, RPF recoils, recovering its initial shape, therefore ROS decreases. The resultant ROS is totally different from that of an intact foot, which has a convex circular trend instead, with a rocker radius depending on the running style (forefoot or rearfoot striking) [5]. It has been observed that in able-bodied people ROS shape remains unvaried when gait parameters change [3], but little is known about the variability of ROS in amputee athletes. Further studies will investigate this theme, including the relationship between ROS, running efficiency and usefulness in RPF bench testing.

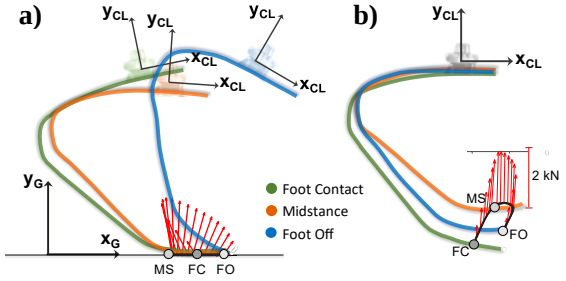

Figure 1 Schematic representation of RPF, GRF and COP/ROS trajectory (black line) at Foot Contact, Midstance and Foot Off. GRF are represented with red arrows for the whole stance phase. a) GRF and COP in Ground CS; b) GRF and ROS in Clamp CS.

CONCLUSIONS

The present study described a method to measure the ROS in an amputee sprinter running on track. This parameter, despite the lack of deep knowledge on this topic, is believed to have a crucial role in the alignment of prosthetic lower limb systems and also in the evaluation of athlete's performance.

INTRODUCTION

Lumbar stress fractures are the most time costly injury in professional cricket [1]. Research has shown greater ground reaction forces to be associated with greater stress fracture injury risk [2]. These forces cause accelerations that are transmitted through the tissues of the musculoskeletal system. Compliance such as tissue deformation extends the impact and reduces accelerations in a distal-to-proximal manner [3]. This study aimed to quantify the magnitude and frequency content of surface-measured accelerations at each major body segment during cricket fast bowling.

METHODS

Eleven male fast bowlers (19 ± 2 years, 80.5 ± 9.8 kg, 1.86 ± 0.06 m) participated in this study. Nine inertial measurement units (IMUs) (Vicon Blue Trident, Oxford, UK) recording at 1600 Hz were placed on: both distal tibia (5 cm superior to the lateral malleolus), both distal thighs (5 cm superior to the lateral femoral condyle), both greater trochanters, and L5, L1 and C7 vertebrae. Six maximum velocity deliveries were recorded in a laboratory environment allowing for a full-length run-up. Peak resultant acceleration in each position and its timing in relation to back foot contact (BFC), front foot contact (FFC) and follow-through contact (FT) were calculated, and the ground contacts were determined from synchronised high-speed video. Power spectral densities (PSD) of each distal tibia acceleration signal were visually inspected to identify common frequency ranges associated with the two main components of joint rotations and the elastic wave [3,4]. PSD integrals within the frequency range associated with the elastic wave component were determined for all signals. All parameters were averaged for the best three trials, determined by hitting the force plate at FFC and fastest delivery using a speed gun. Two-way (position x contact phase) repeated measures ANOVAs were performed in SPSS (Version 24, IBM SPSS Software) for each dependent variable, Bonferroni corrected to a significance threshold of $p < 0.017$. Post-hoc comparisons performed (not all reported for brevity) were again Bonferroni corrected.

RESULTS AND DISCUSSION

Both position ($F = 113$; $p < 0.001$) and phase ($F = 28.1$; $p < 0.001$) had significant effects on peak resultant acceleration (Figure 1). Accelerations decreased significantly with each step up the body until L5, and BFC accelerations were significantly less than FFC and FT. A significant interaction ($F = 10.1$; $p < 0.001$) indicated greater attenuation between positions following FFC and FT than BFC. Position ($F = 26.4$; $p < 0.001$) but not phase ($F = 4.45$; $p = 0.025$) or interaction ($F = 1.15$; $p = 0.331$) had a significant effect on time of peak acceleration (Figure 1). There was a general trend for greater delays at more superior positions. The 2–16 Hz and 16–58 Hz components were identified as encompassing the joint rotations and elastic wave, respectively. All main and interaction effects for elastic wave signal content were significant ($8.55 \leq F \leq 54.2$; $p < 0.001$). These results followed a similar pattern to those for peak resultant acceleration and are similar to previous findings in alternate high-impact activities [3]. Most of the distal tibia (peak) acceleration is attenuated before reaching the L5 region (91 ± 2%, 86 ± 5%, and 88 ± 4% following BFC, FFC, and FT, respectively), suggesting that the post-impact elastic wave may be unlikely to contribute to lumbar stress fracture risk. It is important to consider that surface accelerations do not represent internal bone loads, given the disregard of muscle forces [5]. Future research may quantify the attenuating effects of specific structures and effects on inverse and forward dynamic calculations. This is of particular relevance to experimental and theoretical attempts to understand lumbar stress fracture aetiology in cricket fast bowlers.

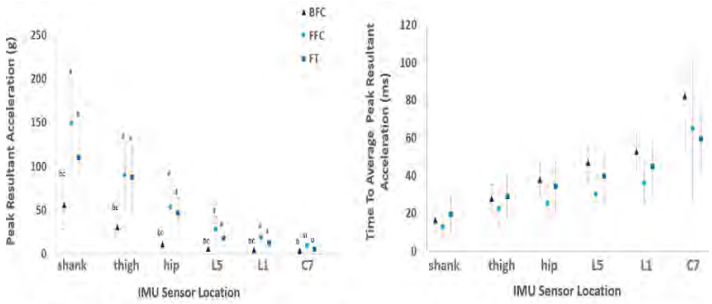

Figure 1. Peak (*left*) and time to peak (*right*) resultant acceleration (mean ± SD) at each position. a/b/c: significant difference ($p < 0.005$) between BFC-FFC / BFC-FT / FFC-FT, respectively.

CONCLUSIONS

Distal accelerations are greater during the FFC and FT phases, although the body remains capable of attenuating these. Mechanisms within the body prevent excessive accelerations from reaching the lumbar region. Results highlight the need to consider elastic wave attenuation within inverse and forward dynamics investigations of cricket fast-bowling.

INTRODUCTION

Medial tibial stress syndrome (MTSS) is an overuse injury that commonly affects female athletes [1]. MTSS is thought to be caused by tibial bone bending and a bone stress reaction above the tibia's remodeling capacity [1]. The sagittal plane tibial bending moment is reportedly associated with peak tensile strain at the site of MTSS pain and is influenced by an individual's leg alignment relative to the ground reaction force generated during the stance phase [2]. Despite MTSS commonly affecting females, no published study has assessed the sagittal plane leg alignment or peak vertical force generated by female long-distance runners with MTSS relative to their uninjured counterparts. Therefore, we aimed: (i) to determine whether sagittal plane leg alignment and the active peak force generated during running differed between female MTSS symptomatic and asymptomatic long-distance runners, and (ii) to present a prospective case study to determine the role of these variables in MTSS development.

METHODS

Eight MTSS symptomatic female long-distance runners (age = 32.1±10.9 years; mass = 65.9±6.2 kg; height = 1.69±4.6m) were matched on age, height, limb dominance and training load with 8 asymptomatic female controls (age = 32.4±10.4 years; mass = 62.9±3.2 kg; height = 1.68±6.8 m). All participants ran at least 30 km per week or were training for a long-distance event within the previous 6 months. Participants ran on a treadmill at a speed equivalent to their 10 km race time. 3D motion capture and plantar pressure-measuring insoles were used to determine each participant's sagittal plane hip, knee, ankle, and tibial alignment angles at the time of the active peak force generated during the stance phase. One female (P1; age = 47.5 years; mass = 71.8 kg; height = 1.59 m) developed bilateral MTSS symptoms during the study and is presented as a case study. A mixed-model linear regression and independent samples *t*-tests identified whether a significant difference existed between MTSS symptomatic and control limbs ($p<0.05$). Control group outcome variable means and standard deviations were used to calculate the minimally important difference to determine whether a substantial difference existed between the control group and P1 [3].

RESULTS AND DISCUSSION

MTSS symptomatic participants displayed a significantly slower running speed ($p=0.018$) and lower normalized active peak force ($p=0.002$) compared to control participants (see Figure 1). There was, however, no significant between-group difference in sagittal plane leg alignment. Compared to the control group, P1 displayed a substantially slower running speed, lower normalized active peak force, and a more vertical tibia (see Figure 1). We speculate that the slower running speed demonstrated by the symptomatic participants is to reduce pain and/or due to decreased plantar flexor strength and endurance [4]. Development of MTSS by P1 suggests that a slower running speed, lower active peak force, and more vertical tibia do not prevent individuals from developing MTSS.

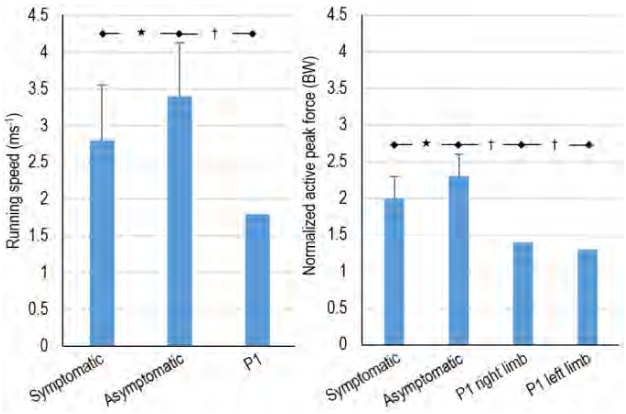

Figure 1 Mean running speed (+SD) and mean normalized active peak force (+SD) for 8 symptomatic, 8 asymptomatic controls and mean values at baseline for P1. ★ = significant difference between symptomatic and asymptomatic ($p<0.05$), † = substantial mean difference between asymptomatic and P1.

CONCLUSIONS

The slower running speed and lower active peak force displayed by participants with MTSS could be to reduce pain or an inability to maintain the same running speed as control participants over a prolonged duration. Developmet of MTSS by P1, despite a lower normalized active peak force and more vertical tibia, suggests the active peak force generated during running is of limited use as a screening tool to identify long-distance runners at risk of MTSS.

A CONSUMER-GRADE WEARABLE TECHNOLOGY IS VALID FOR THE ASSESSMENT OF WALKING GAIT "IN THE WILD"

INTRODUCTION

The clinical biomechanical analysis of gait can be an important tool for identifiaction of disease, physical deterioration, and gait abnormalities. Traditional gait analysis is typically lab-based, requires trained staff, and costly equipment, with single and sporadic assessments only showing a snapshot of the patient's gait. One approach that has been strongly advocated to overcome many of these limitations is the use of wearable sensors to perform in-field gait analysis for an extended period of time. Pressure-based insoles have been proposed as an effective method of portable gait analysis, typically targeting the calculation of spatiotemporal gait metrics. The purpose of this study was to evaluate whether the low cost and commercially available NURVV system is valid for the assessment of clinical gait parameters.

METHODS

Twelve healthy males (6) and females (6) walked on a split belt instrumented Bertec treadmill sampling at 1000 Hz. Participants wore a pair of NURVV run insoles inside modified Nike Free run trainers and a set of reflective markers were attached on both limbs (Figure 1). A 12-camera Qualisys motion capture system sampling at 250 Hz collected marker positions as participants completed a multi-stage walking protocol. Speeds ranged from 3-6 km/h, including trials where the participant was asked to imitate a limp on each leg. Using treadmill force data, initial foot contact and toe off events were taken when the vertical force exceeded and dropped below 40 N, respectively. Footstrike type was classified [1] from foot angles calculated in Visual3D using a modified version of the IOR foot model [2]. Timelines were synchronised and these results were compared to those output from the NURVV system that combines pressure data from 16 sensors with inertial measurement unit data to calculate real time metrics. Average Error, Limits of Agreement (LoA), Mean Absolute Percentage Error (MAPE), and Typical Error (TE) were calculated to compare lab-based and wearable systems.

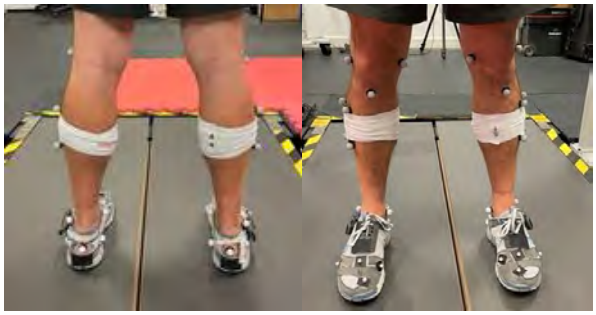

Figure 1 Experimental set-up and marker-set

RESULTS AND DISCUSSION

Identification of stride time and therefore cadence and stride time asymmetry by the NURVV system proved most accurate (Table 1). A small systematic error was seen in ground contact time, likely due to inaccurate identification of toe off timing, which in turn affected estimation of stance time (%) and swing time. These results are comparable to similar technologies previously tested. [3] On average the NURVV system overestimated walking speed in comparison to treadmill speed. However, participant positioning on the treadmill was not controlled for, which could limit the confidence in the comparison. Finally, the two systems had a 97.7% agreement on footstrike type with less than 0.1% of foot contacts being out by two classifications (i.e forefoot-heelstrike).

CONCLUSIONS

The NURVV system showed high agreement with the criterion lab-based measures. This system could be used as an effective tool to perform continuous and long-term gait analysis more easily on clinical populations in their daily life.

Reduced number of motor modules recruited during stair descent in patients with knee osteoarthritis

Lasse Hansen, Jana Rogoschin, Igor Komnik and Wolfgang Potthast
Institute of Biomechanics and Orthopaedics, German Sport University Cologne, Cologne, Germany
Email: l.hansen@dshs-koeln.de

INTRODUCTION

Knee osteoarthritis (KOA) is a prevalent and severe condition with complex effects on human locomotion and activities of daily living (ADL). The concept of modular control focuses on underlying neuromuscular control strategies to identify groups of muscle synergies, referred to as 'motor modules'. Motor modules can be extracted from surface EMG data of multiple muscles using non-negative matrix factorization (NNMF), which is described as the most favorable method to identify muscle synergies in walking and running [1]. The number of motor modules is often used to describe the complexity of a movement, with a higher number being associated with more complex movements and improved motor performance [2]. Correspondingly, lower numbers of motor modules have been reported in connection with populations showing impaired motor performance, e.g. patients with dissatisfactory knee function after knee joint arthroplasty [3]. Since the effect of KOA on motor control strategies during locomotion has only been studied in level walking and results appear inconclusive [4, 5], the purpose of this study was to investigate neuromuscular organization in participants with KOA during level walking as well as stair climbing.

METHODS

Participants with diagnosed medial KOA (n = 12, 62 ± 7.7 years, 81 ± 10.3 kg, 6 female, 6 male) and an age-matched control group (n = 10, 64.1 ± 6.6 years, 68.1 ± 7.7 kg, 5 female, 5 male) carried out a minimum of 6 repetitions of level walking and stair climbing. Surface EMG of 8 lower limb muscles was recorded on each side, ground reaction forces and 3D kinematics were recorded and used for step detection. Subsequently, NNMF was performed on the EMG data. The appropriate number of motor modules was identified using a bootstrapping approach, whereby the variance in each bootstrapped sample of the original EMG accounted for (VAF) by the reconstructed EMG was calculated. The final number of motor modules was determined as the lowest number of modules which fulfilled the following criteria: Firtsly, the lower boundary of the 95% CI of the VAF in the sum of all muscles over all bootstrapped samples must be larger than 90%. Secondly, the VAF for each individual muscle must be larger than 70%, or the addition of another module does not raise the lower boundary of the 95% CI by a minimum of 5% [1, 6]. A two sample t-test was used to assess differences between the mean number of modules in the two groups. No outliers were excluded, test assumptions were examined and significance levels were set to .05 for all statistical tests. All calculations were carried out in MATLAB [R2022B, Natick, Massachusetts: The MathWorks Inc].

RESULTS AND DISCUSSION

In level walking and stair ascending, no difference in mean module count was observed between the two groups. During stair descending, the participants with KOA fulfilled the task with a significantly lower mean module count (M = 4.33, SD = 0.24) than the control group (M = 4.81, SD = 0.53); t(21) = -2.16, p = 0.049

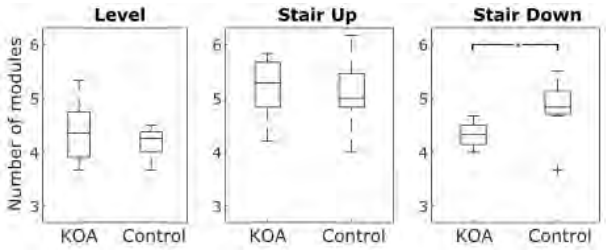

Figure 1 Mean number of modules in each condition. Asterisk indicates statistically significant difference at p < .05.

Descending a staircase is one of the physically most demanding ADL at knee joint level [7]. Therefore, it might more clearly point out existing differences in neuromuscular organization in patients with KOA. With further analysis of the recorded dataset, including more participants, incline walking, as well as kinematic and kinetic analysis, we aim to gain a deeper understanding of the effects of KOA on neuromuscular control.

CONCLUSIONS

The lower number of motor modules recruited in participants with KOA relative to healthy controls during stair descent indicates impaired motor performance in KOA patients during physically demanding ADL. To our knowledge, this has not been studied in a population with KOA for other tasks than level walking.

INTRODUCTION

Adaptive locomotion is a prerequisite behavior of animals that helps increase its chances of survival. The central pattern generator in the spinal cord is responsible for the basic rhythm of locomotion through sensory feedback coordination, resulting in energy-efficient movement patterns [1]. Individuals with symmetrical lower limbs have energy-efficient symmetrical locomotion when on flat ground. In contrast, lower limb amputees with morphologically asymmetrical lower limbs exhibit asymmetrical locomotion patterns [2]. However, little is known about how the nervous system controls the lower limbs under these distinct conditions. Thus, we examined how individuals with unilateral transfemoral amputation (UTFA) control their intact and prosthetic limbs during locomotion using forward dynamics simulations of a neuromusculoskeletal model.

METHODS

We constructed a two-dimensional musculoskeletal model with 7 segments and 18 muscles as well as a neural model with a central pattern generator and sensory feedback systems (Figure 1A). The model included 51 free parameters that had to be determined to achieve stable locomotion. We employed a standard genetic algorithm (GA) to search for these parameters [3]. Then, we investigated two adaptation scenarios using a transfemoral prosthesis. In the first scenario, we re-searched 16 symmetric sensory feedback parameters for both lower limbs, which we called the "symmetric control model." This locomotion control strategy was the same as the normal model. The other scenario included 32 asymmetric sensory feedback parameters for both lower limbs, which we called the "asymmetric control model." We evaluated whether each model could acquire stable locomotion when walking for continuous 10 s periods.

RESULTS AND DISCUSSION

The tested models excluding the symmetric control model successfully acquired stable locomotion after 2000 generations of GA (Figure 1B). The locomotion pattern of the normal model qualitatively resembled that of human bipedal locomotion, while the asymmetric control model showed an asymmetric gait pattern (Figure 1C). These results suggest that individuals with UTFA acquire different control strategies from those of able-bodied individuals to achieve bipedal locomotion.

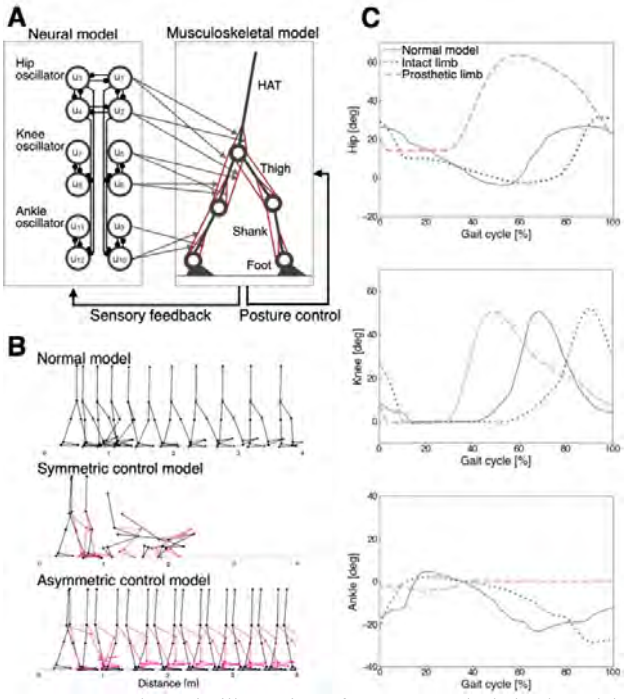

Figure 1 A: Schematic illustration of neuromusculoskeletal model. B: Stick pictures of normal, symmetric control, and asymmetric control models during walking. C: Joint angles during walking for the normal model and asymmetric control model.

CONCLUSIONS

We constructed a musculoskeletal model with UTFA. The results of the present study suggest that individuals with UTFA can re-acquire bipedal locomotion using modified neural control strategies. Moreover, our findings provide insight into effective gait assessment and clinical evaluation for gait rehabilitation.

THE EFFECT OF EXERCISES DERIVED FROM CLINICAL GAIT ANALYSIS ON LOW BACK PAIN - A RANDOMIZED CONTROL TRIAL

Christina Kaltenbach[1], Markus Maier[1], Lena Tepohl[1] and Gert Krischak[2]
[1] Institute for Research in Rehabilitation Medicine, Ulm University, Bad Buchau, Germany.
[2] ZAR Friedrichshafen, Friedrichshafen, Germany.
Email: christina.kaltenbach@uni-ulm.de

INTRODUCTION

Musculoskeletal disorders rank as the number one cause of chronic pain worldwide, affect men and women of all ages, and have a major socioeconomic impact.
Research has shown that people suffering from low back pain exhibit limitations in motor control such as reduced mobility [1] or altered abdominal and back muscle activity [2]. Additionally, fear-avoidance behavior [3] can result in long term protective mechanisms [4]. Even though research has shown that low back pain affects gait (e.g. reduced stride length, increased asymmetry, and reduced spinal range of motion), research using clinical gait analysis as an assessment instrument to derivate exercises for rehabilitation is rare. Therefore, the aim of this study was to use clinical gait analysis to derive gait-specific exercises for patients with low back pain based on a randomized controlled trial.

METHODS

Patients (n=70) from a stationary rehabilitation centre suffering from low back pain were randomly assigned to an intervention (IG) or control group (CG). Clinical gait analysis was performed on an instrumented treadmill for 45 sec at a self-selected speed at the beginning (baseline) and after 3 weeks at the end of rehabilitation (follow-up 1). Subsequently, videos and graphically prepared abnormalities in the gait pattern were shown and explained to the IG. In addition, IG got specific and individual exercises, derived from the results, which were additionally performed during the next three weeks of rehabilitation. Main outcome was the present back pain, collected with the numerical rating scale (NRS) and spatio-temporal gait parameters were calculated with MyoResearch Software 3.14 (Noraxon Inc., Arizona, US). NRS was also examined three months after the rehabilitation (follow-up 2). A linear Mixed-Effect Modell was calculated for the NRS and a 2x2 rmANOVA was done for the gait parameters.

RESULTS AND DISCUSSION

After excluding dropouts, 30 patients (66.67% male, age: 55.1±7.2) and 28 (50% male, age: 52.3±8.3) remained in the IG and CG, respectively. The mean NRS at baseline was similar in both groups: IG (4.17±2.17) and CG (4.18±2.33). At the end of the rehabilitation the low back pain decreased 25% in the IG and 20% in the CG. 3 months after rehabilitation the IG continued to reduce low back pain by 18%, whereas in the CG the pain level increased by 0.6% (Figure 1). The linear mixed model examined the effect of the time and group (fixed effect) on NRS (predicted variable) and showed a significant effect for time ($F = 11.0$, $p = 0.004$), indicating that the time had a significant negative effect on low back pain. No interaction effects were found for gait parameters, but main effects were found for stride time ($F = 6.78$, $p = 0.010$), step time ($F = 6.78$, $p = 0.010$) and cadence ($F = 6.39$, $p = 0.013$).

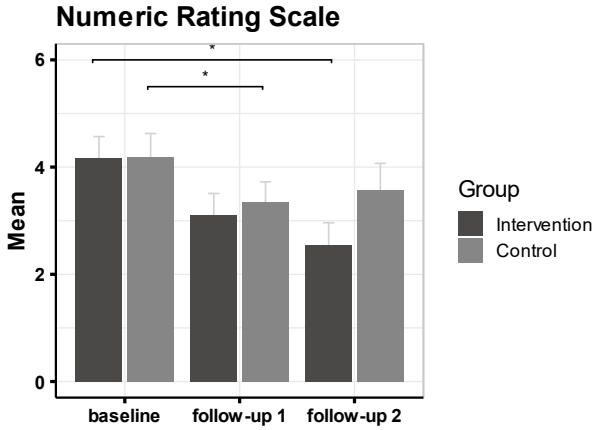

Figure 1: Present LBP on NRS at the beginning of rehabilitation (baseline), after 3 weeks of rehabilitation (follow-up 1), and three months after rehabilitation (follow-up 2). Mean + SEM is displayed.

CONCLUSIONS

The results showed that the individualized exercises for rehabilitation derived from gait analysis aided in reducing low back pain. Furthermore, low back pain in the intervention group reduced sustainably until follow up 2, whereas it worsened again in the control group after three months. The three-week rehabilitation had no effect on gait parameters in either group. However, further analysis with a healthy control group might reveal differences in gait parameters.

Altering foot orientation changes knee loading in people with and without knee osteoarthritis during three daily activities

Yi Wan[1], Polly Mcguigan[1], James Bilzon[1] and Logan Wade [1]
[1] Department for Health, University of Bath, Bath, United Kingdom.
Email: yw2984@bath.ac.uk

INTRODUCTION

Knee osteoarthritis (KOA) is a highly prevalent joint disease and a leading cause of disability, especially in the elderly population. Pathological changes such as bone spurs, cartilage loss and joint space narrowing generally occur in the medial compartment of the knee [1], where loading magnitude is commonly represented by knee adduction moment (KAM) [2]. Additionally, KAM impulse accounts for both the magnitude and duration of loading, which can provide insights into long-term wear. Foot orientation modifications have been found to reduce knee loading [3], although previous research has only examined KAM during walking and it remains unknown if KAM is similarly reduced during stair climbing and sit-to-stand activities. This study aimed to compare foot orientation modifications on knee loading in KOA and healthy participants, across several different daily activities.

METHODS

Twenty-seven KOA patients (67% female, 57 ± 5 years, 168 ± 10 cm, 78 ± 13 kg) and twenty-nine healthy participants (59% female, 56 ± 5 years, 170 ± 8 cm, 74 ± 14 kg) performed overground walking, sit-to-stand and stair ascent activities on force plates embedded in the ground or two-step stairs. Participants moved at their preferred speed during three, foot progression angle (FPA) conditions; 10˚ toe-in (I), 10˚ toe-out (O) and 0˚ neutral (N), with each condition repeated five times. Three-dimensional kinematic (200Hz) and kinetic data (1000 Hz) were recorded and processed to identify FPA using the frontal angle of the foot, and knee moments (normalised to body mass) using inverse dynamics (Visual 3D). Statistical analysis was performed using general linear mixed effect modelling (MATLAB) on FPA and 1st peak KAM.

RESULTS AND DISCUSSION

During all three activities, toe-in FPA led to a lower peak KAM in both KOA and healthy groups (Fig 1, $P < 0.001$). As FPA became more toe-in, there was a greater reduction in peak KAM for the healthy group, compared to the KOA group across all three activities ($P \leq 0.001$), despite the KOA group having a higher overall KAM. Toe-in FPA significantly reduced KAM impulse during stair ascent and sit-to-stand, in both healthy and KOA populations ($P < 0.05$), but was not significantly altered during walking ($P = 0.560$). Reducing KAM impulse, indicates less cumulative loading on the knee, which may slow the disease progression and reduce the rate of developing KOA in higher risk populations.

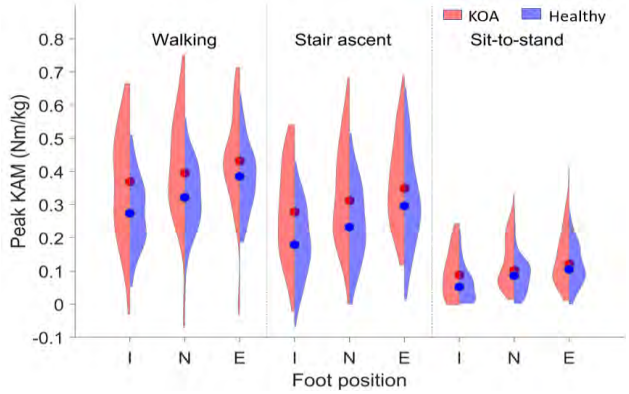

Figure 1 Violin plots of median peak KAM (range) during walking, stair ascent and sit-to-stand during toe-in, neutral and toe-out conditions for KOA and healthy population. I = toe-in, N = neutral, E = toe-out.

Toe-in FPA reduced KAM moment arm length, thus reducing the overall magnitude of KAM. This is consistent with previous literature that toe-in FPA can potentially migrate ground reaction force vector closer to the knee joint centre. In addition, toe-in FPA appeared to increase step width, which is an important factor to reduce knee loading.

All results showed a significant decrease in knee loading with toe-in FPA, indicating that toe-in gait can not only reduce knee loading during walking, but also in stair climbing and sit-to-stand, for both KOA and healthy populations. The results of this study suggest that gait modifications could assist in early clinical intervention and gait rehabilitation to slow the disease progression in KOA population, and could also be used as a preventive exercise strategy for people who are at increased risk of KOA. Future studies should consider the efficacy of long-term personalised gait retraining in patients with KOA, to assist with knee joint unloading and pain relief.

CONCLUSIONS

These results demonstrate the effectiveness of gait modification for clinical rehabilitation, which may also have substantial impact in preventive applications.

IMPACT OF AGE ON MUSCLE ACTIVATION PATTERNS WITH A PROLONGED WALK

Athulya Simon, Skylar Holmes, Kiichi Ash, and Katherine A. Boyer
Department of Kinesiology, University of Massachusetts Amherst, USA
Email: kboyer@umass.edu

INTRODUCTION

Maintaining mobility is fundamental to extending our healthspan. Muscle weakness and neural changes with age that contribute to gait alterations in older adults may be compounded by muscle fatigue [1] exacerbating mobility deficits following activities of daily living. We have reported, in response to a 30-minute treadmill walk (30MTW) that induced knee extensor muscle fatigue, greater changes in gait mechanics for older as compared to younger adults [2]. The time course of changes in muscle activation patterns in response to this fatiguing walk are not known. The aim of this study was to quantify age-related differences in muscle activation patterns with a 30MTW. We hypothesize that older adults would experience increases in both proximal and antagonist electromyography (EMG) amplitude due to the 30MTW.

METHODS

EMG and foot kinematics were quantified for 7 younger (Y; 36.7 ± 3.4 years, 2 female) and 9 older (O; 71.4 ± 1.1 years, 5 female) healthy adults during a 30MTW at a preferred speed. At minutes (M) 7, 14, and 20 the treadmill was raised to a 3% incline for a 1-minute challenge period to mimic environmental challenges. The university IRB approved all procedures. EMG was recorded for 10 muscles (gluteus maximus-GM, biceps femoris-BF, semitendinosus-ST, vastus lateralis-VL, vastus medialis-VM, rectus femoris-RF, tibialis anterior-TA, gastrocnemius medialis-MG, gastrocnemius lateralis-LG, soleus-SO) every two minutes in the 30MTW. EMG were band-pass filtered (10-300HZ), rectified, and filtered using a 4th order lowpass Butterworth filter resulting in a linear envelope. EMG envelopes for each muscle were amplitude normalized to the maximum signal from an overground walk at 1.2m/s and time normalized to 100% of the gait cycle. Principal Component Analysis (PCA) was used to find variations in the dominant patterns of EMG activation for each muscle. PCs needed to describe >95% of the variation in the signals were retained for analysis resulting in 4-6 PCs for each muscle. PC scores were calculated by projecting participant waveforms onto the PCs. The PC scores for each muscle were compared between age groups and across time using repeated measures ANOVAs with $\alpha \leq 0.05$.

RESULTS AND DISCUSSION

Age related differences were seen in the LG, BF, and RF PC2 and VM PC3 scores with greater activation in older adults. Time differences, primarily increases in activation due to the incline, were seen in the ST and LG PC1 and MG and SO PC2 scores. Age x time interaction effects, showing age related differences in response to the 30MTW, were seen in the VL and BF PC3 and ST PC4 scores (Figure 1). VL and BF PC3 both represent variation in signal amplitude in mid and late stance and early swing. While VL PC3 scores were similar for the groups at M2, increases in score with time only for older adults indicate greater VL activation in mid stance and swing for older, but not younger, adults with the 30MTW. At M2, there were smaller BF PC3 scores for older adults indicating less BF activity at toe-off. However, at M30, the changes in BF PC3 scores indicate older adults increased BF activity around toe-off while younger adults decreased. ST PC4 represents variation in the signal amplitude and peak timing at heel-strike. While scores for ST PC4 in older were similar over time, a decrease in score with time for younger indicated there was an increase in peak ST EMG and delay in the timing of the peak for younger adults with exertion.

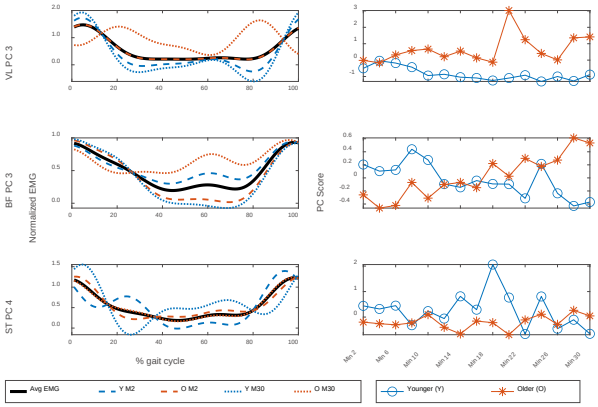

Figure 1 Left column: Average EMG activity throughout the gait cycle along with the PC*PC score from M2 and M30 added to the average EMG and multiplied by a factor of 5 for easier visualization. Right column: PC Scores over the 30MTW for each age group.

CONCLUSIONS

The EMG response to a 30MTW was not the same for younger and older adults. Older, but not younger, adults tended to shift to hip dominant activation patterns [3] while also increasing the co-activation of knee flexor and extensor muscles. These changes in activation patterns may lead to a more metabolically costly gait pattern with an increase in exertion for older adults.

Predicted Ground Reaction Force Is Plausible to Use in Inverse Dynamics Based Musculoskeletal Simulation During Gait

Ryo Ueno[1,2], Ryotaro Numata[1] and Yasuaki Tsuyuki[1], Harukazu Tohyama[2]

INTRODUCTION

The musculoskeletal simulation needs ground reaction forces (GRF) as an external force input to the multibody dynamics. Although measured GRF are often used to compute joint torques with the kinematics data, the residual forces and moments, which is the error between measured kinematics and forces, are observed and affect the inverse dynamics simulation [1]. A previous study reported that the GRF can be predicted from a kinematics data with lower residuals [2]. It helps clinicians to obtain the kinetics data without force plates. However, the validity of muscle forces/activations computed using the predicted GRF has remained unclear. Therefore, the purpose of this study was to determine the plausibility of predicted GRF for the estimation of muscle activation in the inverse dynamics based musculoskeletal simulation.

METHODS

An open-source motion capture dataset that contains gait data from 50 healthy subjects was used as the experimental data [3]. The data included marker trajectories, GRF and electromyography (EMG) from 8 lower limb muscles. CusToM [2] was used for the musculoskeletal simulations. Model calibration, inverse kinematics, external force prediction, inverse dynamics (ID) and static optimization (SO) were performed. In the prediction of GRF, forces on 14 contact points for each foot were optimized by minimizing forces on the contact points while satisfying multibody dynamics equations. Two sets of ID and SO were performed, one used predicted GRF (PRED) and another used experimentally measured GRF (EXP). Pearson's correlation was calculated to evaluate the similarity between EMG and estimated muscle activations for both PRED and EXP. To evaluate the differences between PRED and EXP, paired t-test was used to compare the trial-wise Pearson's R of the muscle activation similarity and root mean square of residual forces/torques. Additional Pearson's R between residuals and joint torques were computed to investigate how residuals affect computation of muscle activations.

RESULTS AND DISCUSSION

The mean value of the correlation between EMG and estimated muscle activation from the 8 muscles was significantly higher in PRED (R = 0.551) than EXP (R = 0.484) (P = 0.001 from t-test, Table 1). The residuals were 2-4 times higher in EXP compared to PRED (P < 0.001). In EXP, the highest correlation between residuals and joint torques was found between the hip extension moment and sagittal plane residual torque (R = 0.467). This would explain the lower muscle activation similarity from the hip extensors such as semitendinosus and gluteus maximus in EXP. Since the prediction of GRF eliminated the residuals during the optimization, the overall muscle activation similarity was better in PRED compared to EXP (Figure 1).

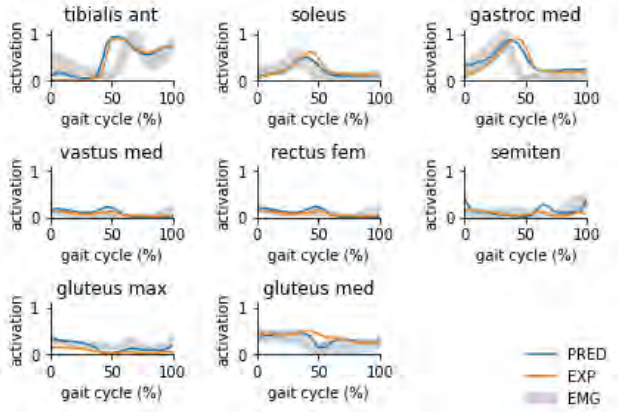

Figure 1 Estimated muscle activations using predicted GRF (PRED) and measured GRF (EXP) compared to EMG.

CONCLUSIONS

The muscle activations were plausibly and better estimated with predicted GRF than measured GRF in inverse dynamics based musculoskeletal simulation. Prediction of GRF helps to obtain kinetics data and muscle forces/activations in clinical applications.

PREDICTION OF GROUND REACTION FORCE AND MOMENT BY INERTIAL MEASUREMENT UNITS USING A 3D FORWARD DYNAMICS MODEL

INTRODUCTION

Ground reaction force (GRF) and moment (GRM) are measured by force plates. While they measure GRF and GRM accurately, they have a limitation for the location of measurement. Previous studies have reported methods to predict GRF and GRM using inertial measurement units (IMUs) and a biomechanical model without the force plate [1]. While they predict GRF and GRM without a statistical model, they have a limitation for the prediction during the double support phase because of a closed-loop structure. Following the issue, recent studies have proposed methods for the prediction using a contact model [2,3]. However, there is still no method for the prediction based on a 3D biomechanical model with a simple system. Therefore, we developed a new method to predict GRF and GRM for application to clinical and use in sports. The present study aims to verify the validity and effectiveness of the new method.

METHODS

We developed a system for predicting GRF and GRM by a 3D forward dynamics model and experimental data recorded by IMUs. Firstly, to match the motion of the model and that of a participant, optimization determines the motion of the model that minimizes the cost function defined by physical loads and errors between the motion of the model and that of the participant recorded by IMUs. Then, the system computes GRF and GRM using a contact model between foot and ground based on the position of the contact points. We constructed the system using MATLAB 9.9 (MathWorks, Inc., USA).

18 participants volunteered for the walking experiment. 6 IMUs (TSND151; ATR-Promotions Inc., Japan) measured the motion of the whole body. For validation purposes, we recorded GRF and GRM by the force plate (TF-4060-D; Tec Gihan Co. Ltd., Japan) and motion capture system (OptiTrack Flex3; Natural Point Inc., USA). The IMUs data were input into the prediction system to compute the error with the motion of the model and predict GRF and GRM. We also calculated GRF and GRM about the projection of the ankle joint center using the force plate and motion capture data. The agreement between the measured and predicted data was derived from Pearson's correlation coefficients (ρ) and the relative root mean square error (rRMSE) [4].

RESULTS AND DISCUSSION

The vertical GRF and sagittal GRM throughout a gait cycle are shown in Figure 1. We succeeded in predicting them based on the present system. The system has an advantage in terms of versatility because it predicts GRF and GRM based on the 3D biomechanical model without a statistical model and complex system. Hence, the system might be applied for biomechanical analysis in various fields compared with previous methods.

The comparison of prediction accuracy with previous studies is shown in Table 1. The present method has a disadvantage in the lower accuracy than that of the previous studies which use a 2D biomechanical model or complex system.

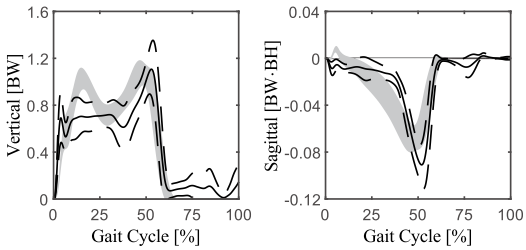

Figure 1 Vertical GRF normalized to body weight (BW) and sagittal GRM normalized to body weight (BW) times body height (BH). Solid and dashed lines represent the result predicted by the system and shaded area represents the result measured by the force plate.

Table 1: Pearson's correlation coefficients (ρ) and the relative root mean square error (rRMSE) observed in this study and reported by previous studies [2,3].

	Vertical GRF		Sagittal GRM	
	ρ	rRMSE	ρ	rRMSE
This study	0.884	18.2(3.9)	0.792	18.4(5.0)
Karatsidis et al., 2019	0.91	15.0(2.4)	0.91	17.5(6.8)
Dorschky et al., 2019	0.95	9.7(2.1)	-	-

CONCLUSIONS

We developed a new system for predicting GRF and GRM using IMUs and a 3D forward dynamics model. The present system might be applied for biomechanical analysis in various fields because the method does not require a statistical model and a complex system. In construct, the present method has a disadvantage in the lower accuracy than that of the previous studies.

Participant-informed models of the tibia-fibula complex: influence of geometry and density prediction errors on bone strain

Olivia L. Bruce[1,2,3], Jean Tu[2,3], and W. Brent Edwards[1,2,3]

INTRODUCTION

Bone geometry and material properties greatly influence finite element (FE)-predicted bone strain [1, 2]. In the absence of subject-specific FE models based on computed tomography (CT) data, statistical appearance models (SAM) may provide a valuable tool to generate accurate, participant-informed models. The purpose of this study was to quantify errors in bone geometry, density, and FE-predicted bone strain of the tibia-fibula complex generated from a SAM and skin-mounted anatomical landmarks.

METHODS

Twelve markers were placed at palpable landmarks on the left lower leg of thirty (15 female, 15 male) young physically active participants. CT scans of the left lower leg and markers were subsequently obtained. The scans were used to generate participant-specific models and to determine mean offsets between the skin-mounted markers and corresponding landmarks on the bone surface. Landmark coordinates were also measured using a motion analysis system. Tibia-fibula geometry and density distribution were then predicted by morphing an existing SAM [1] along the first 1 through 5 cumulative principal components, minimizing the sum of squared distances between predicted and motion analysis-measured landmarks, accounting for soft tissue offsets.

Meshes predicted from landmarks and only the first principal component along with the CT-based meshes were used to generate finite element models. Muscle and ankle joint loads at the time of peak ankle joint contact force during running were calculated using an inverse dynamics-based static optimization using motion analysis data for each participant. Root-mean-square- error (RMSE) relative to the participant's CT-based model were calculated for geometry, density, and pressure-modified von Mises strain. Bland-Altman plots were created to evaluate agreement between models for strained volume, defined as the volume of elements experiencing strain above 4000 με; The acceptable limits of agreement were defined as ± 5%.

RESULTS AND DISCUSSION

RMSEs in geometry and density were not different between landmark-based predictions using 1 through 5 principal components ($p \geq 0.128$, median geometry RMSE = 4.4-4.8 mm, median density RMSE = 0.118-0.142 g/cm^3). The first principal component described isotropic scaling; the lack of improvement with additional principal components suggests that skin-mounted landmarks did not provide sufficient information to characterise variations in tibial geometry.

Geometry and density prediction errors led to large differences in strain and strained volume when compared to CT-based models. Median strain RMSE was 492 με. The agreement range for strained volume (-200% to 140%, Figure 1) when compared to the CT-based models far exceeded the acceptable limits.

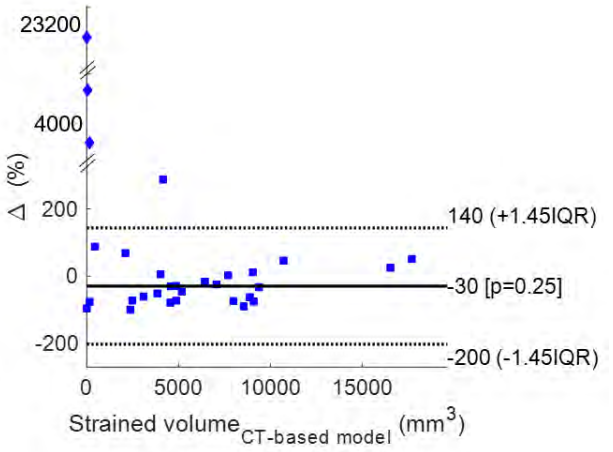

Figure 1 Bland-Altman plot showing percent differences in strained volume calculated from the landmark-predicted model and the CT-based (gold standard) model. Diamonds represent statistical outliers.

CONCLUSIONS

Skin-mounted landmarks were insufficient to capture tibial geometry and associated variations in density, leading to large errors in finite-element predicted bone strain. This approach for generating finite element models should not be used when making comparisons between groups to avoid possible errors in geometry. Some form of medical imaging is likely necessary to generate an accurate participant-informed tibia model.

SENSORIMOTOR NOISE MIGHT EXPLAIN EFFORT IN AMPUTEE GAIT: A SIMULATION STUDY

INTRODUCTION

Metabolic cost of walking is higher in transtibial amputees than in intact individuals due to reduced push-off from the prosthetic ankle. Although active ankle prostheses restore ankle push-off, improvements in metabolic cost of walking have been modest [1]. It has been hypothesized that this is because active prostheses do not restore balance control. Sensorimotor noise continuously disturbs locomotion and hence humans continuously control walking balance through sensorimotor feedback. The lack of both direct control of and sensory information from the ankle impairs balance control in amputees. Here, we used computer simulations of amputee walking to investigate whether the need to stabilize walking in the presence of sensorimotor noise might explain the increased metabolic effort in amputee as compared to intact walking. We hypothesized that effort would increase more with sensorimotor noise in transtibial amputees than in intact individuals due to impaired feedback control. We evaluated two types of prostheses: a passive and an active one. We expected that walking with an active prosthesis that provides a predetermined (optimal, see below) torque pattern would require similar effort as intact walking at low levels of sensorimotor noise due to the ability of the active prosthesis to generate push-off. At high levels of sensorimotor noise, we expected that walking with an active prosthesis requires similar effort to walking with a passive prosthesis.

METHODS

We simulated gait using a conceptual 2D torque driven model with 5 degrees of freedom [3], Fig. 1A. Torques consisted of a feed-forward component and linear, time-varying full state (angular positions and velocities) feedback. We solved for feed-forward torques and feedback gains that minimized expected effort for a full stride (imposed duration of 1.6s and length of 1m) in the presence of sensorimotor noise [2]. Effort was modelled as the squared sum of total (feed-forward and feedback) torques. We modelled walking with an active prosthesis by removing sensory information from the ankle and feedback control of the ankle on one side. We modelled walking with a passive prosthesis by additionally imposing zero ankle torque on one side (pin joint rather than spring as the conceptual model has no foot segment). We solved the stochastic optimal control problem using a previously proposed numerical approach [2] for different levels of sensory noise with constant motor noise.

RESULTS AND DISCUSSION

Differences in expected effort between amputee and intact gait increased with higher levels of sensorimotor noise mainly due to a larger increase in feedback torques (Fig. 1B-D). Walking with an active prosthesis reduced the biological feed-forward toque as compared to walking with a passive prosthesis and even intact walking at low levels of noise (Fig. 1C). However, the active prosthesis did not notably reduce the expected feedback effort explaining why it could not restore normal levels of effort.

CONCLUSIONS

Our simulations suggest that active prostheses should aim at supporting balance control in addition to providing push-off power to reduce the metabolic cost of amputee walking.

INTRODUCTION

The shoulder is an unconstrained joint that relies on a delicate balance of soft tissue forces for joint stability and function. To better understand this balance, ex-vivo shoulder simulators are used to replicate in-vivo loading during simulated active motion. Existing simulators use control architectures that oversimplify muscle function by trivializing their effect on joint position or by neglecting to differentiate between functional groups within a muscle, namely the superior and inferior portions of the subscapularis. These architectures do not adequately represent the loading environment in the shoulder and are limited to performing simple planar motions within well defined regions. The objective of this study was to develop a control architecture that incorporates the complex function of each muscle to simulate multiple planes of motion.

METHODS

The developed shoulder motion simulator used an open-loop tendon excursion control architecture with iterative learning to simulate active motion by actuating eight muscles in the shoulder. The simulator performed scapular plane abduction (SPA), forward flexion (FF), internal/external rotation (IER), and circumduction (CIR) in eight cadaveric specimens (57 ± 6 years). Optical markers were used to track joint kinematics and a uniaxial load cell mounted onto each muscle actuator measured tendon load. For each motion, kinematic tracking accuracy was assessed using root mean square error (RMSE) and maximum absolute error (MAE).

RESULTS AND DISCUSSION

RMSE was less than 1.4 degrees and MAE was less than 6.3 degrees for all simulated motions and all three joint rotations (Table 1). Consistent with a previous EMG study [1], the anterior deltoid had more of a role in humeral elevation during FF (Figure 1) ($p < .001$), whereas the lateral deltoid contributed more to SPA ($p < .001$). Infraspinatus force was higher during FF than SPA ($p = .004$) indicating the infraspinatus has a role in elevation during FF. Superior subscapularis played a major role during both FF and SPA and was higher than the inferior subscapularis force ($p < .001$) supporting previous findings that the superior portion of the subscapularis contributes to arm elevation [2]. During IER, internal rotation was associated with an increase in inferior subscapularis force ($p < .001$). External rotation was associated with an increase in supraspinatus force ($p = .001$) providing biomechanical evidence for the external lag sign observed in patients with supraspinatus tears [3]. During circumduction, the anterior deltoid had the highest force when the arm moved anteriorly away from the scapular plane and the lateral deltoid force was greatest when the humerus moved posteriorly into the scapular plane.

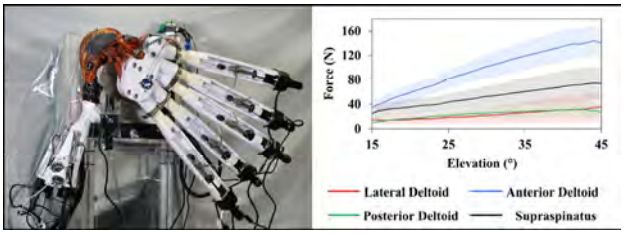

Figure 1 (Left) Cadaveric shoulder motion simulator. (Right) Average deltoid and supraspinatus forces vs. glenohumeral elevation during forward flexion.

Table 1: Root mean square error for all simulated motions.

	SPA	FF	IER	CIR
Elevation (°)	0.7	0.8	0.2	0.7
Plane of Elevation (°)	0.7	1.4	0.8	0.9
Axial Rotation (°)	0.7	1.2	0.9	1.2

CONCLUSIONS

This study presents the validation of a novel shoulder motion simulator that uses open-loop excursion control to achieve high accuracy when simulating multiplanar motions. The force relationships found in this study are consistent with those found in other biomechanical studies and can provide biomechanical evidence for clinical observations. This simulator is a valuable tool that will be used to improve our understanding of soft tissue forces in the shoulder.

Treadmill versus Overground Gait Characteristics in Autistic Individuals

Kevin A. Valenzuela[1], Melissa Bittner[1], Amanda Young[1] and Hunter J. Bennett[2]

INTRODUCTION

Current research evaluating gait utilize both overground walking and instrumented treadmills, depending on availability. Some variables have been shown to be statistically equivalent between modalities of measurement for healthy young adults [1]. However, certain populations with disorders, such as Parkinson's disease, have shown differences between the conditions [2]. It is currently unknown if young adult Autistic individuals currently show similarities or differences between these conditions. Therefore, the purpose of this research was to assess spatiotemporal gait characteristics in young adult Autistic individuals.

METHODS

Thirty-three Autistic individuals between the ages of 18-22 were recruited from local school districts to participate in this study. The inclusion criteria for the study included an educational diagnosis of Autism Spectrum Disorder and an ability to walk independently without assistance. A 15 camera Qualisys motion capture system (240Hz), Bertec force plates, and a Bertec instrumented treadmill (1200Hz) were used to collect raw marker and force data. On day one, subjects walked on a treadmill for three continuous minutes in order to establish a preferred gait speed. Subjects then had retroreflective markers attached bilaterally to their feet. Subjects performed three minutes of continuous walking at their self-selected speed. On day two, the same marker set was attached. Subjects performed ten overground walking trials on a 20m walkway. Data were imported into Visual3D. Spatiotemporal gait characteristics were calculated. A two-tailed paired samples t-test ($p<0.05$) was used to assess differences between the treadmill and overground gait conditions.

RESULTS AND DISCUSSION

Velocity, stride length, and step lengths were significantly increased during overground walking ($p<0.001$). Cycle time, double support time, stride width, and stance time were significantly decreased during overground walking (Table 1). While neurotypical adults have shown similar patterns between the two activities when gait velocity is matched [1], Autistic individuals showed reduced preferred gait velocity during overground walking, which altered spatiotemporal characteristics. Velocities were not matched in order to determine the differences in preferred velocity.

CONCLUSIONS

While research on the Autistic community continues to expand, the modality used to measure gait characteristics is important as the preferred velocity is different between the two tasks. Comparison of overground data to treadmill data should be interpreted cautiously.

INTRODUCTION

Wheelchair racing is accessible to athletes who have impairments and are classified according to their level of impairment defined by the International Paralympic Committee (from T51 to T54). For such race, the acceleration phase is an important component of performance and has been directly linked to the ability of the athletes to apply high amounts of horizontal force and power [1]. This is well known to be the phase during which the maximum power is produced by the athletes. In Paralympics disciplines, it has been shown that more powerful athletes could achieve better results in speed tests [2]. A macroscopic method made it possible to calculate various biomechanical variables during able-bodied sprint running on the field [1]. Hence the objective of this study was to propose a protocol for estimating the power developed by the athletes during a wheelchair sprint.

METHODS

Five para-athletes of the national French para-athletics team and two former para-athletes volunteered for this study (EudraCT / IDRCB n° 2020-A02919-30). After a specific warm-up, the athletes performed two sprints of 50 m with 0 N, 10 N, 20 N and 30 N resistances. The 1080 Motion Sprint was used to apply in the field the resistances and collect horizontal velocity at 333 Hz. Photocells (WITTY, Microgate, USA) were used to measure time in the non-resistance sprints (0N). Using the 1080 Sprint and photocells raw data, maximal velocity (V_{max}), estimated time to 100 m, maximal horizontal force (F_{max}), and maximal power (P_{max}) were calculated (Table 1). Horizontal propulsion force (F_h) was calculated using the mass of the athletes and the wheelchair (m), the horizontal acceleration (a_h), the drag resistance (F_{aero}), the rolling resistance (F_{roll}), and the 1080 Sprint resistive force (F_{1080}):

$$F_h(t) = ma_h(t) + F_{aero} + F_{1080} + F_{roll}$$

RESULTS AND DISCUSSION

For all participants, increasing the resistance increased their estimated time to 100 m, while it decreased their maximal speed and power. Maximal force remained constant despite increasing resistance (Table 1). Force-velocity and power-velocity profiles differed between the subjects, and the highest maximal power was achieved by the S1, an athlete classified as T54, and the lowest was achieved by the athlete classified as T52 (Figure 1). Depending on the classification and sport specialty, the maximum power output varied, and the addition of resistance had different impact.

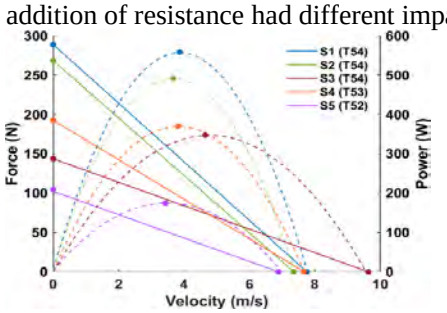

Figure 1 Force-velocity and power-velocity (dashed line) relationship of French para-athletes with 10 N resistance.

CONCLUSIONS

This study proposed a novel method to compute power developed by wheelchair athletes in the field. The protocol developed can be used by athletes for their training, as it can provide the power generated during a sprint and allow them to draw their force-velocity profile and track their progress. Both parameters are of great interest for both athletes and their coaches.

THE IMMEDIATE EFFECT OF A HOP-STABILIZATION PROGRAM ON GROUND REACTION FORCE DURING CUTTING MOVEMENTS IN INDIVIDUALS WITH CHRONIC ANKLE INSTABILITY

Teerapat Laddawong[1], Hiromi Saito[1], Toshiaki Soga[1] and Norikazu Hirose[2]
[1] Graduate School of Sport Sciences, Waseda University, Japan.
[2] Faculty of Sport Sciences, Waseda University, Japan.
Email: teerapat.l@fuji.waseda.jp

INTRODUCTION

Lateral ankle sprains (LASs) have been reported in 62.7% of soccer players, and up to 40% of first-time LASs patients suffer from chronic ankle instability (CAI). Prevention is essential since CAI causes 47% of recurrent ankle injuries. Cutting movement is a crucial dynamic motion in sports, and a change in biomechanical control may increase the risk of recurrent injury in individuals with CAI [1]. The hop-stabilization program may be implicated as a warm-up before engaging in the cutting movement to activate biomechanical patterns and is also effective for preventing recurring ankle sprains [2]. This study aimed to identify the effects of a hop-stabilization warm-up program on ground reaction force during cutting movement in individuals with CAI.

METHODS

Eight individuals with CAI and eight healthy subjects participated in this study. Each subject participated on two separate experiment days: a hop-stabilization and a control warm-up program, according to a crossover design. Before and after the warm-up program, the ground reaction force (GRF) during 45-degree cutting movements was administered. A two-way mixed-design ANOVA was used to find data differences between and within groups.

RESULTS AND DISCUSSION

The hop-stabilization warm-up programs reduced the peak posterior GRF in CAI subjects with mean differences of -0.052 ± 0.021, p=0.017 (Table1). The hop-stabilization warm-up programs had no influence on the GRF in the other direction and had no effect on the time to peak GRF. The peak posterior GRF could reduce ankle joint impact during cutting movement.

CONCLUSIONS

The hop-stabilization warm-up programs immediately reduced the peak posterior GRF in the CAI subjects during 45-degree cutting movements. The program might enhance the capacity to absorb GRF. These findings suggest that the program can benefit individuals with CAI by improving kinetic patterns prior to dynamic training.

INTRODUCTION

Aerials are highly complex manoeuvres in which surfers project a surfboard above the lip of a breaking wave before landing back on the wave's face. Executing such a difficult skill requires sophisticated neuromuscular coordination, particularly of the lower limbs [1]. Traumatic lower limb injury, however, can compromise an individual's ability to perform complex movements, unless they are able to make appropriate neuromuscular adaptations [2]. We present a case-control study of a highly skilled male surfer who, despite losing most of his left lateral quadriceps muscle during a shark bite, was able to return to performing aerials after extensive surgery and intensive rehabilitation. We investigate how this individual's lower limb muscles adapted following the loss of muscle mass to enable him to perform aerials. To control for time between experiments, we compared the surfer's data to a matched control.

METHODS

The participant who sustained the injury (P1, age: 26 years, height: 178.4 cm, mass: 67.3 kg) and the matched control (P2, age: 26 years, height: 176.2 cm, mass: 69.4 kg) both completed five repetitions of a surf-like simulated aerial task [1] in 2014 (pre-injury) and 2019 (post-injury). Medial gastrocnemius (MG), vastus medialis (VM), and semitendinosus (ST) muscle activity were collected for both limbs of each participant using Delsys Trigno wireless (1926 Hz; 2014) and Trigno IM systems (1111 Hz; 2019). We selected these muscles because they were not directly affected by the shark bite. Custom MATLAB scripts were used to process the data and align the EMG data with the landing impact markers [1]. Linear envelopes of the 500 ms before and after foot-surfboard contact in each trial were then evaluated using Statistical Parametric Mapping to compare muscle activation patterns [3]. The participants' trials were treated as independent. A 2x2 ANOVA was used to compare the EMG waveforms between participants (P1, P2) and limb (lead/uninjured, trail/injured). Where a main effect or interaction was found, we performed *post hoc* tests using a Bonferroni correction ($p < 0.05$).

RESULTS AND DISCUSSION

Pre-injury two-way ANOVA results suggested there were participant main effects for both MG and VM. Similarly, a main effect of limb was also present in VM and ST. However, following *post hoc* comparisons, only VM demonstrated significant differences.

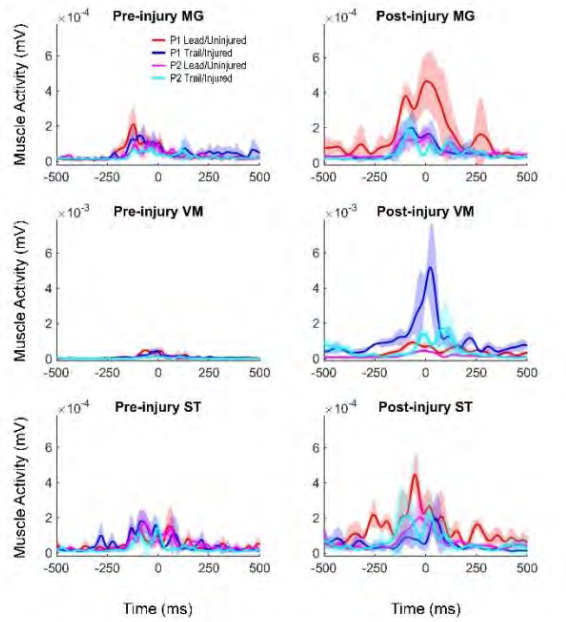

Figure 1 Mean ± SD waveforms of pre- and post-injury data for the lead/uninjured and trail/injured medial gastrocnemius (MG), vastus medialis (VM) and semitendinosus (ST).

Post-injury analyses revealed significant main effects of participant and limb for MG, VM and ST, with both VM and ST also showing significant interaction effects. Interestingly, only VM retained *post hoc* significance for participant and limb main effects, and interaction effects. Specifically, P1 displayed greater activation of the trail/injured VM compared to the lead/uninjured VM between 222-284 ms before landing ($p < 0.001$), as well as during landing (-3 to 13 ms; $p = 0.019$). This result suggests that P1 (the case) needed to contract the VM of his injured leg earlier, with increased EMG amplitude, to prepare for and dissipate the forces generated when landing an aerial. Although not significant in *post hoc* comparisons, additional adaptations to both MG and ST in the lead/uninjured limb may have occurred to accommodate P1's injury.

CONCLUSIONS

This unique study highlights that substantial adaptations to the neuromuscular control of landing a complex task, such as an aerial, can occur following traumatic injury.

INTRODUCTION

A diagnosis of Attention Deficit Hyperactivity Disorder (ADHD) is typically established using a combination of several psychological assessments and occasionally surface electrophysiological mapping. Recently, MRI studies have shown the very real potential to establish useful ADHD biomarkers [1]. However, one clinical characteristic of ADHD that has yet to be explored using fMRI is fidgeting motor skills. In this pilot study, we investigated the potential for using fMRI integrated with a functional cognitive task to identify if fidgeting behaviour might modify medial prefrontal cortex (mPFC) activation.

METHODS

Ethical approval was received from the New Zealand Health and Disability Ethics Committee. The MRI setup used a 3T (GE Discovery Signa Premier) with a AIR™ 48-channel head coil. The lower limb was isolated with knee supports to prevent motion artifacts from influencing the head coil. Data collected when motion artifacts exceeded 3mm were removed from processing. Two volunteers (one diagnosed with ADHD and one neurotypical) participated in this pilot study. A fMRI sequence was used to evaluate the impact of fidgeting motor skills while performing an executive functioning assessment, the Flanker task [2]. The Flanker task consisted of each volunteer being asked to identify the direction of a central arrow symbol (using a clicking device) in an array of arrows. The default mode network (DMN) activations were contrasted using the standard network atlas Yeo2011[3] in the CONN toolbox [4].

RESULTS AND DISCUSSION

Activation in the mPFC increased by 94% in the ADHD participant while fidgeting and performing the Flanker task. In contrast, the neurotypical (NT) participant showed a decline of 82% in activation again under the same conditions (Figure 1 - top). This suggests that fidgeting might be a learned adaptive behaviour in the ADHD brain to improve higher executive functioning, whereas fidgeting might distract neurotypical participants and be perceived as a secondary loading task when it is not natural for them.

The ADHD participant showed a strong correlation between activity in the mPFC (circled area in Figure 1 - bottom) and the DMN during the Flanker task. Importantly, the ADHD volunteer's ability to shift away from the DMN during the Flanker task only improved while fidgeting. In contrast, the NT volunteer easily shifted from the DMN when performing the Flanker task without the need to fidget. Though it is known that those with ADHD have trouble transitioning from the DMN this is the first empirical MRI evidence that fidgeting activity assists this transition.

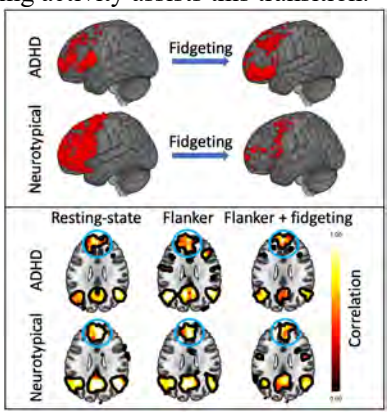

Figure 1 Top: brain activation (RED) for ADHD and NT participants with and without fidgeting. Bottom: Default mode network (DMN) correlation maps for ADHD and NT participants showing resting, Flanker task, and Flanker+fidgeting. The circled area is the mPFC seed point.

CONCLUSIONS

This study has revealed, for the first time, that fidgeting motor skills, may assist executive functioning in ADHD by increasing activation in the prefrontal cortex. This may assist those with ADHD shift from the DMN to other task-positive brain networks and offer clinicians an alternative to current medical interventions.

INTRODUCTION

Force plates have a wide variety of uses in both high performance and rehabilitation [1,2], but their feasibility of use is limited by their large size, lack of portability, and high cost. Acino, a spinout company from the University of Cape Town, have developed a novel low-cost, light weight, 3-axis and portable force plate (NFP). The aim of this study was to validate kinetic and temporal variables of the NFP was assessed against the AMTI gold standard, during walking, vertical drop, and drop jump protocols; as well as to test the intra-session validity and reliability of the Acino force plates using these same protocols.

METHODS

The three-dimensional (3D) kinematic metrics were captured using a six camera Vicon Vantage motion analysis system capturing at 240 Hz, using CGM 2 model 40 marker-set. With temporal and kinetic variables measured with the NFP overlayed on top of AMTI force plates. 21 healthy physically active participants were recruited for this study (11 males and 10 females, height 172.7 ± 10.5 cm, weight 79.9 ± 20.9, age 25.3 ± 2.4 years).They performed eight walking trials, 6 vertical jump and drop jump trials over the force plates.

RESULTS AND DISCUSSION

Pearson's coefficient of correlation showed positive correlations between AMTI and Acino measurements across all variables with *r* values of exactly or very close to 1 for both force and time measurements during walking.

Table 1: Comparisons between temporal and kinetic variables measured on Acino and AMTI plates

Vertical Drop				
Variable	AMTI	NFP	Pearson's *r*	Cohen's *d*
Peak force (N)	2472.50 ± 388.49 *	2465.84 ± 386.22	r = 1.00	-0.60
Time to peak force (ms)	55.58 ± 14.75	56.58 ± 14.75	r = 1.00	†
Drop Jump				
Variable	AMTI	NFP	Pearson's *r*	Cohen's *d*
Peak force early stance (N)	2319.49 ± 407.44	2323.52 ± 414.36	r = 1.00	-0.09
Peak force late stance (N)	1380.84 ± 362.62	1386.74 ± 369.12	r = 1.00	-0.25
Stance time (ms)	475.62 ± 95.84	475.82 ± 95.95	r = 1.00	-0.10
Time to peak force: early stance (ms)	57.43 ± 10.31	57.92 ± 10.31	r = 0.97	-0.20
Time to peak force: late stance (ms)	329.55 ± 103.62	329.23 ± 101.89	r = 1.00	-0.06

There was no significant difference between AMTI and NFP for temporal or kinetic variables measured during vertical drop and drop jump trials (Table 1). Reliability, using coefficient of variation (CV) for AMTI and NFP was similar for temporal and kinetic variables. During walking trials, the CV for NFP was relatively low at 2.25 ± 1.05 and 3.34 ± 2.39 for peak force and stance time respectively; this was lower than that of the AMTI plates (3.76 ± 2.03 and 4.58 ± 3.28). The CV for the NFP was slightly higher with the peak force variable of the vertical drop trials at 4.88 ± 4.30%. The highest CV was for drop jump stance time (11.64 ± 5.73% ; 11.52 ± 5.65) for both NFP and AMTI respectively). Figure 1 highlights the agreement of measurement between NFP and AMTI plates during walking trials, with the large majority of points falling between the limits of agreement, similar results were found for the vertical drop and drop jump trials.

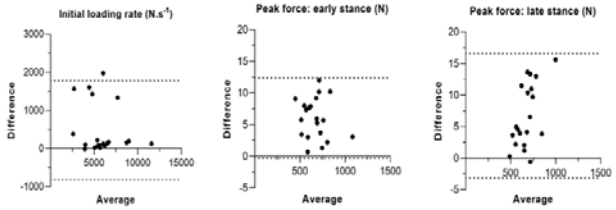

Figure 1. Bland-Altman plots for variables recorded during walking trials with 95% confidence intervals

CONCLUSIONS

The NFP showed high intra-session reliability, with low coefficients of variation and high intraclass correlation coefficients. The NFP was therefore found to be both valid and reliable in their measurements of kinetic and temporal variables in comparison to the AMTI plates, making them low-cost and portable alternatives to current industry standards.

INTRODUCTION

Understanding how low back pain (LBP) affects back muscle composition is important because muscle performance and function are determined in part by muscle structure. Ultrasonography is extensively used as the first line of imaging for the evaluation of muscle composition because is safe, accessible, and provides real-time imaging. Most previous studies using ultrasound only consider muscle size. Analysis of muscle structure has largely been restricted to analysis of fat and muscle in MRI. Some studies have implementing ultrasound for analyses of structure, but with problems related to high inter-operator variability, dependence on echo-intensity and interpretation of structural features. New image processing approaches can overcome these limitations and provide measures of connective tissue content (which is challenging with MRI). Texture analysis characterises the spatial variation of pixel intensities within ultrasound images. These complex image processing features can provide surrogates of muscle composition and tissue characteristics. This study aimed to explore whether texture features of the multifidus muscle differ between individuals with and without LBP.

METHODS

Transverse ultrasound images from the right multifidus muscle at the fifth lumbar vertebrae were used. Texture features [1] (local binary patterns and histograms of oriented gradients) from the thoracolumbar fascia (i.e., region-of-interest with connective tissue texture) were used to train a support vector machine that was used to classify each pixel within the image area covered by the multifidus muscle (segmented by an evaluator with experience). The support vector machine model was trained with 1014 region-of-interests from 20 healthy participants. Images from twelve healthy participants and twelve with acute LBP (within 2 weeks of onset of pain) were used to calculate the percentage of pixels within the multifidus image presenting connective tissue-like texture. Values were compared between groups (t-test, significance < 0.05).

RESULTS AND DISCUSSION

The support vector machine resulted in an accuracy of 75.6(0.6)% for the local binary patterns and 85.3(3.6)% for the histograms of oriented gradients. Both texture measures suggest a lower number of pixels with connective tissue texture in the LBP group than the healthy group (Figure 1).

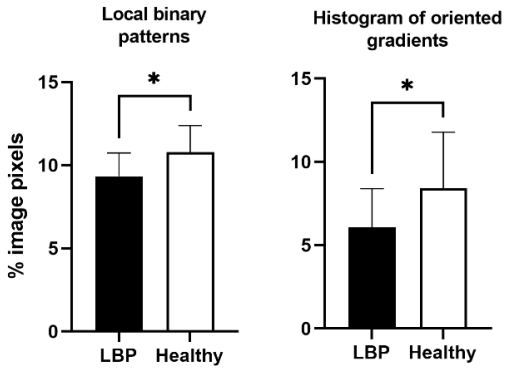

Figure 1 Percentage of pixels within the multifidus muscle image presenting connective tissue-like texture, comparison between groups.

This study shows for the first time the potential utility of texture features extracted from ultrasound images to characterise muscle composition in the multifidus muscle. Both textures utilised here detected differences in muscle composition between healthy and acute LBP participants. As both textures are different in nature [1], we are confident that the findings are not circumstantial to the texture used. Less connective tissue in the multifidus muscle in acute LBP could have several interpretations including a greater proportion of other tissue such as fat, differences in connective tissue prior to LBP, and so on. Further work is required to consider these possibilities. Our findings open the door for the use of more complex multiclass/multitexture classifiers for detailed quantification of fat and connective tissue infiltrations within the multifidus muscle. Future studies could explore the usefulness of other types of textures, combination of parameters (e.g., region region-of-interest size) and learning models (e.g., deep learning) to improve the accuracy of the classification models.

CONCLUSIONS

Ultrasound images of the multifidus muscle of individuals with acute LBP present a lower number of pixels with connective tissue texture in comparison with healthy subjects. This result suggests that texture analysis could be used to evaluate back muscles composition in patients with LBP.

INTRODUCTION

To study musculo-skeletal loading in cycling, the accurate determination of pedal reaction forces is essential. Therefore a pedal including a three-axis piezoelectric sensor [9251A, Kistler, Winterthur, Switzerland] was developed. Pilot testing showed that with uniaxial force application, the inbedded sensor exhibits excelent linearities in all three spatial axes using a standard calibration matrix. However, with combined loading in multiple axes, as is common in cycling [1], linearity decreases and error values increase inacceptably. Here, there seem to be complex interactions between sensor and pedal body that cannot be solved by a linear calibration. Therefore, a neural network approach was chosen to increase accuracy. The aim of the present study was to validate the pedal sensor and its error correction.

METHODS

A multilayer perceptron (MLP), which is a fully connected class of feedforward artificial neural networks, was chosen for error correction. In order to provide a sufficient number of training data, a test rig was developed, allowing for standardized and combined loading cycles along the mediolateral (ML), anteroposterior (AP) and vertical (VERT) axis. The recorded data set included a total of 458700 data points with sinusoidal, multiaxial loadings in the range from 0 N to 500 N. This range was derived from typical force values of cycling [1, 3]. The data set was divided into two subsets to avoid overfitting (70% training set; 30% validation set). For the test data, a separate set was recorded to simulate cycling at a power of 300W and a cadence of ~70 rpm to test the MLP predictions with a cycling specific force pattern [1]. The sensor outputs were transformed to force values using a standard calibration matrix, normalized from 0 to 1 and then used as inputs for the MLP. The forces introduced to the pedal by the test rig served as target values.

For the configuration and training of the networks, the Scikit-learn library in Python was used [2]. Using the three data sets, a grid search was performed to find the optimal hyper parameter configuration. A stochastic gradient descent solver was used, the hyperbolic tangent activation function was assigned to each node of the hidden layers and an adaptive learning rate was applied. The number of hidden layers and nodes were systematically increased. Root mean squared error (RMSE), normalized RMSE (nRMSE), maximum absolute error (MAE) as well as the coefficient of determination R^2 were calculated for each prediction of the test data set. For each sensor axis, the MLP configuration with the lowest nRMSE in the test data set was selected afterwards.

RESULTS AND DISCUSSION

The grid search resulted in different MLP configurations for each sensor axis (ML: 44 nodes in 3 hidden layers; AP: 80 nodes in 3 hidden layers; VERT: 98 nodes in one hidden layer). The predictions of the best performing MLPs lead to substantial error reductions in all sensor axes ranging from -21.8% to -93.1% compared to the matrix calibration. The remaining RMSE was in the range of 0.21N to 1.69N, which corresponds to an nRMSE range of 0.10% to 3.21%. The maximum deviation between MLP predictions and target values was 8.87 N and occurred in the AP direction (Table 1). Further, R^2 could be increased from 0.973 to 0.999.

Using MLP corrections, the pedal shows lower error values than comparable pedal sensors [1, 3] as well as mobile force plates [4] and is at a comparable accuracy to permanently installed force plates [5]. Thus, the remaining error values can be classified as acceptable.

Table 1: MAE, RMSE and nRMSE values in all three spatial axes using the matrix calibration and the MLP predictions. Arrow indicates increase or decrease of error values with given relative difference.

	ML	AP	VERT
MAE [N]	3.52 $\downarrow^{-52.9\%}$	8.87 $\downarrow^{-52.7\%}$	3.07 $\downarrow^{-49.7\%}$
RMSE [N]	0.61 $\downarrow^{-21.8\%}$	1.69 $\downarrow^{-81.4\%}$	0.21 $\downarrow^{-92.7\%}$
nRMSE [%]	2.27 $\downarrow^{-22.5\%}$	3.21 $\downarrow^{-84.1\%}$	0.10 $\downarrow^{-93.1\%}$

Conclusion

Using a neural network approach, error values of the cycling pedal sensor could be reduced, and high accuracies could be achieved. Future work will evaluate the performance of the system *in situ*.

INTRODUCTION

Ground reaction forces (GRFs) and *center of pressure trajectories* (CoPs) are required for a comprehensive biomechanical analysis [1]. They are also important outcome measures in sports sciences or clinical areas [2,3]. GRFs and CoPs are usually measured by force plates settle in the center of a walkway. In the stair walking scenarios, staircases instrumented with at least two force plates are required to record a full gait cycle of both the left and right limb's GRFs and CoPs. However, such customized staircases are not the standard configuration of biomechanical labs and are also very difficult to fulfill in out-lab scenarios. Thus, it is desired to estimate GRFs or CoPs during stair walking without force plates.

METHODS

We developed a novel *convolutional neural network* (CNN) based model for estimating complete GRFs (include the vertical F_V, *anterior-posterior* (AP) F_{AP} and *medial-lateral* (ML) F_{ML} dimensions) and CoPs (include the AP C_{AP} and ML C_{ML} dimensions) during both stair descent and stair ascent scenarios using kinematics data as input. The CNN architecture, named V-Net is shown in Figure 1, top. The input of the network is a 260×42 tensor. The output scale is 260×10, where the second dimension stands for (F_V, F_{AP}, F_{ML}, C_{AP}, C_{ML}) of both left and right foot. This architecture involves five blocks. The inner structures of such blocks are shown in Figure 1, bottom. The scales of features passed among the blocks are labelled in blue. We built a relatively large dataset $D = \{K, F, C\}$ for training and validating our model, which includes 3782 stair walking trials collected from 172 subjects. The recruited subjects include healthy subjects and individuals with knee osteoarthritis or moderate-to-high risk of cardiovascular diseases. The dataset includes the whole-body kinematics K and their corresponding GRFs F and CoPs C recorded by force plates embedded in our customized staircase. The GRFs and CoPs are normalized to *body weight* (BW) and "foot length".

We used an inter-subject ten-fold cross validation to investigate the performance of our proposed model. The performance of our model is evaluated by comparing the predicted GRFs and CoPs of the entire gait cycle with those measured by force plates using normalized root-mean-squared error (nRMSE).

RESULTS AND DISCUSSION

Our model achieves the state-of-the art estimation performance with the nRMSE of 2.525%~7.518% and 5.012%~19.434% on the GRFs and CoPs estimation.

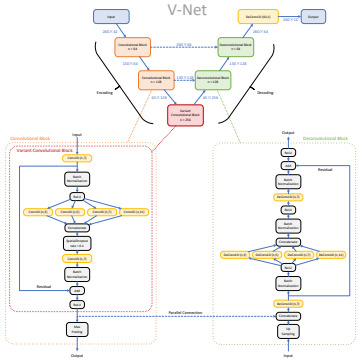

Figure 1 V-Net architecture

Table 1: Mean (standard deviation) of nRMSE (%) between our estimated GRFs and CoPs with their corresponding ground truth.

	Stair descent	Stair ascent
F_V	2.525 (1.165)	3.162 (1.382)
F_{AP}	3.220 (1.165)	7.130 (2.993)
F_{ML}	7.518 (3.595)	7.130 (2.993)
C_{AP}	11.298 (8.174)	19.434 (18.612)
C_{ML}	5.012 (2.121)	6.140 (2.324)

CONCLUSIONS

Our model achieved the state-of-the-art accuracy for estimating GRFs and CoPs during stair walking based on kinematic data. Such performance can meet the requirements of clinical use or sophisticated biomechanical study. Using our proposed model, GRFs and CoPs during stair walking can be estimated without force-plate-embedded staircases.

INTRODUCTION

Mathematical models help us simulate real world behaviors in science and engineering. To develop these models, scientists can use their understanding of first principles to determine relationships between underlying variables. Depending on the complexity of the system, this can be a long process that requires extensive modeling expertise. Neural networks can optimize this process. They can approximate the input-output relationship, without explicitly knowing every detail, such as fixed parameters, of the system. Here, we test this premise by comparing how well a neural network model and a physics-based model predict mechanical power in cycling.

METHODS

First, we developed the physics-based model and the neural network model. For the physics-based model we used first principles to derive the power from the cadence, the gear ratio (defined as the ratio between the front bracket size and the rear bracket size), some fixed bike and participant parameters (such as weight and wheel diameters), and the drag [1]. For the neural network model, we used a recurrent neural network, consisting of one long-short-term-memory layer with eight nodes and a ReLU activation function.

To collect the required data for the models, we had nine participants cycle on a flat running track. Participants did two trials of 16 minutes, with one rear gear over, and one rear gear under their preferred gear ratio, respectively. A metronome commanded step changes in cadence of ±10% of their preferred cadence, and we measured the applied power from an SRM power meter (Dura-Ace, SRM GmbH).

Using this data, we trained and tested our models in predicting the measured power. For the physics-based model we used a Levenberg-Marquardt optimization algorithm to optimize for the only unknown, the drag number [2]. For the neural network model, we used an Adam optimization algorithm. To test the performance of the two models, we used k-fold cross-validation and split up the data into six sets, three per trial. We reserved one test set and trained the model on the remaining two of the same trial. We repeated this process for each test set and calculated the normalized root mean square error (NRMSE) as the respective test set's root mean square error's percentage of the mean of the measured power. To get the model's performance for a participant we averaged the six results. We then compared the mean NRMSE between the physics-based model and neural network model using a paired t-test.

RESULTS AND DISCUSSION

There were no significant differences between the physics-based model and the neural network model (Figure 1). The NRMSEs were 19.6±5.1% and 18.2±6.0% for the physics-based model and the neural network model, respectively ($p = 0.34$).

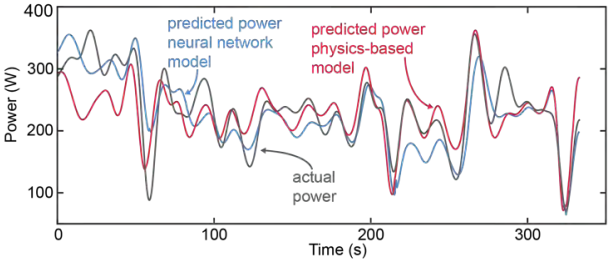

Figure 1 Neural network model (blue) prediction and physics-based model (red) prediction of the actual power (grey) in one representative participant's trial.

In our study, both models converged to similar, but not perfect, prediction accuracies. We expected this imperfect performance as there are many variables in cycling, such as continuous wind direction and speed, that affect the power output that we did not include in our models [3].

Adding more variables would be simpler with the neural network. With the physics-based model we would have to well understand the model to properly add a new variable. To add an additional variable to the neural network simply requires retraining the model with the added new variable in the input data.

CONCLUSIONS

If enough data is available, neural networks can help scientists to efficiently develop working models. If the goal is to properly understand a natural process, physics-based models remain the gold standard.

INTRODUCTION

Traditionally, practical medical skills have been taught through hands on training with an expert instructor available to evaluate performance and provide feedback. While successful, this approach provides inconsistencies in training quality as the feedback is qualitative, not all instructors are equally skilled, and they may have personal biases that affect their feedback. To address these issues, a new approach is needed in which unbiased, quantitative feedback can be provided to trainees to improve their skills. In this study, we utilized markerless biomechanics combined with machine learning technology to address these goals to build a prototype system that can automatically identify errors in a suturing skill.

METHODS

In order to develop a machine learning system capable of identifying errors in a medical skill, a training data set was needed. Utilizing a custom markerless biomechanics hand tracking system developed at SwRI, a training data set of 13 attendings, surgical residents, and medical students was collected. Each subject was asked to perform a 5 cm simple running suture on a reusable training surrogate (DAISE) while being recorded with four Sony RXO-II cameras placed around the table. Each subject performed the activity multiple times to increase the dataset size. Each individual was labelled as an expert (attendings, late year residents) or novice (medical students, new residents). Following data capture, each individual take was processed through the hand tracking system that outputs the kinematics of the subjects' hands during the motion.

Once processed through the markerless biomechanics system, the data from the experts was pre-processed to align each take in time and space to normalize variations in starting conditions. Next, each expert recording was broken up into 20 frame clips resulting in approximately 57,000 individual training samples of suturing kinematic data. This data was then used to train a Long Short Term Memory (LSTM) recurrent neural network autoencoder. This network is trained to predict an expert's future movement based on an input movement sequence. Once trained, this prediction can be compared to the actual measured movement to identify areas where subject movement deviated from expectation. Following training, each of the novice and withheld expert takes was processed forward through the network, and the reconstruction error was calculated to evaluate the networks performance.

RESULTS AND DISCUSSION

Figure 1 shows the normalized path prediction errors (difference between network predicted and measured movement) for both the novices and withheld expert takes. Novices had a higher proportion of their movements with larger errors compared to the experts, which can be used to identify thresholds for defining what prediction error level should be considered an error. For this study, any prediction error above 4 was labelled as a mistake, and each novice recording was evaluated to look for time regions with errors above this point. Once identified, the original videos were reviewed to verify that errors had in fact occurred and an interesting range of errors were identified. These included obvious errors, (needle driver slipping off the needle, retracting and reinserting the needle, etc.), as well as subtle errors that are not obvious to lay observers (e.g., grasping needle with wrong instrument).

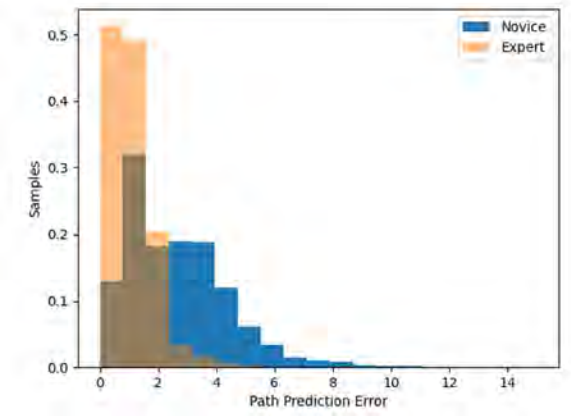

Figure 1 Normalized histograms of path prediction error for Novice and withheld Expert motions.

CONCLUSIONS

We have successfully shown that a prototype system that combines markerless biomechanical hand tracking and an LSTM autoencoder can accurately identify errors while trainees perform a suturing task. This system will lay the groundwork for building out a fully automated training tool which will allow trainees to receive unbiased, quantitative feedback while practicing key skills without the need for an expert instructor to be present.

INTRODUCTION

Musculoskeletal simulators have empowered biomechanical research in the last twenty years, with the most advanced one being the open-source simulator OpenSim [1]. OpenSim offers detailed models and precise simulation. The control of the complex model availble (neural control surrogate) offered in OpenSim is based on control theory which solves muscles redundancy based on pre-determined objective functions. This create the question on how human optimized movemen, whicht is still an open question but the current standard is based on reduction of muscle effort. Meanwhile, machine learning and the field of reinforcement learning (RL) have made impressive progress in the last couple of years. RL allows solving complex tasks and generalising to similar tasks family. This allows having policies, once trained, that can solve complex tasks from start to finish and that can adapt to non stationary condition. One of the well known limits of RL is the important number of training steps needed, requiring fast simulator which is currently not possible with OpenSim. This is why we developed MyoSuite [2], which allows the training and use of RL policy to control neuromusculoskeletal models. In this paper, we present available models and baseline policy in MyoSuite.

METHODS

MyoSuite is an open-source software[1] based on the Mujoco simulator and Gym AI library. We developed multiple upper-limb models based on the MOBL OpenSim model. Namely, a finger model (4 degrees of freedom (DOF) and 5 muscles), a wrist and hand model (23 DOFs and 39 muscles), an elbow model and an elbow and exoskeleton model (1 DOF and 6 muscles). We also integrated different conditions such as sarcopenia and muscle fatigue. Furthermore, we trained policy for tasks such as finger reaching, finger pose, elbow pose, hand reach, hand pose, turning a key, pen twirl and boading ball (Fig. 1).

RESULTS AND DISCUSSION

Results showed that MyoSuite was 60x to 4000x faster than OpenSim (depending on the number of muscles simulated) while having a difference in muscle force of only 4.1 ± 2.0%. Most tasks were able to be solved for a fixed target under 5 million steps except for the baoding ball task. When the target is randomized, only the finger pose and elbow pose are solved consistently (100% success rate). We also looked at the effect of conditions change in learned policy. Elbow pose policies (with and without exoskeleton assistance) were tested on different static (sarcopenia) and dynamics (fatigue) conditions without retraining. The exoskeleton assistance (percentage of elbow torque) was able to compensate for the induced weakness with an error of only a few degrees compared to 10 degrees error without exoskeleton for the sarcopenia conditions and the effect of fatigue reduced by half. Finally, to try to solve the problem of the generalization gap (fixed versus randomized), we organized the MyoChallenge[2] at the NeurIPS22 conference to solve the boading ball and a new task based on die rotation. The top teams were able to solve random die rotation with a success rate of 13% and baoding ball with a success rate of 55%. This show that human neural control and dexterity are still far superior to that of the latest AI algorithm and further research is needed both in AI and neural control to understand and solve this disparity. Our future work consist of implementing other model such as a lower-limb model to study locomotion or a bi-arm model to study complex manipulation.

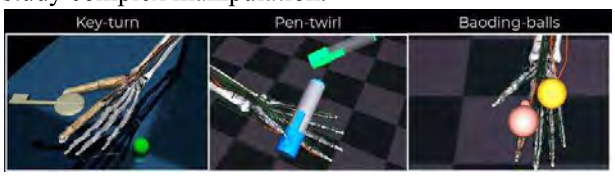

Figure 1 Task using the hand and wrist neuromusculoskeletal model for key-turn, pen-twirl and baoding ball.

CONCLUSIONS

MyoSuite opens new avenue to merge AI with neuromusculoskeletal modelling and provide in the future adaptative and fast biomechanical simulations. This will provide new solutions to advance rehabilitation, *in silico* study of neural control but as well in the field of AI with neural network advances.

INTRODUCTION

Vaulting gait (plantar flexion in the intact limb during the single-limb support phase) is a typical gait pattern to increase toe clearance of the contralateral prosthetic limb in unilateral transfemoral amputees. Since the vaulting gait induces the secondary degenerative diseases in their intact limb [1,2], the whole-body posture estimation in their daily live could be an effective preventive strategy. In this study, we propose a deep-learning model to estimate the whole-body posture during walking with two inertial measurement units (IMUs) on the prosthetic shank and the heel of the intact limb in unilateral transfemoral amputees.

MATERISLS AND METHODS

First, we trained a deep-learning model with the gait data of able-bodied subjects. Then, we estimated the whole-body posture during walking in unilateral transfemoral amputees by re-training the pre-trained model with their gait data.

DhaibaWorks [3], a motion analysis software developed by AIST, was used to generate datasets from existing motion databases, the AIST Gait Database 2019 [4], and the datasets of the left-sided unilateral transfemoral amputees [5]. To obtain motion-related IMU data, we calculated the acceleration and angular velocity of the points on the left shank and right heel along their local coordinate.

After removing the abnormal data by visual inspection, the data on able-bodied subjects was 2741 trials of 290 subjects, while the data on left-sided transfemoral amputees was 40 trials of eight subjects (five trials per subject) which was divided into four trials for re-training and one trial for testing.

The network comprises two long short-term memory (LSTM) layers with 256 units and one dense layer with 51 units. It considers acceleration and angular velocity inputs from the previous 49 frames and the current frame (i.e., a total of 0.25 s) and estimates the three-axis joint angles of 17 bones. ReLU was used as the activation function in the LSTM layers, and a linear function was used in the dense layer. The loss function, learning rate, mini-batch size, number of epochs, and optimization algorithm were set to the mean squared error, 1e-3, 64, 30, and Adam, respectively. For re-training, we used fine-tuning. All layers were fine-tuned with the data of each subject. The hyperparameters used for fine-tuning were the same as those used for pre-training.

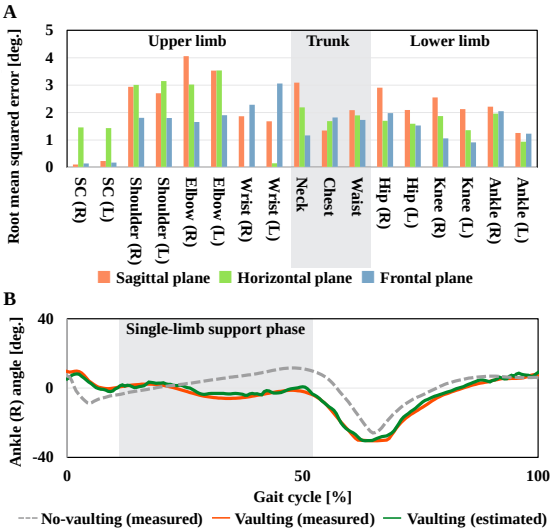

Figure 1 A: Average root mean squared errors of each joint angle. "SC" indicates sternoclavicular joint. B: Time sequences of the measured and estimated flexion-extension angle of the right ankle (intact limb) for the specific subject with vaulting gait.

RESULTS AND DISCUSSION

Average root mean squared errors of each joint angle for all subjects estimated from the proposed model are shown in Figure 1 A. It was less than 4.1 degrees. Time sequences of the measured and estimated flexion-extension angle of the right ankle (intact limb) for the specific subject with a vaulting gait are shown in Figure 1 B. It is clear from this figure that plantar flexion in the intact limb during the single-limb support phase, which characterizes a vaulting gait, can be estimated.

CONCLUSIONS

Our method would quantitatively measure the walking motion of unilateral transfemoral amputees in daily life, although it is necessary to fill the gap with real data.

INTRODUCTION

The current state-of-the-art method to evaluate biomechanics of sport movements is through using 3D motion analysis and force plates. Such systems can be integrated with other acquisition devices and are accurate and reliable. However they are time-intensive, restricted to laboratories, expensive and require skilled operators [1]. Inertial measurement unit sensors (IMUs) have demonstrated high potential as an alternative in the mobility of conducting biomechanical testing in the field [1]. Traditional analysis includes correlations, linear regression and SPM, however for these complex datasets alternative techniques such as machine learning may offer new insights [2]. The aim of this research was to identify critical factors estimated using IMUs that best predict ball release speed (BRS) in cricket fast bowling with machine learning.

METHODS

Eight English County level bowlers (age 20 ± 2 years; height 1.80 ± 0.05 m and body mass 80 ± 5 kg) were recruited for the study with informed consent obtained in accordance with the Loughborough University Ethical Advisory Committee. Two Vicon blue trident inertial sensors (Vicon, Oxford, UK) sampling at 250 Hz were placed at the thorax and pelvis. Four high-speed Bonita cameras were positioned sagittal (ipsilateral), superior, posterior, and anterior of the bowler for qualitative reference. The testing protocol comprised a 2-over bowling spell performed with a 4-minute active rest period between each over in a laboratory environment that allowed for a full-length run-up. Sensor data of 64 deliveries (8 deliveries per bowler) were exported and analyzed in MATLAB and its Regression Learner App (Release 2022a, The MathWorks, Inc., Natick, Massachusetts, United States) with 5-fold cross validation. Regression models such as support vector machine (SVM) and Gaussian process regression (GPR) models were used to predict BRS. Statistical measures of root mean square error (RMSE), mean absolute error (MAE) and R-squared values were used to evaluate the performance (Table 1).

RESULTS AND DISCUSSION

Data showed a non-linear relationship between the performance variables and BRS. A GPR exponential model gave the best fit with five features explaining 82% of the variation in BRS with least error (Figure 1). The best predictors of BRS were change in linear velocity of the pelvis (lateral) from back foot contact (BFC) to front foot contact (FFC); change in linear velocity of the thorax (anterior) from BFC to FFC, and FFC to ball release (BR); change in thoracic angular velocity (transverse) from FFC to BR; and time duration from BFC to FFC. These variables add to the current knowledge of biomechanical variables linked to BRS.

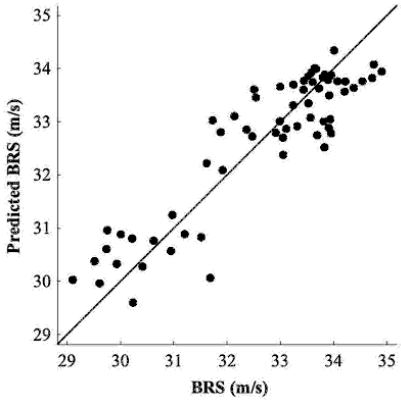

Figure 1: Non-linear GPR model predicted BRS vs true BRS.

CONCLUSIONS

In summary, non-linear regression models with five variables provided the best estimates of BRS with low errors. The methods used here may provide additional understanding of the performance variables linked to BRS that have not been identified with traditional analysis methods, aiding in advancing the current knowledge and understanding of cricket fast bowling.

A Novel method to measuring the slip of foot inside the shoes: Evaluation of socks friction using pressure sensors

Email: kklee@kookmin.ac.kr

INTRODUCTION

Slip of the foot inside the shoes affect the stability and stability of locomotion. Therefore, products with non-slip functions added to socks or insole are being released. However, it is difficult to evaluate the slip prevention performance because it is difficult to check the slip inside the invisible shoe due to the shoe upper. Hence, the purpose of this study is to propose a method to estimate the slip of foot inside the shoes in dynamic situation. Three pressure sensors were installed directly to the inner wall of the shoe, centered on the 5th metatarsal. The force values obtained from the pressure sensors were calculated to distinguish between the different friction characteristics of the socks.

METHODS

Fifteen participants were given three same sized socks with different friction characteristics and performed a shuttle run. The socks used in the experiment were characterized for friction by mechanical test in a previous study [1]: (1) Socks with polyurethane non-slip pad (US). (2) Socks with silicone non-slip pad (SS). (3) Socks without any non-slip pad (NS; Figure 1a). Three pressure sensors (SEEDTECH, Gyeonggi-do, Korea) were attached directly at sidewall inside the shoe (centered on the 5th metatarsal). All participants wore the same size shoe and performed the shuttle run task. The data obtained from the pressure sensor was analyzed into three events centered on the ON and OFF times: (E-A) when the pressure value started to increase continuously (window length more than 10 frames), (E-B) when the pressure value reached a maximum, and (E-C) when the pressure value reached a minimum.

RESULTS AND DISCUSSION

There were significant differences in peak force values and impulse values between sock types ($p < 0.001$; Figure 1b,1c). Bonferroni adjustments found the pairwise comparison results for all socks showed significant differences in peak force values and impulse values. ($p < 0.001$). There was no significant difference in slip time between sock types. ($p = 0.105$). The previous study suggested that there is a greater shift in foot displacement when performing a dynamic task while wearing low-friction socks [2], suggesting that the sidewalls of the shoe may detect greater contact forces with the shift in foot displacement. The pressure sensor installed in this study successfully measured the contact forces, and the data obtained from the sensors successfully distinguished the different frictional characteristics of socks In addition, the pressure value (peak, impulse) of the inner sidewall of shoes measured in this study was generally consistent with the friction coefficient difference pattern through static mechanical tests in previous studies. It was possible to estimate the slip inside the shoe through the force of pushing the inner sidewall of the shoe caught by the slip between the sock and the insole.

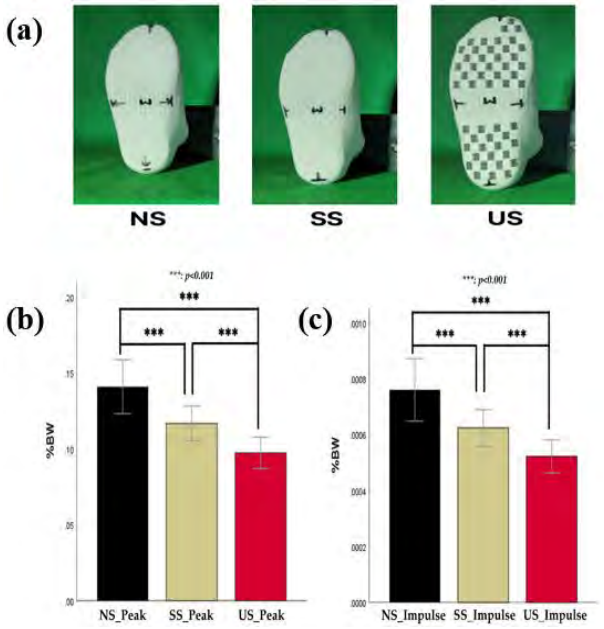

Figure 1 Figures of Socks and Statistical results of peak force values and impulse values. (a) types of socks. (b) peak force values. (c) impulse values.

CONCLUSIONS

The results of the static mechanical test conducted in the prior study [1] were consistent with the results of the dynamic condition task in this study. This suggests that static mechanical test in prior studies [1] can replace dynamic condition task that requires complex procedure.

INFLUENCE OF THE TYPE OF RUNNING SHOES IN THE LOWER LIMB MUSCULAR ACTIVITY

Gonçalo Marta[1], João Folgado[1], Carlos Quental[1] Francisco Guerra Pinto [1,2]
[1] IDMEC, Instituto Superior Técnico, Universidade de Lisboa, Portugal.
[2] FEBOT, NOVA Medical School, Portugal
Email: goncalo.marta@tecnico.ulisboa.pt

INTRODUCTION

Among other aspects, running footwear differs in the cushioning and support it provides to the stride of each practitioner, and the influence of these on muscle activity is still not well understood. The use of surface electromyography (EMG) along with the application of inverse dynamics using a multibody model, allows the development of a complete profile of muscle activity in the lower limbs during various movements. In this study, we aim to investigate the differences in muscle activation patterns for two distinct types of running shoes: neutral cushioning shoes and competition shoes without cushioning.

METHODS

EMG data from 8 different muscles - lateral and medial gastrocnemius, rectus femoris, biceps femoris, tibialis anterior, gluteus maximus, soleus and vastus medialis - were collected in the biomechanics laboratory of Lisbon (LBL). The volunteer's kinematic data were analyzed using the use of reflective markers and 14 infrared cameras. The volunteer ran at a self-selected speed, using the types of shoes under study, on force platforms embedded in the LBL's ground. The estimation of the internal reaction forces and muscle activations was achieved by combining the collected data with an inverse dynamics program. To do this, a whole-body musculoskeletal model with 18 rigid bodies and 80 muscle-tendon units was used. The muscle force sharing problem was solved through static optimization by minimizing muscle energy consumption while ensuring the fulfilment of the equations of motion and the bounds on the muscle activations between 0 and 1 [1]. The estimated muscle activations were validated by the laboratory-collected muscle activity.

RESULTS AND DISCUSSION

The preliminary results for the angles and reaction forces at the ankle, knee, and hip joints and muscular forces were analyzed. For the cushioned shoes, the results suggest increased plantar flexion at toe-off when compared with non-cushioned ones. The reaction forces at the hip, knee, and ankle joints appear to be higher for the non-cushioned shoes compared to the cushioned shoes, as shown in Figure 1(a) for the ankle joint. This result falls in line with what was found by Nigg et al., implying that cushioning reduces the reaction forces applied in the foot while raising the stance time [2] , as can be seen in Figure 1(a). Similarly, the estimated muscle activations had overall higher maximum values for the non-cushioned competition shoes, as illustrated in Figure 1(b) for the gastrocnemius lateral.

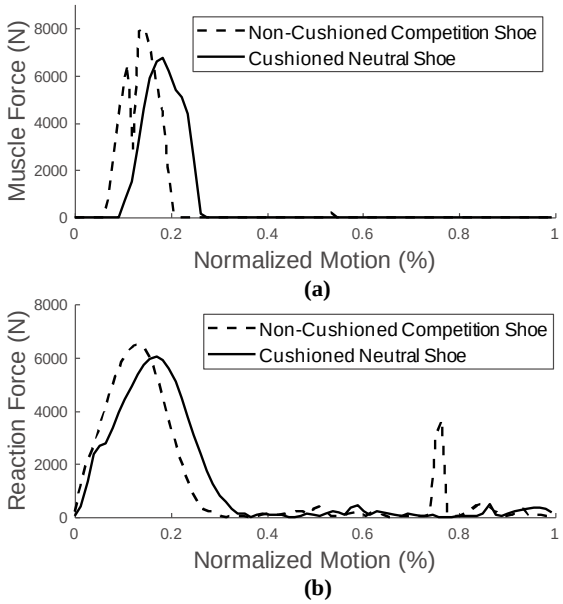

Figure 1. Depiction of estimated (a) ankle joint reaction forces and (b) muscular forces in the gastrocnemius lateral muscle for cushioned and non-cushioned running shoes.

CONCLUSIONS

A more comprehensive understanding of the impact that different types of running shoes have on the mechanisms of muscle or joint injury is necessary. The availability of such studies enables runners to have biomechanical knowledge to choose shoes that are suitable for their physical characteristics and goals.

INTRODUCTION

One of the most common injuries among runners is patellofemoral pain (PFP), which can be caused by excessive repeated loading of the patellofemoral joint (PFJ) [1]. The development of PFP in runners can potentially be influenced by footwear [2]. Footwear companies have designed variations in running shoe cushioning in an attempt to reduce injury risk, including reducing midsole cushioning (minimal shoes) and increasing midsole cushioning (maximal shoes). Current evidence on these shoes has focused on ankle biomechanics and ground reaction forces, with mixed evidence related to injury risk in both types of shoes [3]. Much less is known regarding the effect of varying midsole cushioning on proximal kinematics and kinetics at the knee and hip [4]. Therefore, the purpose of this study was to compare knee and hip kinematics and kinetics between traditional, maximal, and minimal shoes.

METHODS

Twenty-seven healthy experienced runners (8 men and 19 women) ranging from 18-45 years of age who ran a minimum of 10 miles per week with no major injuries for at least the previous 6 months and who have never trained in a minimal or maximal shoe were recruited to participate in this study. The maximal and minimal shoes for this study were custom designed by adding or removing cushioning from the traditional shoe (New Balance Fresh Foam Boracay) by the shoe manufacturer. Participants were asked to complete five running trials on their dominant leg while an 8-camera motion capture system and two embedded force plates were collected three-dimensional kinematic and kinetic data of the knee and hip in all three conditions. Quadriceps force, patellofemoral joint force (PFJF), contact area, and patellofemoral joint stress (PFJS) were estimated based on the methods outlined by Salem & Powers [5]. Peak knee and hip joint angles and moments and patellofemoral joint kinetics were compared between shoes using a repeated measures ANOVA ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Knee moment data can be seen in Table 1. The peak knee extension moment (Figure 1) and peak knee internal rotation moment were significantly reduced in the minimal shoe. In addition, the peak hip adduction angle (trad: 11.28 ± 3.71°, max: 11.12 ± 3.85°, min: 10.33 ± 3.67°, $p = 0.035$), peak quadriceps force (trad: 66.07 ± 9.09 N/Kg, max: 67.78 ± 9.91 N/Kg, min: 61.43 ± 8.81 N/Kg, $p < 0.001$), PFJF (trad: 49.46 ± 6.7 N/Kg, max: 50.93 ± 7.68 N/Kg, min: 45.78 ± 7.08 N/Kg, $p = 0.001$) and PFJS (trad: 13.56 ± 2.53 MPa, max: 13.95 ± 2.99 MPa, min: 12.67 ± 2.48 MPa, $p < 0.001$) were all significantly lower in the minimal shoe compared to the other two shoes. No other significant differences were found between shoes for peak joint angles or moments at the knee and hip, $p > .05$.

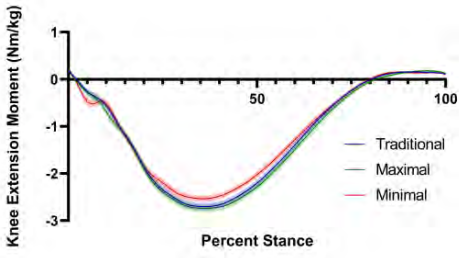

Figure 1: Ensemble curve for the knee extension moment in each shoe condition, (-) extension (+) flexion.

CONCLUSIONS

There were significant differences between minimal and both traditional and maximal footwear when analysing proximal running biomechanics. The decreases in peak knee extension moment, peak hip adduction, and PFJS supports previous research [2] that suggests minimal footwear may reduce the risk of injury to the knee.

A Pilot Study: Effects of an 8-week training intervention in carbon-plated running shoes

Justin Matties[1], K. Michael Rowley[1]
[1] Kinesiology, California State University East Bay, Hayward, United States.
Email: justin.matties@csueastbay.edu

INTRODUCTION

Lab testing with Nike Vaporflys (VP) has revealed running economy (RE) benefits of 2.5-4% [1,2]. With runners also anecdotally reporting less sore calf muscles and less "beat up" legs after hard workouts, use of VP may cause runners to undergo physiological adaptations since their muscles may be aided during training by the shoe's energy returning technology [1]. The purpose of this pilot study is to investigate the long-term effects of using VP in workouts by comparing training in VP vs in VP vs Nike Victory Waffle 5 flats (FL) on race performance and explore physiological and biomechanical adaptations.

METHODS

Collegiate cross country runners (n=8) completed pre- (PRE) and post-intervention (POST) lab testing in both VP and FL. They were assigned either VP or FL for an 8-week intervention. In PRE/POST, vertical jump (Vertec) and plantar flexion strength in knee flexed and extended positions were recorded (MicroFet2). Then runners were instrumented with EMG (Noraxon), a 6DoF lower body marker set (Vicon), and ran on an instrumented treadmill (Treadmetrix). Subjects ran 2 x 3-min trials at a self-selected race pace (7-10 min rest), followed by 4 x 5-min (5 min rest) at a submaximal pace (RER<1), in a randomized order. Metabolic (Cosmed) and biomechanical data were collected and compared. Trial paces were constant in PRE/POST. Using a forward selection technique, due to a large number of predictors and few observations using a full model was not possible, we tried to build an appropriate ANCOVA model to test main effects of intervention shoe assignment (VP/FL) and time point (PRE/POST).

RESULTS AND DISCUSSION

On average all participants' RE improved over the 8-week intervention, though FL group improved more than the VP group (FL: 5.61 ± 1.11%; VP: 0.97 ± 3.64%; p = 0.077, effect size (Hedges g) = 1.409). The FL group improved RE by 5.79 ± 1.02% when running in FL and by 5.43 ± 1.20% when running in VP. The VP group improved RE by 0.84 ± 4.64% when running in FL and by 1.11 ± 2.72% when running in VP. Computing a "VP % benefit" by comparing the RE when running in VP to running in FL shows that between PRE and POST, the VP intervention group increased their VP % benefit compared to FL (VP: 0.21 ± 2.23%; FL: -0.38 ± 0.24%; p = 0.433, effect size = 0.148), see Table 1. In this pilot phase there were no significant correlations between biomechanical measures and metabolic measures, though non-significant differences were observed in ankle angle (Figure 1), ankle moment, metatarsophalangeal joint angle, ankle power, vertical jump, plantar flexion strength, and the ratio of soleus and medial gastrocnemius muscle activation.

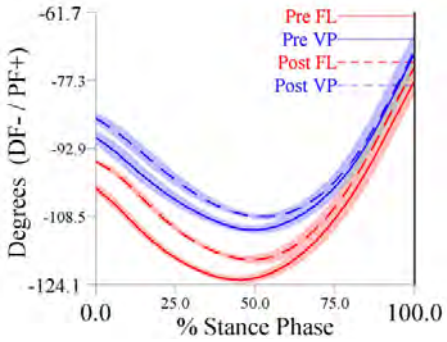

Figure 1 Representative graphs from a FL group subject showing ankle angle during stance phase during PRE & POST in VP & FL.

CONCLUSIONS

This pilot study suggests a specificity of training effect where participants improved relative RE more from PRE to POST when running in the shoe type they trained in. Overall, the FL group improved RE to a greater extent, suggesting that training in FL is more optimal for race performance despite decreasing the acute RE benefits incurred from super shoes. Heterogeneity of foot strike techniques likely prevented group biomechanical differences from being observed. We will use the effect sizes of these differences to power the next larger phase of the study.

ACKNOWLEDGEMENTS

We would like to thank the Nike Sports Research Lab (Beaverton, OR) for providing footwear for this study.

INTRODUCTION

Midsole cushioning is the foundation for all performance running shoes. In recent years, modernization of cushioning materials has allowed for an increase in midsole stack height while minimally compromising the mass of footwear. Researchers have suggested the regulation of this aspect of footwear design for competition [1]. Governing bodies have followed suit, implementing limitations to midsole thickness. However, the isolated effects of increasing midsole thickness are not well understood.

The purpose of this study was to measure the isolated effects of stack height on running economy and spatiotemporal step parameters.

METHODS

12 trained runners participated in this study. Sets of weight-matched footwear conditions were worn (30mm EVA, 40mm EVA, 60mm EVA, 60mm NITRO (a PEBA based material)) in size UK8/UK10 (m = 465g/515g). Subjects ran twice in each shoe condition in randomized, mirrored order (ABCDDCBA) for 5 minutes at 14 km/h with 5 minutes rest. We measured their oxygen uptake and carbon-dioxide production, and we calculated running economy as metabolic power for the final 2 minutes of the trial when aerobic steady state was achieved. Spatiotemporal variables were measured over 10 strides during the final minute of each running trial. One-way repeated measures ANOVA was used to evaluate the effects of shoe condition and Tukey's HSD analysis to evaluate shoe-by-shoe differences.

RESULTS AND DISCUSSION

Overall, there were significant effects of shoe condition on running economy and contact time. Within the firm EVA midsole material, larger stack height led to a non-significantly worse running economy. Post-hoc testing showed that 60 NITRO had a significantly lower metabolic power (16.09 ± 0.99 W/kg) than 60 EVA (16.52 ± 1.01 W/kg, -2.6%) and 40 EVA (16.44 ± 1.13 W/kg, -2.0%). 60 NITRO had a significantly longer contact time (0.212 ± 0.011s) than 40 EVA (0.209 ± 0.012s, +1.5%). Step frequency, step length, and peak vertical ground reaction force were similar between shoe conditions.

Overall, NITRO had better running economy than firm EVA. In real-world applications, this effect may be larger, as the NITRO shoes were lighter than EVA before weight-matching. Moreover, this reiterates the findings of Tung et al. that more cushioning is not always better [2,3]. However, the same may not be said for modern PEBA materials. While both materials seem to possess a capacity for reducing the "cost of cushioning" of the lower limbs, the mechanical properties of compliance and resilience in the PEBA midsoles may allow for an additional benefit from mechanical energy return, rather than dissipation.

This study has some limitations: the primary issues may be the mass at which the shoes were matched to (465g-515g), compared to typical mass of modern performance shoes (200g-250g). Additionally, longitudinal bending stiffness and rocker geometry cannot be identical between shoes due to their inherent link to stack height.

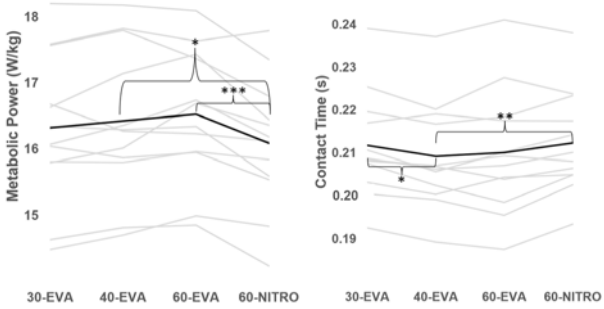

Figure 1 Metabolic power and contact time for all shoe conditions. Grey lines are individuals, and the black lines are group averages. Significance code: *P < 0.05, **P < 0.01, ***P < 0.001.

CONCLUSIONS

Increasing stack height alone does not lead to significant improvements in running economy. However, midsole materials with greater compliance and resilience can significantly improve performance. These findings aid in the future of performance footwear design and the rule creation of the governing bodies of performance running.

The Effect of Initial Condition at the Onset of Stimulation on the Ratio of Muscle Stiffness to Force during Isometric Contraction

Siwoo Jeong[1] and Kiisa C. Nishikawa[2,*]

INTRODUCTION

Active shortening prior to isometric contraction affects the ratio of muscle stiffness to force (SFR) during isometric contraction [1]. Because this result cannot be solely explained by either the sliding filament theory or constant titin stiffness, it suggests that weakly-bound cross bridges or force-dependent titin stiffness may contribute to the varying SFR. However, it still remains unknown how SFR changes during isometric contraction.

To systemetically investigate which sarcomeric elements affect the SFR, we designed an experiment in which muscles develop force isometrically following two different conditions: 1) passive stretch, and 2) passive force enhancement.

METHODS

Maximal isometric force at $1.1L_0$ was established for whole soleus muscles isolated from wild-type mice (n=8). Two protocols were performed: 1) passive stretch (PS) from $0.9L_0$ to $1.1L_0$; and 2) active stretch from $0.9L_0$ to $1.1L_0$, rest for 10s (passive force enhancement, PFE), then held isometrically for four pause durations which allowed isometric force development (100, 200, 400 and 1000ms). Instantaneous muscle stiffness was measured at the four pause durations by a quick transient ($0.9\%L_0$ amplitude at a speed of $3L_0$/s). For comparison, muscle force and stiffness were also measured during isometric contractions (ISO) at $1.1L_0$ without passive or active stretch at the same pause durations after the onset of stimulation.

ANCOVA was used to compare muscle stiffness and force among different conditions (PS, PFE and ISO). Condition was the main effect, individual was a random effect nested within condition, and force was the covariate.

RESULTS AND DISCUSSION

The slopes (ANCOVA, $p < 0.05$) of the relationship between muscle stiffness and force differed significantly among conditions (PS, PFE and ISO). For the PFE condition, the slope was significantly smaller than PS (HSD, $p < 0.05$) and ISO (HSD, $p < 0.05$).

The different slopes of the relationship between muscle stiffness and force cannot be explained solely by cross bridge and/or constant titin stiffness. As isometric force increases, stiffness should increase equally regardless of initial condition given constant titin stiffness, since both muscle stiffness and force depend on the number of formed cross bridges. Therefore, the different slopes imply that titin stiffness changes during isometric force development.

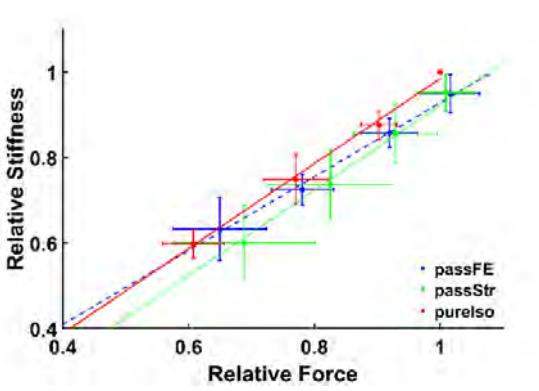

Figure 1. Force vs. Stiffness for PS, PFE and ISO (n=8).

Passive force enhancement is thought to be produced by increasing passive force developed by titin-actin binding [2]. We found that the PFE condition had a significantly different slope from both the PS and the ISO conditions, suggesting that the initial state of titin at the onset of isometric contraction produces a change in titin stiffness during isometric contraction.

CONCLUSIONS

This study shows that passive force enhancement induces different increasing rate of stiffness as muscle force increases. The sliding filament theory and constant titin stiffness are insufficient to explain the result. This finding suggests that titin stiffness changes during development of isometric force depending on the initial state at the onset of isometric contraction.

Preload affects muscle fascicle mechanics during maximal voluntary MTU lengthening actions

INTRODUCTION

Muscle fascicle kinematics can be decoupled from muscle-tendon unit (MTU) kinematics due to MTU compliance, such that muscle fascicles can even shorten during MTU lengthening [1]. Understanding how preload (PL) affects decoupling during MTU lengthening actions is crucial to understand muscle mechanics and subsequent morphological and functional chronic adaptations to MTU-lengthening exercises. Therefore, this study aimed to evaluate how PL affects fascicle mechanics and force output during and following maximal voluntary MTU lengthening actions of the human tibialis anterior (TA).

METHODS

Twelve participants (five women; age (mean±SD): 25.6±2.7 yr) were in a reclined sitting position (~68° recline) with their right foot attached to a modified footplate that was connected to a dynamometer crank arm (~90° between footplate and tibia refers to a 0° ankle angle). The dynamometer (Isomed 2000, Ferstl, Germany) measured torque and crank arm angle. After a standardized warm-up, participants performed three maximal voluntary fixed-end reference contractions at ankle angles of 5° dorsiflexion (REF_S) and 35° plantarflexion (REF_L) in a randomized order. Three maximal voluntary MTU lengthening actions per randomized preload condition were then performed from REF_S to REF_L at 40°/s. PLs were 0% (PL_0), 50% (PL_{50}), and 95% (PL_{95}) of the REF_S peak torque. Participants received real-time visual feedback of their net ankle joint torque during each contraction, which they attempted to match within ±5% of two predefined torque ramps to reach PL levels of 50% and 95%. Participants were also instructed to contract as hard and fast as possible when the dynamometer crank arm started moving and to maintain each contraction for 5 s after MTU lengthening. Torque, crank arm angle, and TA muscle activity were recorded at 2 kHz using a 16-bit analog-digital converter (Power3 1401, CED, UK), and TA muscle fascicle kinematics were recorded at 33 fps using B-mode ultrasound (ArtUs, Telemed, Lithuania).

RESULTS AND DISCUSSION

For PL_0 and PL_{50}, fascicles actively shortened before they actively lengthened during MTU lengthening (Fig. 1). Fascicle lengthening amplitudes increased from 16.2±3.8 mm to 20±4.7 and 23.2±4.3mm for PL_0, PL_{50}, and PL_{95}, respectively. Similarly, negative fascicle work during MTU lengthening increased from -8.7±3.3 J to -11±4.7 J and -12.8 ± 4.7 J for the same respective conditions. Despite different fascicle kinematics, peak torque during MTU lengthening did not differ among conditions, but occurred at different fascicle lengths and ankle joint angles (14.8±4°, 10.9±5.4°, and 7±5.4° for PL_0, PL_{50}, and PL_{95}, respectively). Conversely, peak fascicle force, which was similar among conditions, occurred at similar fascicle lengths (~53.3±11.3 mm), fascicle velocities (~23.6±6.1 mm/s), and ankle angles (~17.5±4.7°). Residual force enhancement (rFE) of ~7% following MTU lengthening was similar among conditions, despite differences in stretch amplitude and in the amount of positive work (1.4±0.8 J, 1.4±1.1 J, and 1.9±1.0 J for PL_0, PL_{50}, and PL_{95}, respectively).

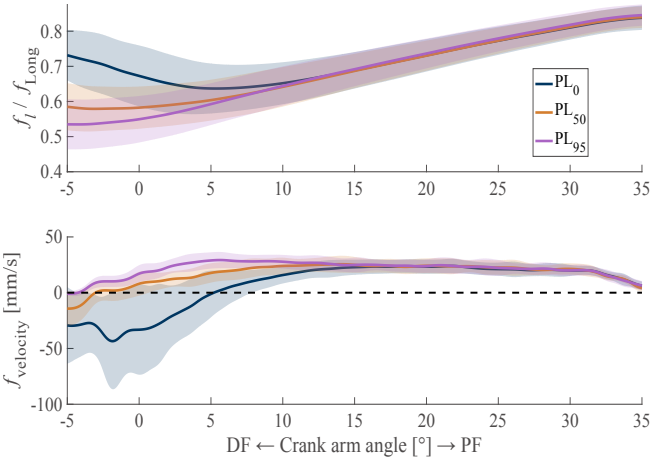

Figure 1: Normalized fascicle length changes (top panel) and fascicle velocities (bottom panel) during maximal voluntary MTU lengthening actions with different preloads (PLs).

CONCLUSIONS

Our results highlight that PL magnitude affects the decoupling of MTU and fascicle behavior, which leads to different fascicle mechanics despite identical joint kinematics. As altered fascicle mechanics during MTU lengthening might induce different chronic morphological and/or functional adaptations following MTU-lengthening exercises, decoupling needs to be considered when designing training programs. Further, rFE seems to be unaffected by positive work magnitudes and stretch amplitudes [2], suggesting that any force depression effect is abolished by the following stretch [3].

MULTISCALE HAMSTRING MUSCLE ADAPTATIONS FOLLOWING A NINE WEEK ECCENTRIC TRAINING PROGRAM

INTRODUCTION

Hamstring strains are one of the most prevalent injuries occurring in high-speed running sports, rising by as much as 4% annually [1]. Eccentric training has been proposed as a potential modality for preventing hamstring injury [2]. However, it is still unknown what muscle adaptations are facilitated by eccentric exercises over longer periods (>3 weeks) [3]. Therefore, we aim to quantify the multiscale hamstring muscle adaptations in response to 9 weeks of eccentric training.

METHODS

Four recreationally active participants (2 males, 2 females out of the 10 participants that are recruited for the ongoing study) completed 9 weeks of eccentric Nordic hamstring training. The training volume totalled 867 repetitions across the 9 weeks. Eccentric hamstring force was measured during the Nordic exercise from load cells measurements at the ankle. Sarcomere and fascicle lengths were measured in vivo using microendoscopy and 3D ultrasound. Resting fascicle length, sarcomere length, and serial sarcomere number (passive fascicle length divided by passive sarcomere length) in the biceps femoris long head muscle in central and distal region were compared before and after the training intervention.

RESULTS AND DISCUSSION

The pilot results (Fig. 1) show that Nordic eccentric training increased eccentric knee flexor force by 54% (p=0.040). Fascicle lengths increased by 19% in the central (p=0.007) and 36% in the distal region (p=0.004). The length of sarcomeres did not change significantly in either the central (p=0.324) or the distal region (p= 0.571). The estimated number of sarcomeres in series increased by 28% in the central (p=0.027) and 46% in the distal region (p=0.027). Overall, an addition of sarcomeres in-series appears to have enabled a conservation of sarcomere length.

CONCLUSIONS

Our study provides novel insights into multiscale hamstring muscle adaptations to eccentric training. Together with a report that showed that sarcomerogenesis is not detectable after 3-weeks of the same eccentric exercise [3], this preliminary work provides the first evidence that prolonged exercise is required to induce additions of sarcomeres in series within muscle fibres.

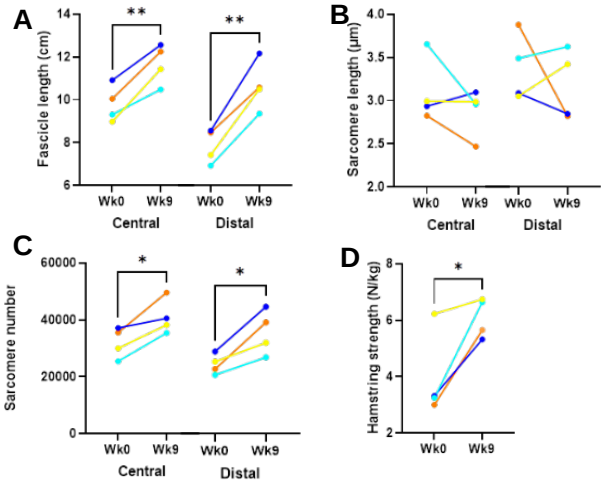

Figure 1. Multiscale Biceps Femoris Long Head muscle adaptations after 9-weeks of Nordic eccentric training. A) fascicle length, B) sarcomere length, C) sarcomere number, and D) eccentric strength. * and ** indicate statistically significant changes (p<0.05).

TYPICALLY DEVELOPING CHILDREN AND CHILDREN WITH CEREBRAL PALSY HAVE SIMILAR LEG MUSCLE MOMENT ARMS

INTRODUCTION

Differences in moment arms between typically developing children and children with cerebral palsy could contribute to the frequently observed differences in joint strength and stiffness. Previous investigations of Achilles tendon moment arms in children with cerebral palsy have reached opposite conclusions, namely that their moment arms are smaller [1] or larger [2] than in typically developing children. These studies used relatively small samples of 8 [1] and 16 [2] children with cerebral palsy. Here, we compare Achilles tendon and tibialis anterior moment arms of 50 children with cerebral palsy and 200 typically developing children.

METHODS

Anatomical MRI scans (mDixon and/or T1-weighted scans) were obtained from the lower legs (including the talus) of 200 typically developing children (117 boys and 83 girls aged 5 to 15 years) and 50 children with cerebral palsy (30 boys and 20 girls, aged 5 to 15 years, 62% GMFCS1, 30% GMFCS2, 8% GMFCS3) while the ankle was in 15 degrees plantarflexion.

The tibia, talus, Achilles tendon and tibialis anterior tendon were semi-automatically segmented from the images. Tibia length was calculated as the maximum distance along the first principal component of the tibia surface model. The ankle joint axis of rotation was estimated as the axis of a cylinder fitted to the talar dome [3]. Moment arms of the Achilles tendon and tibialis anterior tendon were determined as the shortest distance from the joint axis of rotation to a 3rd-order polynomial fitted in 3D through points on the Achilles tendon and tibialis anterior tendon, respectively [3].

The effect of cerebral palsy on the relationship between tibia length and moment arm was examined using multiple linear regression.

RESULTS AND DISCUSSION

Moment arms of the Achilles tendon and tibialis anterior scale linearly with tibia length for both typically developing children and children with cerebral palsy (Fig. 1). In contrast to previous reports, we found no systematic difference in moment arms between children with cerebral palsy and typically developing children (likelihood ratio test p=0.08 for Achilles tendon; p=0.13 for tibialis anterior).

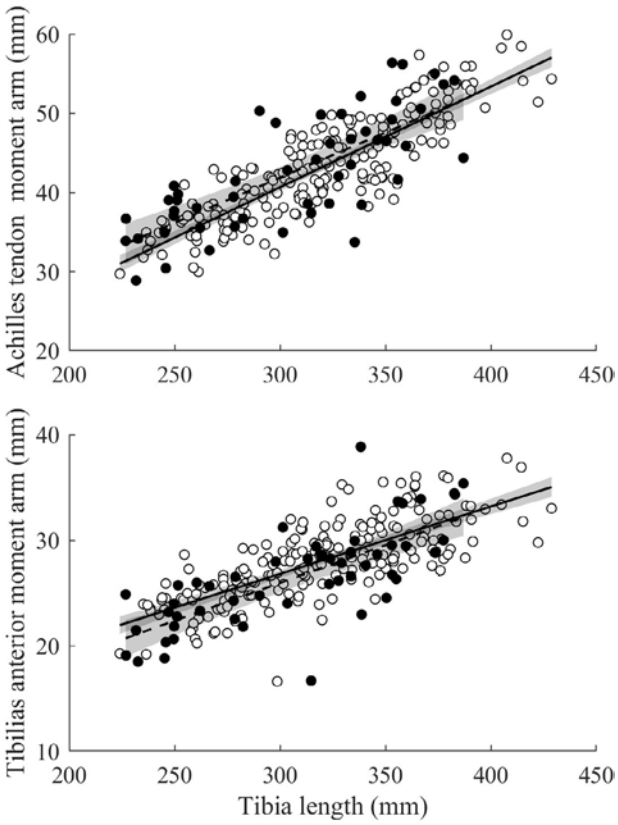

Figure 1 Achilles tendon moment arms (top) and tibialis anterior moment arms (bottom) vs. tibia length for children with cerebral palsy (n=50, black circles, dashed line) and typically developing children (n=200, white circles, solid line). Lines are regression lines and shaded areas are 95% confidence intervals.

CONCLUSIONS

Differences in moment arms around the ankle are unlikely to play a major role in group-level differences in strength and stiffness between typically developing children and children with cerebral palsy.

MUSCLE- AND SEX-SPECIFIC LEG MUSCLE VOLUMES IN CHILDREN WITH CEREBRAL PALSY

INTRODUCTION

Children with cerebral palsy usually have much smaller leg muscles than typically developing children [1-3]. Previous investigations of muscle growth in children with cerebral palsy (CP) either evaluated only one muscle (usually the medial gastrocnemius muscle; e.g., [2]), or investigated multiple muscles on a small sample of children with cerebral palsy [3]. Therefore it is largely unknown if cerebral palsy impairs growth equally across muscles. In this study, we use muscle volume data from 208 typically developing children to develop reference distributions ('growth charts') of the relationship between age and muscle volume for typical lower leg muscle development. We then use the charts to determine where on those distributions the individual muscle volumes of 50 children with cerebral palsy lie.

METHODS

mDixon and T1-weighted MRI scans were acquired from the lower legs of 208 typically developing children (121 boys and 87 girls, including 8 infants aged 0.14 to 0.26 and 200 children aged 5 to 15 years) and 50 children with cerebral palsy (30 boys and 20 girls, age 5 to 15; 62% GMFCS1, 30% GMFCS2, 8% GMFCS3). Volumes of ten lower leg muscles/muscle groups were calculated from surface models which were constructed by semi-automatically segmenting MRI images [4].
Muscle volumes of typically developing children were regressed against age using quantile regression with B-spline basis functions [5]. The models were fitted separately for boys and girls. The regression models were used to create muscle growth charts specific to age, muscle, and sex. Muscle volumes of children with CP were expressed as percentiles from the distributions of typically developing children. For example, a percentile of 10 indicates 10% of typically developing children of the same age have smaller muscles.

RESULTS AND DISCUSSION

Muscle volumes were typically much smaller in children with cerebral palsy than in typically developing children (Fig. 1). The median percentile of total muscle volume for children with cerebral palsy was 11 for boys and 18 for girls. The lowest median percentiles were found for the tibialis anterior (boys: 1, girls: 2.5) and medial gastrocnemius muscles (boys: 1, girls: 10). The highest median percentile was found for the popliteus muscle (boys: 20, girls: 28). For all muscles except tibialis posterior, boys had lower median percentile scores than girls.

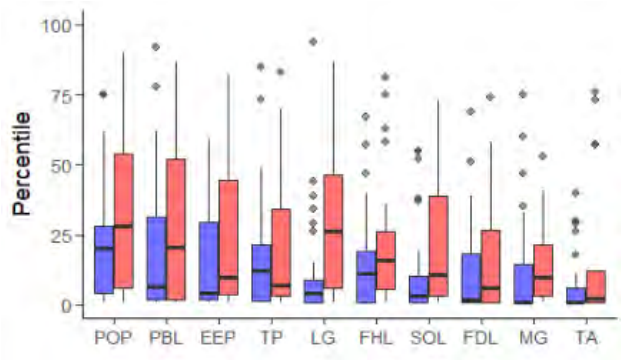

Figure 1 Boxplots of volumes of individual muscles in boys (blue, *n*=30) and girls (red, *n*=20) with cerebral palsy. Boxes span the 1st and 3rd quartile and whiskers span the full range excluding outliers, displayed as dots. POP=popliteus, PBL=peroneus brevis+longus, EEP=extensor digitorum longus, extensor hallucis longus, peroneus tertius, TP=tibialis posterior, LG=lateral gastrocnemius, FHL=flexor hallucis longus, SOL=soleus, FDL=flexor digitorum longus, MG=medial gastrocnemius, TA=tibialis anterior.

CONCLUSIONS

All lower leg muscles of children with CP are typically much smaller than those of typically developing children. While all leg muscles are affected, some muscles – particularly the medial gastrocnemius and tibialis anterior – appear to be more affected than others. Muscles appear to be more affected in boys than in girls.

A NEW MODEL FOR THE MOLECULAR MECHANISM OF MUSCLE CONTRACTION

INTRODUCTION

For more than half a century, muscle contraction has been associated with the contractile proteins actin and myosin in sarcomeres [1]. Just over 20 years ago, we discovered a new mechanical property of skeletal muscle now referred to as "passive force enhancement" [2]. In the following decade, the structural protein titin was identified as the source of this passive force enhancement, and a role for titin in active muscle contraction emerged. However, the detailed molecular mechanims of the interplay between actin, myosin, and titin remain elusive. Here, we propose a new model of muscle contraction that fits current experimental observations. It involves actin and myosin in their traditional roles and adds titin-actin interactions that modulate titin's stiffness/force upon muscle activation.

METHODS

All results presented, and associated formulation of the new model for muscle contraction, were obtained from rabbit psoas single fibre, myofibril, and sarcomere experiments. Fibres, myofibrils, and sarcomeres are isolated and set up in a mechanical testing chamber that allows for controlled activation, controlled length changes and accurate force measurements [e.g., 3]. The results presented here are based on experiments in which preparations were stretched normally, with calcium activation but inhibition of cross-bridge attachment [e.g., 5], with fluorescent anti-body labelling of titin segments [4], and using strong/rapid (<1ms) stretching that caused "slippage" [6].

RESULTS AND DISCUSSION

Active stretching of single fibre, myofibril and sarcomere preparations resulted in an increase in steady-state force following stretching, i.e. "residual force enhancement" (rFE) (Fig. 1). rFE always occurs when preparations are stretched within the limits of their force generating capacity. We also observed that rFE was associated with an increase in titin stiffness and force up to four times its passive value [3], and that this increase in stiffness is associated with a stiffening of the proximal titin segment, likely caused by titin binding to actin [4]. However, this increase in titin-based force did not occur when cross-bridge formation was inhibited or was restricted to the weakly bound state [5]. Similarly, when active myofibrils were stretched rapidly producing slippage, no rFE or increase in titin stiffness/force was observed [6]. ***These results suggest that rFE and increased titin stiffness/force crucially depend on strong actin-myosin cross-bridge formation***. Based on these results we propose the following model for muscle contraction:

(i) When a muscle is activated cross-bridges engage, and titin binds its proximal segment rigidly to actin, thus increasing its stiffness and force.

(ii) Titin-actin interactions do not occur in the presence of activation (calcium) alone and do not occur when the strong cross-bridge state is inhibited chemically, mechanically, or by regulatory protein alteration.

(iii) Since the regulatory protein tropomyosin (TPM) controls cross-bridge attachment through a configurational change, and since further TPM configurational changes occur when cross-bridges go from weakly to strongly bound states, we propose that titin attachment to actin requires the configurational change of TPM when cross-bridges transit from weakly to strongly bound states.

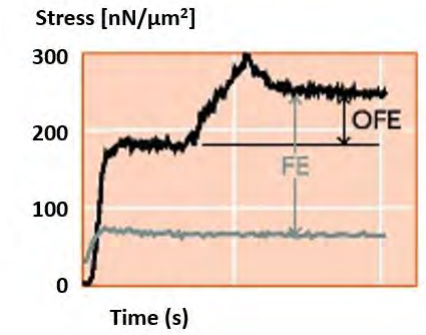

Figure 1 Force enhancement (FE) observed following active stretch (black) compared to a reference isometric contraction (grey) in a single sarcomere preparation.

CONCLUSIONS

Based on our experimental results, we propose that titin-actin interactions, responsible for the rFE property and active force production in skeletal muscle, are controlled by configurational changes of tropomyosin when cross-bridges go from the weakly to the strongly bound state.

IS THE APONEUROSIS PROTECTED FROM GREAT LENGTH CHANGES WHEN ACTIVE MUSCLE FORCES CHANGE DRAMATICALLY?

Fransiska M Bossuyt[1,3*], Sarah Abramovic[2], Tim Leonard[3], Andrew Sawatsky[3], Colin Smith[2], William R. Taylor[2], Walter Herzog[3]

INTRODUCTION

Muscular aponeuoses consist of collagen fibres which transfer forces from the muscle to the tendon in a complex manner [1,2,3]. Given that isolated aponeuroses fail at forces below those observed during active muscle contraction [4], it can be hypothesised that aponeuroses require protection from large elongations when forces are high. The purpose of this study was to compare in-vivo aponeurosis length changes when the muscle forces are high with length changes when the muscle forces are low during locomotion in the Medial Gastrocnemius muscle (MG).

METHODS

In this abstract, we performed new analyses on data that has been published previously [1]. Specifically, sonomicrometry crystals were implanted in the MG of four sheep to measure proximal aponeurosis (i.e., continuation of the short, proximal tendon of the muscle) length changes at 496 Hz and a custom-built buckle-type transducer was implanted to measure muscle forces at 500 Hz. Data were collected while the sheep walked at 8 different combinations of speeds and inclination angles on a motorized treadmill. Force data were filtered using a fourth-order, low-pass (10 Hz), recursive Butterworth filter. Sonomicrometry data were pre-processed using SonoCleaner Software after which a low-pass (50 Hz), fourth-order, recursive Butterworth filter was applied. Absolute aponeurosis length changes were calculated when muscle forces exceeded and were below 30% of the peak force during the respective cycle (see Figure 1 left presenting the selected portion for 7 steps of one condition of one exemplary sheep). Length changes of the loading and unloading phase of at least five consecutive steps for each sheep and locomotion condition were averaged and statistically compared using non-parametric Wilcoxon signed rank test (SPSS Statistical Software with alpha = 0.05).

RESULTS AND DISCUSSION

Due to technical limitations and differences in walking ability between sheep, we focus on one walking speed where aponeurosis length changes were obtained for all four sheep (0.67 m/s). Aponeuroses length changes were about 3 times greater when forces were low (corresponding primarily to the swing phase of walking) compared to length changes when forces were high ($p=0.066$) (primarily stance phase - Figure 1, right). If we were to assume that all data points are truly independent observations, we would observe a highly significant difference in aponeuroses length changes between the high and low muscle force conditions ($p<0.001$). Regardless of sheep or treadmill condition, aponeuroses length changes were always greater when forces were low. We conclude from these results that the sheep MG aponeuroses is protected from large elongations when forces are high. The mechanisms underlying this protection remain unclear.

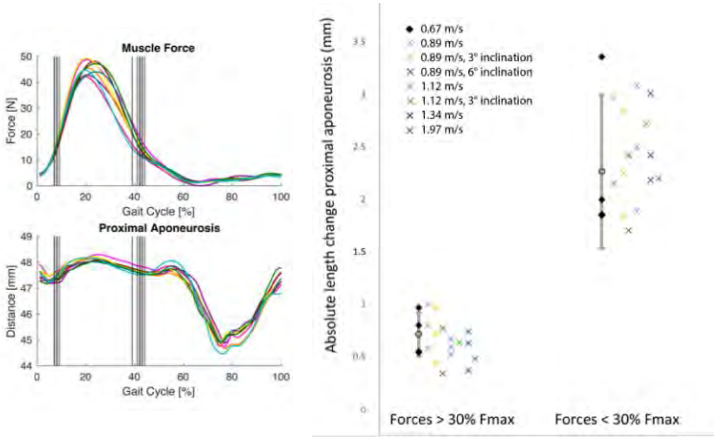

Figure 1: Left: Aponeurosis length and muscle forces of 7 steps of one sheep. Vertical black lines represent cut-off when forces are > or < 30%Fmax for each step. Right: Absolute length changes when forces > 30%Fmax and when forces < 30%Fmax for different conditions (see legend)

CONCLUSIONS

Aponeuroses length changes were small when muscle forces were high and aponeuroses length changes were large when muscle forces were small. High muscle forces were mainly found during the stance phase when the muscle actively produces force while low forces were mainly observed during the swing phase when the muscle only produces passive forces. This result supports the notion that aponeuroses are protected from high forces when muscles are activated. If confirmed in other muscles, it would be of interest to study how this aponeuroses protection works.

RELATHIONSHIP BETWEEN KNEE VALGUS ANGLE AND LATERAL TRUNK BENDING ANGLE DURING VOLLEYBALL SPIKE JUMP

INTRODUCTION

Anterior cruciate ligament (ACL) injuries often occur during jump landings. During jump landing, an increased lateral trunk bending angle increases the knee valgus angle of the bent trunk lateral side, which is a risk factor for ACL injuries. In volleyball, video analysis has shown that ACL injuries occur more commonly during spike jump landing of the nondominant leg, which is thought to be related to trunk movement [1]. However, it is unknown whether lateral trunk bending and the knee valgus angle are affected by ball position during spike jumps. Therefore, the purpose of this study was to investigate whether the relationship between the knee valgus angles and the lateral trunk bending during spike jump landing varies with ball position. We hope this study to provide basic information for the prevention of ACL injuries in volleyball.

METHODS

Fourteen female college volleyball players (20.5 ± 1.8 years) with at least 5 years of experience participated. Participants performed volleyball spike jumps in five trials. The ball positions during the spike jump were set at normal, dominant, and non-dominant positions. The normal position set a line perpendicular to the floor through the acromion. The measurement items were the knee valgus and lateral trunk bending angle at the initial contact (IC) of the spike jump landing using a three-dimensional motion analysis system (Vicon Motion Systems) with a sampling frequency of 100 Hz. The IC was defined as the point at which the ground reaction force exceeded 10 N. Outcomes were confirmed using Pearson correlations to examine the relationship between the knee valgus and lateral trunk bending angles. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

In the kinematic data, a positive correlation was observed between the knee valgus and lateral trunk bending angles in the non-dominant position ($r=0.60$, $p<0.05$). We also observed no association between the knee valgus and lateral trunk bending angles in the normal ($r=0.06$, $p=0.83$) and dominant positions ($r=0.08$, $p=0.77$) (Figure 1).

When the lateral trunk is bent, the center of gravity moves laterally, relative to the hip and knee. This causes an increase in the knee valgus angle [2]. In badminton, players must bend their lateral trunk to the non-dominant side when hitting the shuttle in the non-dominant position because the head interrupts the swing [3]. Volleyball has the similar situation when hitting the ball in a non-dominant position during the spike jump. Therefore, the lateral trunk was more bent to the non-dominant side, and the knee valgus angle increased when hitting the ball in the non-dominant position.

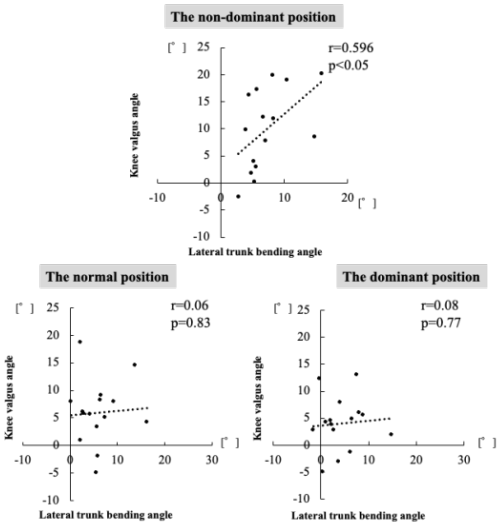

Figure 1 Relationship between the knee valgus angle and lateral trunk bending angle

CONCLUSIONS

This study showed that when the ball was in the non-dominant position, a positive correlation was observed between the knee valgus and lateral trunk bending angles, which may increase the risk of ACL injuries. It is very important that volleyball players and coaches understand the situation and posture that often cause ACL injuries in volleyball. This study might be helpful for the idea and fundamental information which is teaching players and coaches landing techniques and training methods to prevent ACL injuries.

INTRODUCTION

The armstroke in the crawl swimming is important since it mainly contributes to the thrust generation. The optimum armstrokes were solved by optimizating simulation for swimmers without any physical disability [1,2], with hemiplegia [3] and with unilateral transradial deficiency [4]. In those optimizaing simulations, the joint torque characteristics database, which was constructed based on experiments and musculoskeletal simulation [1], were always used as the constraints. However, since the joint torque characteristics vary according to individual, the optimum armstroke for each individual is also considered to vary. For this problem, a framework to solve the optimum armstroke considering subject-specific shoulder joint torque characteristics was proposed in this study.

METHODS

In the framework, the subject-specific shoulder joint torque has to be acquired to customize the database, which is used for the optimizing calculation. For this purpose, the specially customized swim ergometer was developed (Figure 1a). As the basic mechanism as a swim ergometer, paddles are attached to both hands of a participant, who pulls wires in the manner similar to the armstroke of the crawl swimming. The wires draw back automatically during the recovery stroke. The pulling speed of the wires is limited by a ratchet mechanism and an electric motor. The limit pulling speed can be changed by changing the rotational speed of the motor. When the pulling speed by a participant is slower than the designated one, no load acts on the paddles. However, if the pulling speed reaches the designated speed, it becomes very difficult for the participant to pull the wire at higher speed due to the ratchet mechanism. As a result, the pulling speed becomes constant for a certain period. The tension of the wire for the right hand is measured by a load cell. Using the developed ergometer, an experiment was conducted in which two male collegiate competitive swimmers participated. In addition to the measurement of the tension of the wire, an optical motion capture system (MAC3D, Motion Analysis Corp.) was used to measure the body motion. Nine infrared reflective markers were attached to the participants. The participants were asked to perform five armstrokes continuously on the ergometer for the three speeds of slow, medium and high and for the five styles of strokes (normal, horizontally flexed, horizontally extended, internally rotated, and externally rotated).

RESULTS AND DISCUSSION

As examples, the adduction angular velocity and joint torque at the shoulder in the case of medium speed and normal style of stroke are shown, respectively (Figure 1b,c). The averages for the five cycles were taken and two peak points are plotted in the graph for the peaks of the adduction angular velocity (green) and the joint torque (blue). The two values of joint torque at the two peak points were taken. Since such two joint torque values were obtained in one trial, 30 values (3 speeds times 5 stroke style) were obtained for one participant. These 30 values were used to modify the joint torque characteristics database.

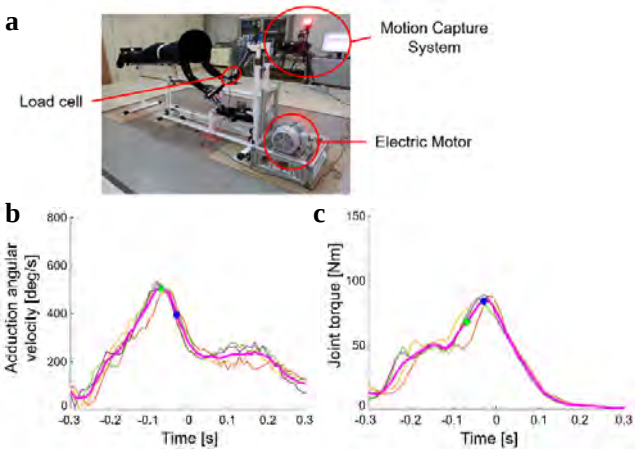

Figure 1 The specially customized swim ergometer (a), results of adduction angular velocity (b) and shoulder joint torque (c).

CONCLUSIONS

A framework to solve the optimum armstroke in crawl swimming considering subject specific shoulder joint torque characteristics was proposed. The shoulder joint torque characteristics database is next modified according to the acquired joint torque data. The optimizing simulation is finally conducted. The results of optimization are presented in the conference.

BARBELL SQUATS FOR CROSSFIT ATHLETES: EFFECT OF FOOTWEAR TYPE AND LOAD MAGNITUDE ON LOWER LIMB JOINT TORQUES

INTRODUCTION

In strength training practice, it is commonly assumed that increasing load during barbell squats results in a proportional increase in the magnitude of joint torques. However, kinematic changes resulting from larger loads may affect this assumption [1]. In some sports, such as CrossFit and Olympic weightlifting, the use of a footwear that elevate the heel in relation to forefoot (i.e., "lifter shoes") is very common. These shoes elicit changes in kinematics that help to overcome limitations on ankle dorsiflexion range of motion and may also affect the contributions of joint torques during squats [2]. In this study, we aimed to test the effects of the type of footwear and load magnitude on the hip, knee, and ankle torques during barbell squats.

METHODS

Sixteen (8M, 8W) professional CrossFit athletes had their three-repetition maximum (3RM) squat load and ankle range of motion assessed. With eight cameras (Vicon-Motion-Systems) and two force plates (AMTI), we conducted a three-dimensional analysis of three repetitions of barbell squat with a load of 50%, 70% and 90% of the 3RM, using a lifter shoe and a control non-lifter shoe (six randomized conditions). Through inverse dynamics, the resultant extensor (or plantar flexor) torques around the hip, knee and ankle were calculated. Torques were normalized to participants' mass and height. A two-factor (footwear and load) repeated measures ANOVA was used ($p<0.05$) to compare joint torques at the instant of maximum total lower limb extensor torque, i.e., when the sum of hip, knee and ankle torques reached its maximum. A statistical parametric mapping approach is being used to compare torque curves, but these results will only be available for presentation in the conference and therefore are not shown in this abstract.

RESULTS AND DISCUSSION

There were no interactions between the effects of load and footwear for the ankle ($p=0.59$), knee ($p=0.89$), and hip ($p=0.89$) torques. Additionally, no effect of footwear on joint torques was observed for hip ($p=0.94$), knee ($p=0.79$), and ankle ($p=0.82$) torques (Table 1). An increase in load resulted in a larger plantar flexor ($p<0.01$), and hip extensor ($p<0.01$) torques (Figure 1). No difference in knee extensor torque was observed across loads ($p=0.59$) (Figure 1). Contrary to what is often assumed, our experimental findings indicate that increasing load does not necessarily increase all lower limb joint torques and is not effective in increasing the demand on the knee extensor muscles during squats, regardless of the type of footwear. The absence of footwear effects might be related to the characteristics of the sample analyzed, such as a wide ankle dorsiflexion range of motion (54° ± 2.5°) and high-level competitive experience (3 years).

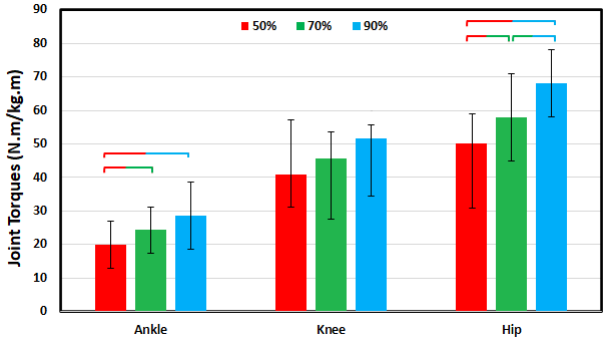

Figure 1 Normalized joint torques during barbell squats at different percentages of three-repetition maximum load. Results were pooled across footwear conditions and brackets show differences at $p<0.05$.

CONCLUSIONS

For professional CrossFit athletes, regardless of footwear, increasing external load from 50% to 90% of 3RM in the barbell squat seem to affect hip and ankle torques, but not knee torques. The analysis of torque curves using statistical parametric mapping will help to better understand these effects.

INTRODUCTION

Running specific prostheses (RSPs) are assistive technologies specifically designed for elite athletes to reach their maximal performance in running competitions. RSPs comprise a custom-made socket, which hosts the residual limb, and a running prosthetic foot (RPF), a carbon-made curved blade. Depending on the amputation level, the RPF is directly clamped to the socket or linked via a knee or pylon to it. The selection of the appropriate RPF is essential to provide balance between flexibility and strength, allowing the athlete to express the maximum potential without putting the physical health at risk. A mechanical test bench was previously designed and constructed for evaluating ankle-foot prostheses [1], by reproducing the biomechanical patterns associated with gait related tasks on the prosthesis in an objective, repeatable, controllable and safe manner. Coming from this background, the aim of the work was the adaptation of such walking simulator into a running simulator for RPF.

METHODS

The test bench has three servo-pneumatic actuators that control simultaneously three degrees of freedom (DOFs) on the sagittal plane, namely the shank rotation around a fixed axis (θ_{shank}), the shank longitudinal displacement and the ground horizontal displacement. The composition of these two latter non-orthogonal DOFs allows to reproduce any relative translation of the shank in the sagittal plane and the corresponding ground reaction force (GRF), measured with a 6-axis load cell placed underneath the moving ground.

Actuators are controlled in position with the implementation of a two-level control architecture: on the low level a commercial controller, on the high level an iterative self-learning algorithm. The control method consists in performing a first iteration of the running simulation using tentative curves and generating new control curves for the following iteration, based on the difference between the simulated results and the reference data. This procedure is repeated until a target of difference between the signals is reached.

The reference data (θ_{shank}, GRF_x, and GRF_y) are retrieved from a previous *in-door* study of the research group [2]. The study involved a unilateral transfemoral medalist athlete (female, height $166cm$, mass $58kg$) running on a commercial treadmill placed over 4 force platforms, while 8 motion capture cameras captured the athlete's kinematics.

RESULTS AND DISCUSSION

The simulator stance duration was increased 8 times ($1.36s$) compared to the original stance duration ($0.17s$) since pneumatic actuators are not powerful enough to withstand the variable inertial loads generated by the rotating shank segment of the simulator at faster speed, leading to system instability. Moreover, pneumatic actuators suffer from internal frictions that resulted in disturbances and difficulties in achieving accurate position control.

However, the comparison between the averaged simulated (blue) and reference (red) signals overall proved that good results were achieved after 13 iterations of the process (Figure 1).

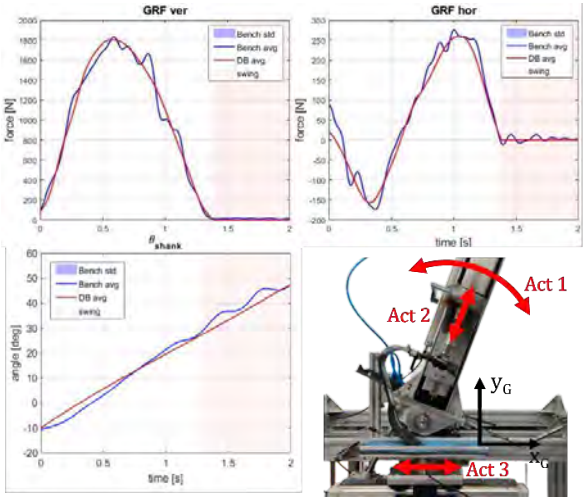

Figure 1 θ_{shank}, GRF_x, and GRF_y results at the 13th iteration of the process. The three DOFs and the Ground reference system are displayed with red and black arrows in the picture of the simulator.

CONCLUSIONS

A robotic walking simulator was adapted to simulate the running cycle of an elite athlete, reproducing collected biomechanical data (θ_{shank}, GRF_x, and GRF_y) with reference data. The agreement between test results validated the running simulator as an *in-vitro* testing scenario to replicate the running cycle and evaluate RPF performance in an objective, controllable and safe manner. Future work will be focused on the improvement of both the tracking performances and the automatic analysis capabilities.

KNEE BIOMECHANICAL DIFFERENCES DURING UNILATERAL LANDING BETWEEN SYMMETRICAL AND ASYMMETRICAL GROUPS CLASSIFIED BY HOP TESTS

INTRODUCTION

Hop tests are used to stratify athletes for risk of injury, post-surgical recovery milestones and return to sport clearance [1]. A 10% performance criterion is broadly used to determine asymmetry in these tests, yet this is somewhat arbitrary [2]. In addition to performance criteria, we need to identify whether performance asymmetry translates into biomechanical differences. Therefore, we aimed to identify whether knee biomechanical differences exist during unilateral landings between symmetrical and asymmetrical groups as identified by hop test performance in male recreational athletes.

METHODS

Fourty-seven healthy men with a mean age (standard deviation) of 25 (3) years old, body mass of 81 (13) kg, height of 177 (7) cm, Tegner physical activity level of 5 (2), knee function in the Lysholm scale of 92 (7) were evaluated. Thirty-nine participants identified their right leg as their preferred leg to kick a ball. Participants performed single, triple and crossover hop tests for distance followed by unilateral drop jumps for biomechanical assessment. Maximal distance by each hop test and a mean of 3 trials of unilateral drop jumps were considered. Knee sagittal plane angle and moment were determined for the landing cycle of 2nd landing [101 points, from initial contact (threshold of 20 N) to the maximal knee flexion].

The participants were classified into symmetrical and asymmetrical groups according to their performance on the single, triple and crossover hops using the criteria of 10% (90 to 110% were considered symmetrical). The agreement between hop classification was assessed by Kappa coefficient. To determine group differences in the temporal series, a two-way functional analysis of variance for repeated measures was applied considering the factors leg (preferred vs . non-preferred) and group (symmetrical vs. asymmetrical) for each classification.

RESULTS AND DISCUSSION

The hop tests classification presented poor agreement among them (single vs. triple: 0.094; single vs. crossover: 0.097; triple vs. crossover: 0.109).

Considering the asymmetry classification during single and triple hop tests, no differences existed between groups or group*leg interaction for knee sagittal plane angles and moments. Knee sagittal angles did not present an effect of group or group*leg interaction considering the crossover hop test classification. However, there was a main group effect for knee sagittal moment. The symmetrical group presented a higher knee flexion moment from 34 to 71% of the landing cycle (Figure 1).

CONCLUSIONS

Asymmetry in the hop tests does not correspond to differences in biomechanical outcomes related to knee sagittal plane kinematics. However, crossover hop test asymmetry classifications can identify some differences in the unilateral landing kinetics; the asymmetrical group landed with lower knee flexion moment in the mid-phase of the landing cycle.

Risk Factor Identification of Adductor Strain in Professional Soccer

Rebecca Davis[1], Benjamin Brewer, MS[2], Martha Hall, PhD[1,3], Jill Higginson, PhD[1,3]
[1] Biomechanics and Movement Science, University of Delaware, Newark, United States

Email: davisrl@udel.edu

INTRODUCTION

Adductor injuries are among the most common hip and groin injuries that occur in soccer and have been found to account for up to 23% of all muscle injuries in a 15-year Union of European Football Associations study.[1,2] These types of injuries have been found to take a median of 14-22 days away from play but depending on the grade of strain can result in missing months.[3,4] This negatively impacts an athlete's playing exposure and career longevity as prior injury has been found to greatly increase the risk of getting a future adductor injury.[3] Determining injury risk factors allow us to understand the causal mechanisms of injury and can make staff aware of the most at-risk player groups. This will save players time and reduce the occurrence of future injuries.

METHODS

Injury data was collected from a professional soccer team from 2016-2021. This included 79 total male athletes (age 25±5.4 years); 17 experienced adductor strain (age 27±4.2 years). We identified the injury types, amount, and mechanism of injury (MOI) with a focus on adductor strain in this population. Position types included Goalkeepers, Forwards, Defenders, and Midfielders. Preseason adductor, abductor, and hamstring strength data were collected from the VALD Forceframe™ and Nordbord™. We assessed previous injury and >15% strength imbalances as risk factors for preventable lower extremity (LE) and adductor injuries. Preventable injuries are defined as any soft tissue injury due to non-contact mechanism that was reported by a player and recorded in the injury log by medical staff. Chi-squared tests, Generalized estimating equations (GEEs) and Random Forest algorithms were used to identify which variables are best able to predict injury outcomes.

RESULTS AND DISCUSSION

Hamstring strains, ankle sprains, and adductor strains accounted for the greatest amount of injuries. Adductor strains made up 15.8% of all preventable LE injuries (n=27). Of these injuries, change of direction, overuse, and running made up 70% of all mechanisms shown in Figure 1. Midfielders had the most amount of adductor injuries but also had the most amount of players in a position group. By position type, 25% of Goalkeepers 23% of Defenders, 18% of Midfielders, and 10% of Forwards had adductor strains during this time.

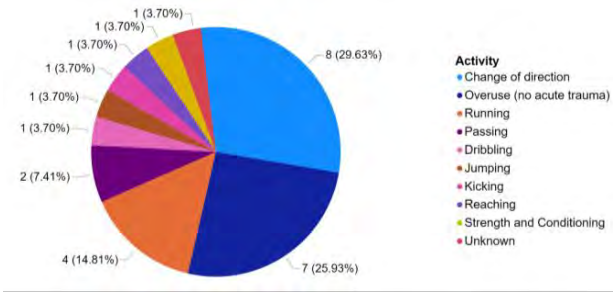

Fig 4. Adductor strain MOI (n=27) from 2016-2021

2021 preseason data showed athletes with >15% average adductor strength imbalance were more likely to experience a LE injury than individuals who did not have a >15% imbalance. No other significant differences in imbalance metrics were identified.
From the GEE, players who had a previous adductor strain were estimated to have 146 times the odds of adductor injury in a future half-season compared to a player who had no previous adductor strain ($p<0.0001$). Position type had no significant effect on an athlete's risk of future injury.

CONCLUSIONS

Our findings support that previous adductor strain is a risk factor for re-injury. Athletes with >15% average adductor strength were more likely to experience a LE injury. Greater evidence with the use of appropriate machine learning algorithms is needed to identify adductor strain risk factors. Further research will include identifying relationships between time since injury and utilizing metrics that can be linked to adductor strain etiology. Risk factor identification for adductor strains has the potential to create better preventative protocols and reduce the risk of injury. This will not only save players time away from play but also save teams money to rehab these athletes.

INTRODUCTION

Landing heel first has been associated with elevated external knee abduction moments (KAM) [1], thereby potentially increasing the risk of sustaining a non-contact ACL injury [2]. Apart from the foot strike angle (FSA), knee valgus angle (VAL) and vertical center of mass velocity (vVEL) at initial ground contact (IC) have been associated with increased KAM in females across different sidestep cuts [3]. While real-time biofeedback training has been proven effective for gait retraining [4], the highly dynamic, non-cyclical nature of cutting maneuvers makes real-time feedback unsuitable and alternative approaches necessary. This study aimed at assessing the efficacy of immediate software-aided feedback on cutting technique in reducing KAM during handball-specific cutting maneuvers.

METHODS

Full-body kinematics (23 Qualisys cameras, 200 Hz) and ground reaction forces (two AMTI force platforms, 1000 Hz) of 50 female handball players (16.7 ± 0.9 years, 1.73 ± 0.07 m, 69.5 ± 9.9 kg) were captured during handball-specific sidestep cuts [5]. Players performed three baseline (PRE) cuts on each leg while peak KAM during early stance and technique variables at IC (FSA, VAL, and vVEL) were calculated immediately (< 3 seconds) upon completion using a custom-made MATLAB (The MathWorks, Inc., USA) application. Following PRE cuts, players received visual and verbal leg-specific feedback on KAM and technique. Critical thresholds for KAM and technique variable magnitudes were defined based on an existing dataset [3] and used for the systematic and organized feedback (Figure 1). Visual feedback was provided on a screen by means of bar graphs indicating KAM and technique variable magnitudes for each cut and a stick figure representing the posture at IC. Following each round of feedback, three more cuts on each leg were performed that were all preceded by combined internal and external cues to facilitate the desired changes in biomechanics. Data were checked for normality, and paired-samples *t*-tests (α = .05) were applied to compare PRE and POST KAM and technique independent of the degree to which the athletes adhered to the feedback. Effect sizes for normally and non-normally distributed data were calculated using Cohen's *d* and matched rank biserial correlation (r_{rb}), respectively.

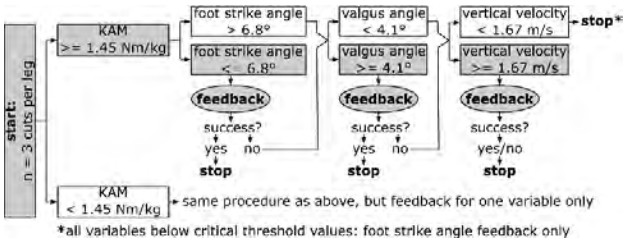

Figure 1 Procedure defining critical thresholds and feedback selection. Feedback was deemed successful if the mean post-feedback external knee abduction moment (KAM) of the three subsequent cuts fell below the predefined threshold of 1.45 Nm/kg.

RESULTS AND DISCUSSION

KAM significantly decreased after feedback (Table 1) aiming at adopting a forefoot strike (-14%, r_{rb} = .41, p < .001) and reducing VAL (-16%, d = .61, p = .019). FSA improved and VAL decreased, on average, by 10.7° (p < .001) and 1.4° (p = .020), respectively. No significant difference in KAM (8%, d = .23, p = .279) was found after feedback aiming at reducing vVEL (-16%, p = .006), however, this feedback was given seven times only as opposed to 79 and 18 times for feedback aiming at achieving a (more pronounced) forefoot strike and a reduction in VAL, respectively (Table 1).

CONCLUSIONS

Immediate individualized feedback on cutting technique shows great potential for reducing KAM and therefore ACL injury risk. Future studies are needed to assess if technique modifications can be retained.

CORTICOKINEMATIC COHERECE: A PROPRIOCEPTIVE BIOMARKER FOR MOTOR PERFORMANCE

Scott Mongold[1], Christian Georgiev[1], Thomas Legrand[1] and Mathieu Bourguignon[1]
[1]Laboratory of Neurophysiology and Movement Biomechanics, Université libre de Bruxelles, Brussels, Belgium.
Email: scott.mongold@ulb.be

INTRODUCTION

Voluntary movement is made possible by a complex neural network spanning the brain, spinal cord, and muscles. Information propagates bidirectionally, as motor commands to the periphery, and as sensory information to the spinal cord and brain. Crucially, much of our understanding of motor performance and the coordination of muscles stems from the former. However, when the processing of proprioception is disrupted, efficient voluntary movement is compromised [1]. Corticokinematic coherence (CKC) is the coupling between brain and movement kinematics that occurs during repetitive movement and is thought to assess the cortical processing of somatosensory afferences [2,3]. Therefore, CKC could complement current assessments of physical performance by highlighting how the brain tracks sensory information. In light of this, we aim to explore whether CKC predicts motor performance.

METHODS

Thirty-seven healthy young adults (21 females) participated in the study. They were fit with an EEG cap (64 electrodes, ANT Neuro) and with EMG electrodes on first dorsal interosseous, biceps brachii, and anterior deltoid (Figure 1). Brain and muscle activity were recorded during 3 trials of the Box and Blocks test (BBT) (Figure 1A). Without brain/muscle recording, participants completed 5 trials of one subtest of the Purdue Pegboard Test (PPT), in which only the right hand was used. CKC was estimated as the coherence between EEG and rectified EMG amplitude. Cross-correlation and mutual information analyses, together with auto-correlation analysis were incorporated to assess coordination and regularity.

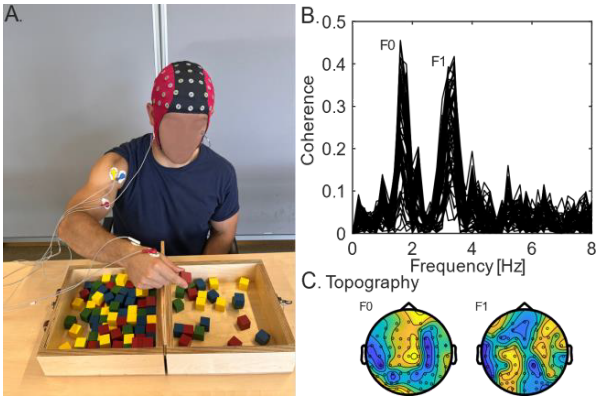

Figure 1. BBT recording set-up (A), and representative Coherence (B) and Topography (C) plots.

RESULTS AND DISCUSSION

In line with previous studies, CKC peaked at movement frequency (F0) and its first harmonic (F1; Figure 1B) with a topography compatible with a sensorimotor cortical origin (Figure 1C) [2,3], confirming that this method can be used in a more dynamic task, as compared to traditional finger tapping [4]. CKC at F1 (but not F0) correlated significantly with BBT scores and PPT scores (BBT, $r = 0.44$; $p = 0.005$; PPT, $r = 0.37$; $p = 0.022$), indicating a behavioral advantage of enhanced CKC, compatible with more effective proprioceptive processing. In addition, CKC at F1 showed no relationship with measures of coordination or regularity ($p > 0.05$). This lack of relationship suggests that CKC indeed captures meaningful information unique to cortical processing. Finally, BBT scores were not correlated with the measures of coordination and regularity ($p > 0.05$). There could be two main—and non-exclusive—reasons for this absence of relationship. First, it could be that regularity and coordination are not adequately captured by muscle activation pattern analyses only. Second, in a task where joint trajectories vary, other aspects of motor control such as flexibility and visuo-motor integration, are more important than coordination and regularity.

CONCLUSIONS

BBT and PPT scores are associated with the cortical processing of kinematic activity, in the form of CKC, indicating that efficient proprioceptive processing may be a functionally relevant contributor to motor performance. Future work should continue to develop CKC as a neuroimaging and biomechanical method to be used as a diagnostic, during clinical follow-ups, or in the sport setting, where risk and talent identification is increasingly quantified.

INTRODUCTION

Spasticity and hypertonia are common symptoms of stroke and cerebral palsy. Literature has suggested that a hyperactive stretch reflex may bear some responsibility. Additionally, literature has suggested that spasticity and hypertonia can be ameliorated through the application of vibrations [1]. As such, the purpose of this pilot study was to investigate what effects local vibration therapy has on stretch reflex modulation. Effects were measured using the H-reflex, a technique which uses the same neural pathway as the stretch reflex [2], but is externally triggered electrically rather than through muscle spindles [3].

METHODS

Ethical approval was received from the New Zealand Health and Disability Ethics Committee. H-reflex was performed on five healthy typically developed adults. Subjects were tested while being seated on a chair, with knee joint angle of 120°, while remaining still with muscles relaxed throughout the experimentation.

The H-reflex setup and recruitment curve protocols were based on that found in the literature [4]. The following experiments were performed with stimulation levels of $H_{50\%}$ determined by the participants recruitment curve.

1. H-reflex during and post 1s of vibration applied to the lateral gastrocnemius and tendon.
2. H-reflex post 1min of continuous vibration to the lateral gastrocnemius and tendon.
3. H-reflex during 1s of vibration to the muscle belly, tendon, and proximal region of the rectus femoris, both ipsi- and contra-lateral.

Five H-reflex baseline and intervention trials were performed for each experiment. Data comparisons followed a within-subjects design.

RESULTS AND DISCUSSION

Subplot A in Figure 1 illustrates the impact 1s vibration has on the H-reflex. As can be seen, the H-reflex was reduced by ~80% during vibration applied to the lateral gastrocnemius muscle belly and tendon. Post 1s vibration, this dampening effect was reduced to ~30%. Effects were greater on the tendon.

Subplot B shows the response in the H-reflex following 1min of vibration applied to the muscle belly and tendon. As can be seen, the tendon appears to have a greater dampening effect on the H-reflex than the belly.

Subplot C illustrates the effect that vibration location has on the dampening effect of the H-reflex. Vibrations applied to the muscle belly and tendon resulted in the greatest dampening, approximately 80% and 75% respectively. The thigh has a smaller effect, this effect was greater with a higher frequency. Vibrations applied to the opposite thigh had the least effect, causing an H-reflex reduction of <%10.

Comparing subplots, the data indicates that the dampening effect persisted longer after 1min of vibration compared to 1s.

According to these findings, vibration has a dampening effect on the H-reflex, with this effect being heightened on the tendon. It can also be said that the effects of vibration persist beyond the time of vibration, albeit attenuating rapidly. Increasing the frequency also appears to prolong the attenuation, however, this can be lost depending on the distance from the target muscle.

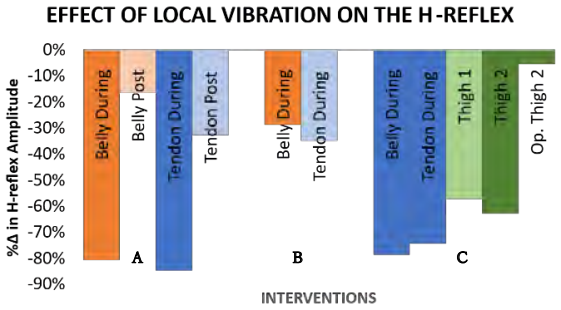

Figure 1 A: H-reflex during and post 1s vibration to muscle belly and tendon. B: H-reflex after 1min of vibration applied to the muscle belly and tendon. C: Influence of vibration location on H-reflex. Captured during 1s vibration

CONCLUSIONS

This study has found that local vibration does indeed have an impact on the H-reflex. Additionally, it has been confirmed that vibration location and duration influence the effect vibrations has on the H-reflex. Greatest effects were achieved by vibrating the muscle tendon.

COMPENSATORY COVARIATION OF BALL LAUNCH VARIABLES IN TENNIS STROKES

INTRODUCTION

Accurate groundstrokes are crucial in tennis. To maintain the accuracy of the shots, there are two ways regarding the ball motion. One is to reduce the variability of the ball launch variables (initial position, velocity, and angular velocity), and the other is to use compensatory covariation of the variables. The compensatory covariation works to maintain the ball landing position regardless of the amount of variance in the launch variables. For example, an increase in launch angle with an increase in angular speed is considered compensatory covariation if the increase in ball flight distance due to the increase in launch angle is reduced by the increase in angular speed. In other words, the compensatory covariation stabilizes the results. In all ball launch variables, ball speed (BS), launch angle (LA), and angular speed (AS) have a considerable effect on the ball landing position, and these variables are determined by the racket motion. Therefore, this study investigates the compensatory covariation among these ball launch variables and their relationship to the racket motion in the tennis groundstrokes of skilled players.

METHODS

Nine collegiate tennis players (age: 19.9 ± 1.2 years, playing experience: 9.1 ± 3.2 years) participated in the experiment. They hit 43 forehand groundstrokes as accurately as possible towards the target on the opposite side of the court. Racket and ball movements were recorded using an optical motion capture system. Ball landing positions were calculated by integrating the equation of motion of a flying ball, taking into account drag and lift forces. The effect of covariation between specific launch variables can be evaluated by comparing hypothetical data sets in which covariation is broken with those in which it is maintained [1,2], as follows. One hypothetical data set was created from the original data set by shuffling all launch variables so that all shuffled variables have no covariation with the other variables (S_All). The other hypothetical data sets were created by shuffling all launch variables except two or three selected variables so that the selected variables retained covariation (S_Selected). The standard deviations of the ball landing position in the hitting direction were calculated from S_All (SD_{ALL}) and S_Selected ($SD_{Selected}$). The Covariation Index (CI) was defined as

$$CI = SD_{Selected}/SD_{ALL},$$

to evaluate the effect of covariation between/among the selected variables. CI statistically less than one indicates the existence of compensatory covariation due to the improvement of the stability of the ball landing position, while CI statistically greater than one indicates the existence of unfavorable covariation due to the deterioration of the stability of the ball landing position. The correlations between the racket swing kinematics just before the ball impact were also calculated to evaluate the effect of the swing motion on the covariation between the ball variables.

RESULTS AND DISCUSSION

The compensatory covariation existed between BS and LA but the compensatory covariation was not observed among BS, LA, and AS (Figure 1). This means that AS breaks the compensatory covariation between BS and LA. This break could be explained by the positive correlation (r = .43) between vertical swing angle and racket face angle (both upward positive). LA increases as the swing angle increases and AS decreases as the racket face angle increases. Both the increase in LA and the decrease in AS could lengthen the ball flight distance, therefore the positive correlation between the vertical swing angle and the racket face angle could break the compensation. The reason for this correlation would reflect the characteristics of the swing motion. Players could not freely adjust the direction of the racket face because they usually immobilize their arms near impact by co-contracting upper extremity muscles [3], which may be due to preparation for impact. When the wrist and elbow are immobilized, the change in shoulder angle affects both the direction of the swing and the face angle. Therefore, the face angle tends to deviate for the same direction for the swing angle.

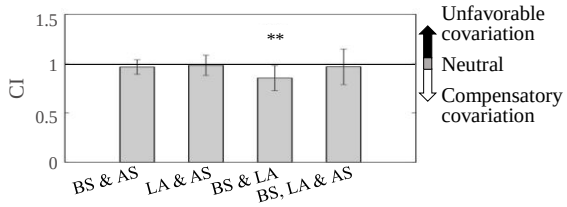

Figure 1 Covariation Index (CI) for all combinations of ball speed (BS), lunch angle (LA), and angular speed (AS). CI less than one indicates compensatory covariation. (**: $p < .01$)

CONCLUSIONS

In the tennis strokes of skilled players, although the ball speed and the launch angle showed compensatory covariation, the ball angular speed broke this compensation. This was due to the correlation between the vertical swing angle and the racket face angle. This correlation could be due to the immobilization of the arm just before impact.

INVESTIGATION OF SENSOR-EMBEDDED KEY TO QUANTIFY DYNAMIC PINCH FORCE DURING KEY TURNING IN YOUNG VS OLDER HEALTHY ADULTS

Li Jing Soh, Jun Liang Lau, Lek Syn Lim, Eloise Lie and Phyllis Liang
Rehabilitation Research Institute of Singapore, Singapore.
Email: junliang.lau@ntu.edu.sg

INTRODUCTION

In rehabilitation, clinical assessments such as Wolf Motor Function Test (WMFT) that tracks motor recovery is essential. Sensor-based measurement can provide more quantifiable assessment in a precise, dynamic and unobstructed manner. Currently, it is known that load cell sensors can measure dynamic pinch force [1]. However, little is known about the dynamic pinch force of healthy adults. In addition, the influence of essential factors, such as key dimension, age and gender, should be carefully considered to allow systematic comparison across groups [2]. Hence, this study sought to provide a standardized instrumented key for systematic dynamic pinch force collection and present the preliminary data of young and older healthy adults.

METHODS

The data were collected from two groups of 10 healthy right-handed subjects from age-group 21-30 (M = 23.8, SD = 3.2, five females and five males) and 61-70 (M = 66.5, SD = 4.5, seven females and three males) to reflect the difference in dynamic pinch force produced between thumb and index finger among the groups. The key module was modified with a miniature load cell placed between a gap of 6.3mm to collect the dynamic pinch force and key turning angle (Fig. 1a). Participants were asked to grasp the sensor-embedded key and turn the key 180° clockwise and then counter-clockwise in a single action six times at the fastest speed. As a result, the right hand begins pronated to supinated, then back to pronated; the left-hand starts in the opposite order. For more information on the motion tasks and key module, kindly refer to the previous paper [3].

RESULTS AND DISCUSSION

The signals were sampled at 200Hz and post-processed with a 6 Hz low-pass filter (second order Butterworth) using R statistical language. During the execution motion of the key turning, the force profile displays a regular bimodal pattern and can be segmented into three phases based on turning angle (Fig. 1b). The force tends to peak at the end of the first and second phases, then drops to zero during the third phase. The older group exerts significantly higher force than the young group for both hands, with $p=0.0353$ for the right hand and $p=0.0224$ for the left hand *(p-value ≤ 0.05)* using t-test statistical method (Fig. 2). In addition, the older group displays significantly higher variance in force than young group for both hands with $p=0.0038$ for the right hand and $p=0.0021\ x10^{-3}$ for the left hand *(p-value ≤ 0.05)* using F-test statistical method (Fig. 2).

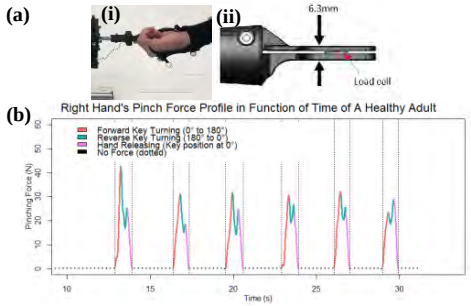

Figure 1 (a) (i) Actual instrumented key with embedded sensor, **(ii)** CAD model with the key module, **(b)** Right hand's dynamic pinch force profile of a representative participant across six repetitions of a key turning. Windows enclosed by every two vertical dotted lines represent one full cycle of the key turning movement.

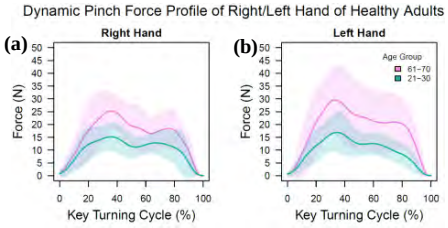

Figure 2 Mean force with the filled area of ± 1 standard deviation of the dynamic pinch force while turning the key.

CONCLUSIONS

This work demonstrated the valuable potential of a sensor-embedded instrumented key which draws preliminary insight that there is a difference in healthy dynamic pinch force profile, displayed in the manner of force modulated during different phases of the key turning motion in young and older age groups. Future work may consider testing on more subjects and exploring its motor recovery's tracking application.

Calibrated muscle-synergies method for missing muscle excitations prediction during walking

Marco Romanato[1], Fabiola Spolaor[1], Zimi Sawacha[1,2]

INTRODUCTION

Despite the effectiveness of surface electromyography (sEMG)-driven models in personalized rehabilitation protocols, their use in out-of-the lab conditions is hampered due to the high number of required sEMG signals [1]. Muscle synergy analysis has been proposed in many fashions to predict unmeasured muscles excitations from the measured signals [2]. However, as best of authors knowledge, the reliability of a calibrated muscle-synergies approach to predict unmeasured muscles excitations, considering few sEMG recordings as muscle primitives, has not been previously investigated.

METHODS

The sEMG data of 4 healthy individuals (age = 60.0±2.1 years, BMI = 26.7±4.1 kg/m^2) have been recorded during walking. The electrical activity of the gluteus medius and maximus, adductor longus, tensor fasciae latae, sartorius, bicep femoris, semitendinosus, rectus femoris, vastus medialis and lateralis, gastrocnemius lateralis and medialis, soleus, peroneus longus and tibialis anterior was collected. Fifteen trials for each subject were divided into a calibration set (10 trials) and a test set (5 trials) after being filtered with standard procedures and normalised to the maximum value over all the trials [3]. Firstly, the calibration set trial was used to extract the 4-dimensional muscle synergies primitives ($W_{4,C}$) and weights matrix ($H_{4,C}$) through non-negative matrix factorization methods. The root mean squared difference (RMSD) between the experimental excitations and W_{4C} was used as metric to determine which subset of 4 sEMG better resembled $W_{4,C}$ ($\hat{W}_4$), while a scale factor was defined as S_f = mean($W_{4,C}$)/$\hat{W}_4$. The average of each H_{4C} of each calibration trial was considered as subject-specific weights matrix ($\hat{H}_4$). Then, per each test set trial, the same muscles defined in $\hat{W}_4$ were selected as "measured" sEMG signals ($\hat{W}_{4,T}$) while the others were treated as "unmeasured". $\hat{W}_{4,T}$ was then multiplied by C and $\hat{H}_4$ to reconstruct the complete set of muscle excitations ($\hat{W}_{4,T}$*C*$\hat{H}_4$). The actual trial-specific primitives ($W_{4,T}$) and vector of weights ($H_{4,T}$) have been extracted and used to predict the muscle excitations ($W_{4,T}$*$H_{4,T}$) with the one obtained with the proposed method. The RMSD, the coefficient of determination (r^2) and the variance accounted for (VAF) were used as metrics to compare the performance against the experimental excitations.

RESULTS AND DISCUSSION

In Figure 1 the considered experimental muscle excitations of a representative subject against the predicted ones are reported as example. Low values of RMSD and concomitantly high values of both r^2 and VAF are reported in Table 1 for both methods, suggesting an accurate prediction of the experimental measures.

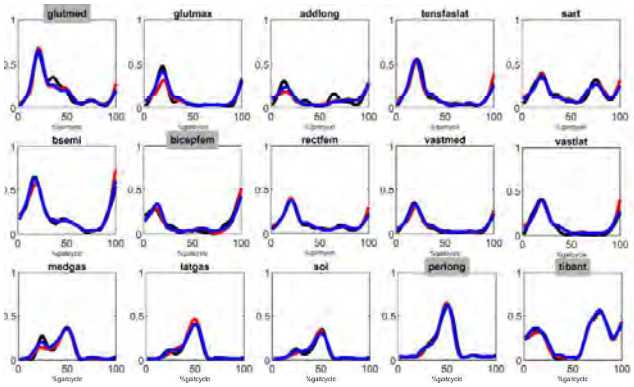

Figure 1 Considered muscle excitations of a representative subject (average of 5 test trials). In black the experimentally recorded excitations, in blue the excitations reconstructed via muscle synergy analysis (4 primitives), in red the excitations reconstructed via the proposed method (4 muscles excitations as primitives, chosen muscles are highlighted in grey).

CONCLUSIONS

The reliability of the proposed method to track "unmeasured" excitations was assessed. This could be pivotal in the creation of reliable sEMG-driven models considering a minimal experimental setup transferable in out-of-the-lab conditions (*i.e.,* home-based therapy, rehabilitation centres, gyms) where there is the need to cope with a reduced number of sensors while maintaining a reliable characterization of the research subject's neuromuscular status.

INTRODUCTION

It has been reported that obesity and its comorbidities result in decreased mobility, leading to a sedentary lifestyle and musculoskeletal degeneration [1]. Previous studies have reported on the effects of consuming a high-fat/high-sucrose diet (HFS) on joint and muscle integrity in adult rats [2,3]. However, the effects of a HFS diet on Juvenile rats have not yet been explored. In view of the ever increasing obesity pandemic in children, it is important to understand the potential differential effects of HFS diets on adult and juvenile subjects. The aim of this study was to investigate the effects of consuming a HFS diet, for 14 weeks from weaning (3 weeks), on knee joint degeneration, and fat and collagen content in muscles of male Sprague Dawley rats.

METHODS

To assess joint degeneration twenty-nine male Sprague-Dawley rats were randomly assigned to either a high-fat/high-sucrose (HFS) diet (n = 15) or a standard chow control diet (CHOW; n = 14). Medial gastrocnemius (MG) muscles were collected from HFS group (n=10) and from the Chow group (n=8). Rats consumed the allocated diet for 14-weeks, starting immediately post-weaning at (3-weeks of age). At the end of the 14-week intervention period, body mass and body composition were analyzed using dual x-ray absorptiometry (DXA). Knee joints were harvested, processed in paraffin and sectioned at 10 µm. Two independent, blinded assessors scored the histological sections using a Modified Mankin scale. MG muscle was analyzed for fat and collagen content. Collagen content was determined using Picrosirius red staining and quantified as a percent of area fraction. Fat content was determined using an assay for triglycerides.

RESULTS

Rats consuming the HFS diet had a significantly greater body mass and percentage body fat ($p<0.001$, $p<0.001$, respectively, compared to rats in the Chow group. Rats in the HFS group had a significant increase in joint degeneration (Figure 1). MG muscle had a significant increase in collagen content compared to chow group rats ($p=0.002$). MG lipid content was similar between groups.

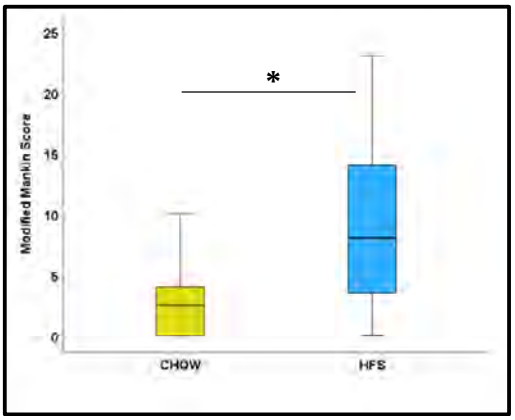

Figure 1: Modified Mankin Score of Knee Joint. (*) $p < 0.05$ (The total possible score for each joint is 68). Note, higher scores are associated with greater knee joint degeneration.

DISCUSSION

The increase in body mass and percent body fat in HFS group rats compared to control may indicate onset of metabolic syndrome that is associated with systemic inflammation [4], which may cause the observed structural changes in the knee and MG. It has been shown that feeding adult rats a HFS diet for 12 weeks caused a significant increase in fat infiltration in muscles [2]. The similarity in MG lipid content in the juvenile control and HFS group rats may indicate that the juvenile rats were better able to cope with the increase in fat in the HFS diet, thus preventing ectopic lipid storage in MG muscle.

CONCLUSIONS

A 14-week HFS diet intervention caused knee joint degeneration and increased muscle fibrosis in juvenile rats.

SUBSTANTIAL REDUCTIONS IN ADULT PHYSICAL ACTIVITY FOLLOW AN EXERCISE-RESTRICTED GROWTH PERIOD IN GUINEA FOWL

Jurestovsky, DJ, Cox, SM, Salzano, MQ, Piazza, SJ, and Rubenson, J
Dept. of Kinesiology, The Pennsylvania State University, University Park, PA, USA.
Email: derek.jurestovsky@psu.edu

INTRODUCTION

Humans have become more sedentary in recent decades. One third of the global population fail to meet minimum exercise recommendations, and this figure rises to a staggering 81% for young people [1]. This decrease in activity has been linked to an increase in morbidity and mortality [2]. The determinants of adult inactivity, however, are poorly understood. While growth period behaviors have the potential to influence adult activity through psychological and physiological mechanisms, longitudinal studies linking growth-period conditions to adult activity levels are lacking. Here, we use an animal model amenable to controlled growth studies, guinea fowl, to test the hypothesis that inactivity during growth reduces adult activity levels. Birds were either permitted to exercise or had their activity limited both by restricting their access to movement and by the application of botulinum toxin type A (BTX-A) to temporarily limit leg muscle function [3,4].

METHODS

We obtained 13 one-day old guinea fowl keets from a regional breeder. At two weeks of age, animals were divided into two groups: an exercise control group (CON, n=7) and a BTX-A and restricted group (RES, n=6). Animals were pen-raised with food and water *ad libitum*. During growth (0-26 wks) CON birds were housed together in a large pen (3.14 m^2) with access to perch jumps and running, whereas RES birds were housed together in a smaller pen (1 m^2) with limited movement. BTX-A was injected into the gastrocnemius muscles at 7-8 wks of age and repeated at every 5 wks, with a total of four injections. After the injection period, when animals reached skeletal maturity (6 mo) all animals from both groups were housed individually in moderately-sized pens (1.49 m^2) with perches 35 cm above the floor. The birds were recorded with overhead cameras at regular intervals up to one year of age. These videos were then analysed to count the number of jumps to perch per minute (jumps/min) sampled randomly and clustered around 6 mo and 12 mo time points.

RESULTS AND DISCUSSION

The CON birds jumped to perch with greater frequency than the RES birds at both time points (Fig. 1). At 6 mo, CON birds jumped at a rate of 0.07±0.09 jumps/min, but not a single jump was recorded for RES birds ($p = 0.041$). The jump frequency for both groups increased at 12 mo, but was significantly higher for CON than for RES (0.16±0.11 versus 0.03±0.06 jumps/min; $p = 0.011$). There were no significant differences in jump frequency between the 6 mo and 12 mo time points within CON ($p = 0.056$) or RES ($p = 0.136$) groups.

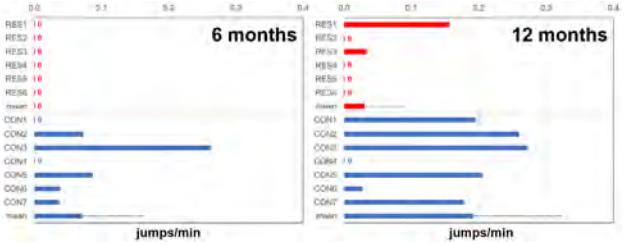

Figure 1. Jump frequency for exercise-restricted (RES) and control (CON) birds at 6 and 12 months with group means and standard deviations at each time point.

CONCLUSIONS

We found a significant reduction in voluntary adult exercise for birds whose growth-period exercise was limited by the dimensions of their living space and through pharmacological intervention. Later as adults, despite equal access to physical activity and the acute effects of BTX-A having been eliminated, the RES group showed a marked reduction in physical activity compared to the CON group. These differences were surprising given that jumping capacity (assessed by mechanical work), albeit lowered, is still substantial following growth-period disuse [5] and BTX-A treatment [Rubenson, unpublished data]. These results suggest that physical activity level during growth may influence adult physical activity levels. However, the present study cannot resolve the underlying mechanism of the activity reduction. It is possible that the RES birds failed to develop habitual jumping behaviours during the growth period. It may also be that RES birds adapted morphologically and physiologically to their growth period inactivity in ways that made jumping more effortful as adults.

CONTINUUM MECHANICAL APPROACH TO RIGID BODY MECHANICS IN BIOMECHANICS

Salvatore Federico
Department of Mechanical and Manufacturing Engineering, The University of Calgary, Canada
Email: salvatore.federico@ucalgary.ca

INTRODUCTION

Since at least the works of the late Prof. Y.C. Fung, the tools of Continuum Mechanics proved to be fundamental in the biomechanics of tissues. However, also the biomechanics of motion, which is based on rigid body mechanics, can benefit from these same tools. Traditionally, rigid body mechanics has been considered as an independent branch of Mechanics. In a more modern approach, it can be considered as a particular case of Continuum Mechanics: a rigid body is represented by a continuum body subjected to the *kinematical constraint* of *rigid motion*. From a didactical perspective, this approach has the advantage of a unified mathematical framework [1]. The purpose of this work is to highlight some of the advantages that this more general presentation of rigid body mechanics can bring to biomechanics education.

METHODS

The *motion* of a continuum body is a time-dependent map

$$\phi(\cdot,t) : \mathcal{B} \to \mathcal{S} : X \mapsto x = \phi(X,t), \tag{1}$$

mapping, at every time t, *material* points X in the body $\mathcal{B}$ into *spatial* points x in the physical space $\mathcal{S}$ [2]. The motion ϕ is *rigid* if the distance between any two points X and X_P is invariant throughout, which implies

$$x = \phi(X,t) = x_P(t) + \boldsymbol{R}(t)\,\boldsymbol{\Xi}(X), \tag{2}$$

where (see Fig. 1) $x = \phi(X,t)$ and $x_P(t) = \phi(X_P,t)$ are the current positions of X and X_P, $\boldsymbol{\Xi}(X)$ is the material local position vector, $\boldsymbol{\xi}(x,t)$ is the spatial local position vector, and $\boldsymbol{R}(t)$ is an *orthogonal tensor*, which preserves distances and angles. The velocity field of the rigid body $\mathcal{B}$ is obtained by differentiating (2) with respect to time and by eliminating $\boldsymbol{\Xi}(X)$ by inverting (2), as

$$\boldsymbol{v}(x,t) = \boldsymbol{v}_P(t) + \boldsymbol{\Omega}(t)\,\boldsymbol{\xi}(x,t), \tag{3}$$

where $\boldsymbol{\Omega} = \dot{\boldsymbol{R}}\,\boldsymbol{R}^T$ is the *spin tensor* and coincides with the *velocity gradient* tensor $\boldsymbol{l} = \operatorname{grad}\boldsymbol{v}$.

RESULTS

One example of the convenience of the continuum mechanical approach is the term $\boldsymbol{\Omega}(t)\,\boldsymbol{\xi}(x,t)$ in (3). In classical rigid body mechanics, this is commonly written $\boldsymbol{\omega}(t)\times\boldsymbol{\xi}(x,t)$, in terms of the associated *angular velocity* $\boldsymbol{\omega}$. However, the spin tensor $\boldsymbol{\Omega}$ is a more fundamental object and indeed, in Biomechanics, it is the object obtained *directly* from motion analysis data.

In standard motion capture experiments, one acquires the positions of a body segment in a reference configuration (usually with the subject standing in anatomical posture) and evaluates the rotation tensor $\boldsymbol{R}(t)$ from the reference configuration to the current configuration at each time t [3]. Once $\boldsymbol{R}(t)$ is known, the spin tensor $\boldsymbol{\Omega} = \dot{\boldsymbol{R}}\,\boldsymbol{R}^T$ can be approximated by

$$\boldsymbol{\Omega}(t) \simeq \frac{\boldsymbol{R}(t+\Delta t) - \boldsymbol{R}(t)}{\Delta t}\,\boldsymbol{R}^T(t) = \frac{\boldsymbol{R}(t+\Delta t)\,\boldsymbol{R}^T(t) - \boldsymbol{i}}{\Delta t}. \tag{4}$$

where $1/\Delta t$ is the sampling rate of the motion analysis system and $\boldsymbol{i} = \boldsymbol{R}(t)\boldsymbol{R}^T(t)$ is the (spatial) identity tensor (the orthogonality of $\boldsymbol{R}$ implies $\boldsymbol{R}^T = \boldsymbol{R}^{-1}$). If needed, the angular velocity $\boldsymbol{\omega}$ can be obtained from the spin tensor $\boldsymbol{\Omega}$ as $\omega_i = \frac{1}{2}\,\epsilon_{ijk}\,\Omega_{kj}$, where ϵ_{ijk} is the Levi-Civita symbol (see, e.g., [1] for the definition).

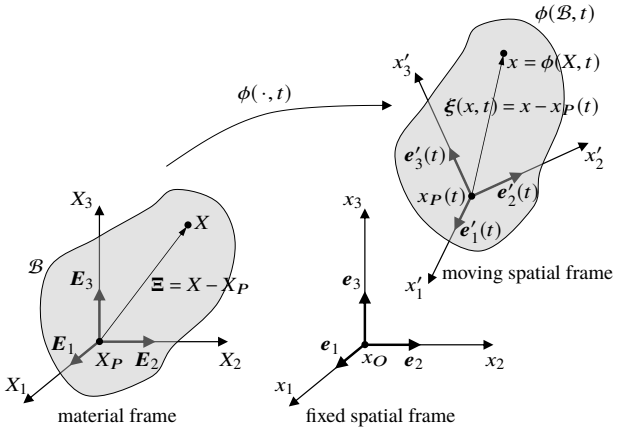

Figure 1: Continuum mechanical approach to rigid body kinematics

CONCLUSIONS

Biomechanics education can much benefit from an approach based on modern Continuum Mechanics. This work emphasised how a continuum mechanical approach to rigid body mechanics can facilitate the extraction of kinematical quantities, such as the spin tensor, from motion analysis data. Moreover, a basic education in modern Continuum Mechanics enables researchers in biomechanics of motion to more easily collaborate with researchers in biomechanics of tissues.

INTRODUCTION

Functional mobility means that a person moves independently in daily life to participate daily activities in a person's ecological environment, such as home, school, work, or community. While motor impairments affect students' daily functional activities, previous studies [1][2] reported that functional movement training is helpful for the children with motor impairments to improve their functional mobility. Thus, this study aimed to design a series of functional movement training to investigate its effectiveness on the child's functional mobility.

METHODS

This research was the A-B-M design, one of single-case study, that recruited a junior high school girl with motor impairment. The whole research was separated into three conditions. First, the baseline condition, the researcher used the measurement, the timed up and go (TUG), to evaluate the participant's functional mobility in each session until the data is stable (three consecutive points within one second). In the intervention condition, the special education teacher provided the functional movement training for the participant twice a week for ten weeks. After ten weeks, the condition entered into a maintenance condition. In the maintenance condition, the researcher only collected the score of motor abilities without providing any intervention four times a month to represent the performance of maintenance.

The functional movement training in this study aimed to improve a student's daily mobility in terms of fluent and stable gait. Two function movement activities, race walking and relay race, were provided. The TUG was used to represent a participant's functional mobility. The

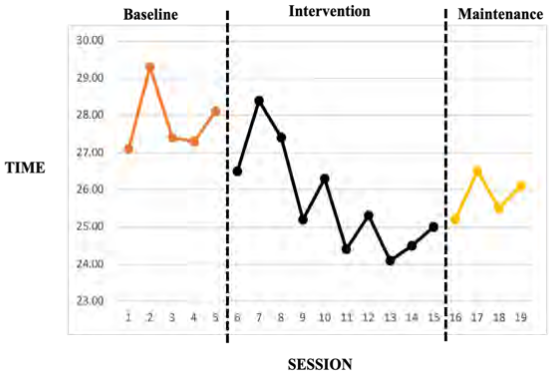
In A-B-M design, the score of percentage Exceeding the Median, PEM common score was calculated to represent the effect size of the dependent variable.

$$PEM = \frac{the\ median(baseline) esceed\ the\ data\ point(intervetion)}{Total\ of\ data\ point\ in\ the\ intervention}$$

RESULTS AND DISCUSSION

Based on visual analysis, we produced the following results (figure 1). (a) In the baseline condition, the average second is 27.84, ranging from 27.1 to 29.3 seconds, and the level change is 1 second. (b) In the intervention condition, the average second is 25.7, ranging from 24.1 to 28.4 seconds, and the level change is 1.5 seconds. (c) In the maintenance condition, the average second is 25.8 seconds, ranging from 25.2 to 26.5 seconds, and the level change is 0.9 seconds. (d) Betweem baseline and intervention, we caculated immedicay of change and PEM. While the former score is 1.6 seconds, the seventh data was higher that the sitxth data. Thergfore, there are not existing the immediately result. However, as the intervention time incresased, the effect could be seen gradually in time. The later is 0.8, representing our intervention completely is high effect size. On the other hands, when the intervention withdrawed, we found the mean time in maintenance condtion was higher than time in intervention condition. It showed the effectiveness of maintenance was not good and participant couldn't effectively keep continously.

Figure 1 The result of functional mobility in three conditions.



***Session 1 to 5 and 16-19, researchers collected the data directly before class**
***Session 6 to 10, researchers collected the data weekly at the end of the last class**

CONCLUSIONS

According to the result, we find that (a) it is effective that using functional movement training as intervention program to teach children with motor impairment. The result finally presents the time of functional mobility declines in the intervention condition. (b) The PEM score in our study is strong effect and can be demonstrated our outcome is significant. However, the maintenance effect can't retain continuously. Thus, we think providing functional movement interventions continuously for students with motor impairment is helpful for them to better their life equality.

INTRODUCTION

Of all STEM fields, engineering is the most underrepresented by women with enrollment statistics for engineering from Australian universities showing that engineering, has the lowest rate of female participation compared to other broad areas of study [1]. The Biomechanics Research and Innovation Challenge (BRInC) is a national program designed to engage high-school girls and early career biomechanists at two critical points when women traditionally disengage. BRInC focused on biomechanics research and/or innovation projects and includes workshops to expose high-school girls to the design thinking framework (empathy, definition, ideation, prototyping and evaluation) and entrepreneurial tools. Our aim was to evaluate the effect of BRInC on attitudes and self-identification in science, engineering, and biomechanics in Year 9-10 high-schoolgirls.

METHODS

Ninety-six Australian girls (Year 9 and 10) from 12 schools enrolled in BRInC. Over the 100-day program, girls were mentored by women early-career biomechanists and most teams met with their mentor(s) weekly to access resources and training, whereby they gained hands-on experience in biomechanics and the biomedical engineering fields.

Pre- and post-program surveys consisting of Likert scale items, assessed changes in three key areas: (i) self-identity as a scientist and engineer, (ii) attitudes toward engineering, and (iii) attitudes toward biomechanics. All survey data was collected online via Qualtrics. Data were downloaded and processed in STATA (StataCorp. 2013. Stata Statistical Software).

RESULTS AND DISCUSSION

Of 96 girls, 29 (30.2%) completed both pre- and post-surveys. We found improvements in all three areas after the girls participated in BRInC (Table 1). The mentees agreed more strongly with statements regarding whether they saw themselves as scientists and engineers, and they had significantly improved attitudes toward engineering and biomechanics specifically ($p \leq 0.01$). After the program, it was also more likely that mentees found:

- science more important, valuable, less confusing, more understandable, less boring, and less difficult and hard;
- maths more important, interesting, less dull, more valuable, less confusing, more exciting, less boring, and less difficult and less hard;
- biomechanics less dull, more valuable, less confusing, and more understandable.

CONCLUSIONS

The change towards positive attitudes could lead to more girls enrolling to study a variety of engineering or biomechanics-related disciplines, ultimately addressing the underrepresentation of women in STEM. These girls will be followed for 5 years to see if the positive shift in attitudes translates to university or career choices in the field.

Table 1: Aggregated scores in scientist/engineer identity and attitudes toward engineering and biomechanics for pre and post BRInC program, where 1= strongly agree and 6= strongly disagree.

Scale	Example Questions	PRE	POST	*p-value*
Scientist/Engineer Identity	I see myself as a scientist	2.5 (2-3)	2.3 (1.8-2.8)	$p = 0.09$
Engineering Attitudes	Engineering is interesting	2.0 (1.7-2.3)	1.3 (1-2)	$p < 0.01$
Biomechanics Attitudes	I understand what biomechanics is	2.2 (1.8-2.8)	1.3 (1.8-2.2)	$p = 0.01$

Data presented are median scores (interquartile range). Pre-post measures were compared using Wilcoxon Signed Rank Test.

THE MECHANICAL ENERGETICS OF WALKING ON INCLINE SURFACES WITH PASSIVE ANKLE EXOSKELETON ASSISTANCE

INTRODUCTION

The energetic benefits of passive ankle exoskeletons during level walking, via off-loading muscle force, are well-established [1]. For example, passive ankle exoskeletons mimic the catapult mechanism of the plantarflexors and Achilles tendon by storing and returning energy to the ankle via a spring-clutch mechanism. However, most exoskeleton studies have focused on human-device interactions during steady-state level walking. It remains unresolved how similar devices influence the biomechanics of movement under more variable gait conditions that would be expected in the real world. Investigation of the mechanics and energetics of unassisted walking on incline surfaces revealed a shift in the ankle, knee, and hip's relative contributions to positive and negative power [2]. Specifically, incline walking reduced the ankle's contribution to positive power which was offset by increased contributions from the knee and hip, compared to level walking. The aim of this study is to investigate the influence of varied levels of exoskeleton assistance on mechanical energetics of the lower limb during level and incline walking.

METHODS

Five participants (23±4 years, 64±7 kg) completed our ongoing study (with the aim to recruit 15 participants total). To familiarize the users with the device, participants walked on an instrumented treadmill (Bertec Corp., USA) at 1.25 ms^{-1} for five minutes at each exoskeleton stiffness (0, 50, 120, 220, 280 Nm rad^{-1}) on level and incline (+5°) surfaces. In a follow-up data-collection session, participants walked at 1.25 ms^{-1} with exoskeleton stiffness and grade pseudo-randomised. Device clutches and slack lengths were consistent with [1]. Exoskeleton moments were determined from dynamic spring displacements, as measured by reflective markers placed on the spring component of the device. Lower limb kinematics and kinetics were recorded using motion capture (120 Hz, Qualisys, Sweden) and force plates (1200 Hz) [3]. Biological ankle joint moments were calculated as the difference between the ankle moment, derived from inverse dynamics, and the exoskeleton moment. Time-varying joint powers were determined as the product of joint angular velocities and moments.

RESULTS AND DISCUSSION

As expected, during level walking, increases in assistance were associated with a more plantarflexed ankle, reduced biological ankle moments and ankle powers. Compared to level walking, incline walking with assistance provided more assistive torque, for all participants, due to larger spring excursions (Fig. 1A).

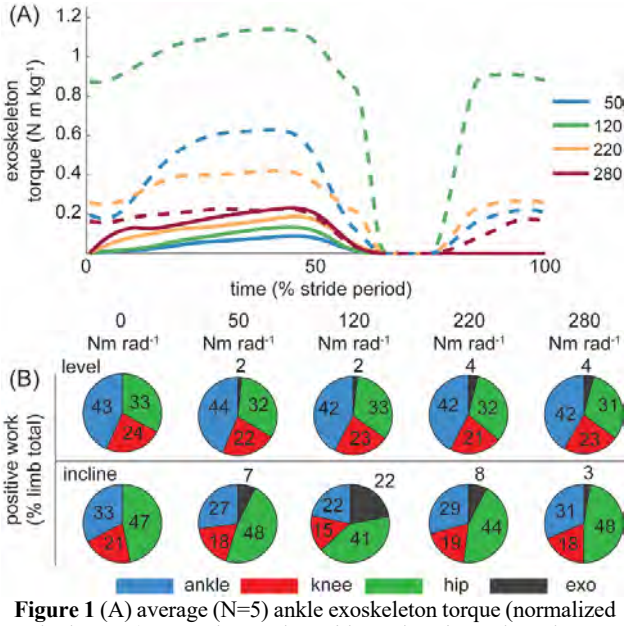

Figure 1 (A) average (N=5) ankle exoskeleton torque (normalized to body mass) exerted over the stride cycle. Line colour denotes device stiffness. Dashed lines represent the incline conditions. (B) relative contributions of the ankle, knee, and hip to positive lower limb work. Pie charts are not scaled to reflect positive work totals.

This behaviour was driven by exoskeleton clutch engagement during the swing phase of incline walking, unlike level walking. However, during incline walking, the largest peak torque did not occur at the high stiffness (280 Nm rad^{-1}) condition, as is the case during level walking, but rather at an intermediate stiffness (120 Nm rad^{-1}) (Fig. 1A). This difference appears to be driven by a reduction in ankle range of motion with increasing device stiffness. Specifically, at the 280 Nm rad^{-1} condition, ankle range of motion was reduced by 3.44°, compared to no assistance. Assisted incline walking led to a reduction in ankle net work at all stiffnesses, apart from the 280 Nm rad^{-1} condition. During incline walking, our preliminary analysis suggests that ankle exoskeletons influence the relative contribution of the knee and hip to total lower limb work (Fig. 1B). This is best evidenced by reduced knee and hip contributions to lower limb positive work at the incline 120 Nm rad^{-1} condition (Fig. 1B).

CONCLUSIONS

Our preliminary analysis suggests device operation should account for the environment (*e.g.,* slope) to best augment locomotion. Future efforts to determine whether these changes in work outputs correspond to improvements in movement economy during uphill locomotion will yield important insights.

PREDICTING INDIVIDUALIZED JOINT KINETICS OVER CONTINUOUS VARIATIONS OF WALKING AND RUNNING

Emma Reznick, Robert Gregg
Department of Robotics, University of Michigan, Ann Arbor, MI, USA
Email: reznick@umich.edu

INTRODUCTION

Gait is as individual as people, and taking this individuality into account in the design of assistive devices enables able-bodied and impaired people alike. In able-bodied individuals, the uniqueness allows powered devices to match the user's gait; tuning assistive devices for impaired populations goes further, enabling the user's ability while minimizing compensations. Kinematic individuality is well characterized and investigated, but cutting-edge assistive devices must also mimic the user's kinetic individuality. Previous studies [1] have shown that gait individuality is consistent within a type of motion, but not between ambulation modes (i.e., walking individuality is similar across inclines, but dissimilar to running). In this study, we investigate whether these kinematic trends apply to joint kinetics.

METHODS

From [2], kinetic individuality is isolated for each able-bodied participant ($n = 10$) at every task (χ): walking at different combinations of inclines ($\pm 0°$, 5°, and 10°) and speeds (0.8, 1, 1.2 m/s), and running at multiple speeds (1.8, 2, 2.2, and 2.4 m/s). The individual *kinetic* contribution (IKC) at each task is calculated by subtracting the individual's joint moments from the leave-one-out average (LOO) of the other participants. To determine how predictive one user's IKC is of their other tasks, we determine the *Modal* baselines for walking (χ_W: 1 m/s, 0°) and running (χ_R: 2 m/s, 0°). Then, we use an RMSE to quantify how well each baseline (and the LOO control) predict the experimental IKC, resulting in task-specific values for the *Walk*, and *Run*, and *LOO* methods. This protocol follows previous work for kinematics [1]. The resultant RMSEs are fed into N-way ANOVAS for each mode: considering subject, incline (walk only), velocity, joint, and method. The ANOVAS are then analyzed using post-hoc Tukey tests to determine significance.

RESULTS

For walking tasks, the Walk method was more predictive than the LOO for 76% of the all subjects, joints, showing improvements of 44%, 18%, and 31% at the ankle, knee, and hip, respectively (Figure 1, left). Similarly, the Run method gave a better estimate than LOO for 87% of running trials, improving fit by 51%, 60%, and 62% at the ankle, knee, and hip (Figure 1, right). Prediction of walking with χ_R showed significant decreases in fit for each joint, while prediction of running with χ_W showed incidental improvement.

The ANOVA for walking suggests that subject, incline, joint, and individualization method all significantly affected the results ($p \ll 0.05$), but velocity had no effect on the resulting RMSE. For the running ANOVA, all factors significantly affected the results. Post-hoc analysis shows that χ_W was a significantly better prediction of all joint IKCs than the LOO for walking, and χ_R was significantly better than the LOO for all running tasks. The inter-mode estimations showed no significant improvement for either mode.

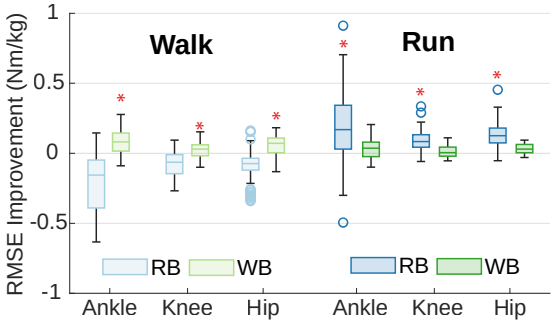

Figure 1: RMSE improvement (positive) over LOO average for walking (left) and running (right) kinetic trajectories. For each mode, we show prediction using both walking (WB) and running (RB) baselines. Red '*' indicate significant improvement.

CONCLUSIONS

Joint moments of an individual across a wide variety of speeds and inclines show significant similarity. Knowing this, we can simplify the individualization process of powered assistive devices by assuming that torque profiles are consistent across all tasks within a mode. For example, after tuning a device at level ground, walking individuality can be propagated to other speeds and inclines. Individualizing joint profiles is an important step towards biomimetic assistance from powered devices.

GAIT ADAPTATION ON REPEAT EXPOSURE TO A ROBOTIC HIP EXOSKELETON

Mark A. Price[1,2], Banu Abdikadirova[2], Jonaz Moreno Jaramillo[1], Meghan E. Huber[2], and Wouter Hoogkamer[1]
[1] Department of Kinesiology, University of Massachusetts, Amherst, USA.
[2] Department of Mechanical and Industrial Engineering, University of Massachusetts, Amherst, USA.

INTRODUCTION

Robotic exoskeletons have strong potential to enable new paradigms in physio- and neurorehabilitation. Recently, we observed signatures of neural adaptation in participants wearing a portable robotic hip exoskeleton [1]. Asymmetric perturbations at the hip joints elicited adaptation and aftereffect patterns for step length asymmetry (SLA), propulsive and braking ground reaction force asymmetry (PGRFA and BGRFA, respectively), similar to typical responses to split belt treadmill walking [2]. To determine the suitability of this intervention for rehabilitation, it is necessary to evaluate the impact of repeated exposures on the user's behavior. Thus, we performed a study with two consecutive exposures to the intervention. We hypothesized that SLA, PGRFA, and BGRFA would be reduced from first to second exposure.

METHODS

We performed a gait adaptation protocol with six healthy young participants. Participants walked at 1.20 m/s on an instrumented dual-belt treadmill (Bertec Corporation) while wearing the exoskeleton for two 20-minute bouts, each consisting of a 5-minute baseline walking phase (motors off), a 10-minute perturbation phase (motors on), and a 5-minute washout phase (motors off). During the perturbation phase, the exoskeleton motors exerted repulsive and attractive torques about the left and right hip joints, respectively. Participants rested 5 minutes between bouts of walking. We recorded the 3D positions of reflective markers placed on each participant at 100Hz with an eight-camera motion capture system (Qualisys, Inc.), and calculated step length as the anteroposterior distance between heel markers at heel strike. We recorded ground reaction forces at 1000Hz with a pair of force plates located under the treadmill belts. We calculated asymmetry ratios for SL, PGRF, and BGRF for each stride as $(x_R - x_L)/(x_R + x_L) \times 100\%$, where x_R and x_L represent the dependent measure for the right and left leg, respectively. We averaged the first 10 strides of the perturbation and washout phases for each participant and compared the asymmetry magnitude between the first and second exposures to the exoskeleton protocol via paired t-tests.

RESULTS AND DISCUSSION

No significant difference was found between the two exposures for any measure, contradicting our hypothesis (Figure 1). This marks a distinct difference between behavioral effects elicited by the hip exoskeleton compared to split belt treadmill training, which has demonstrated significant savings upon second exposure on the same training day [3,4]. It is possible that adaptation to the initial exposure was simply so efficient that only marginal savings could be made, given the relatively minor torques exerted by the exoskeleton (<5 N-m). Performing this study with additional participants or with multiple, immediate exposures [4] may help to clarify whether adaptation to the exoskeleton changes on repeat exposure, with particular attention to PGRF aftereffect magnitude ($t(5) = -2.2$, $p = .08$). Encouragingly, the presence of an aftereffect remains clear upon repeat exposure, indicating that the exoskeleton may continue to cause aftereffects after wearers solidify a modified gait strategy from repeated use.

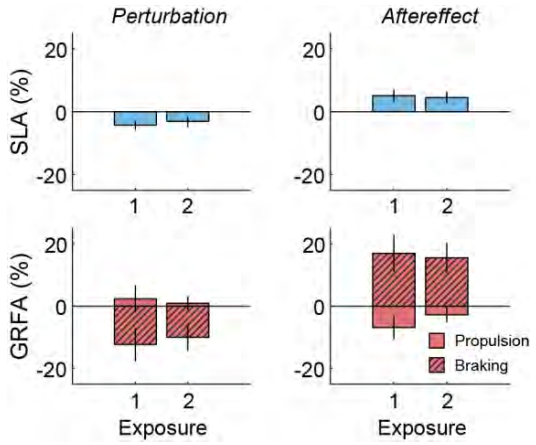

Figure 1 Group means for asymmetry measures between adaptation and readaptation conditions. Error bars reflect 2xSEM.

CONCLUSIONS

A second exposure to a hip exoskeleton asymmetry perturbation did not result in significant savings in the early perturbation or washout response. This may be due to small torques by the motors eliciting fast adaptation to begin with, causing marginal savings to be hidden in the variability between participants.

AN IMPROVED DESIGN OF AN UPPER LIMB EXOSKELETON FOR OVERHEAD TASKS

Georgios Aronis[1], Andrea Ancillao[1], Tommaso Del Grossi [2], Thomas Angeli [1], Margit Gföhler [1]

INTRODUCTION

Over the last years, assistive devices have been attractive to manufacturers as a means to improve the productivity of their workers. Among them, upper limb exoskeletons are considered of great interest since they can relieve the load from workers constantly involved in overhead tasks and activities that can cause severe work-related muscoloskeletal disorders which lead to multiple health leave days [1]. Extended research on the topic is still ongoing and major improvements are needed in terms of ergonomics, weight and efficiency. The aim of this work is to propose a novel upper-limb exoskeleton design and test its effects on the metabolic activity of a person while performing overhead work.

METHODS

The shoulder module of the exoskeleton was based on a previous design originally conceived for the rehabilitation of stroke survivors with limited residual muscle strength [2]. The new design is a passive, lightweight, and durable device aimed to provide the suitable torque to support both arms of the user at shoulder elevation angles larger than 90 deg. The new system was based on compression springs that were ad-hoc designed to provide the gravity compensation to the user while working overhead. The strength of the compensation can be adjusted by changing the tension and the initial position of the springs. More in detail, the spring was dimensioned via an optimization procedure aimed to reach a target support torque for the shoulder that was determined in a previous work [2]. A preliminary metabolic test was conducted on one subject performing an overhead task consisting of lifting a 1.5kg weight with and without the exoskeleton.

RESULTS AND DISCUSSION

The springs were located on the back of the user, parallel to the spine and embedded in the back support. The spring force was transferred to the arm via a cable embedded within the structure. This allowed an ergonomic weight distribution, not interfering with the arm brace. The dimensioning of the spring led to the activation curves shown in (Figure 1). A spring constant of 0.635 N/mm and length of 360mm was found to provide the best support for most of the users. The different coloured curves in (Figure 1) represent the theoretical required torques at different elbow positions; the dashed curve represents the torque provided by the spring. It was observed that the maximum torque is required when the arm is fully stretched. Thus, the spring was designed to provide a reasonable support at this case. The pretension design allowed to shift vertically the curves represented in (Figure 1).
The metabolic analysis showed that the use of exoskeleton led to a decrease in the main metabolic parameters. The respiratory frequency dropped from 20,2 (2,5) l/min to 14,5 (2,3) l/min, respiratory exchange ratio from 1,003 (0,068) to 0,950 (0,042) and heart rate from 85,3 (3,6) bpm to 80,2 (2,2) bpm.

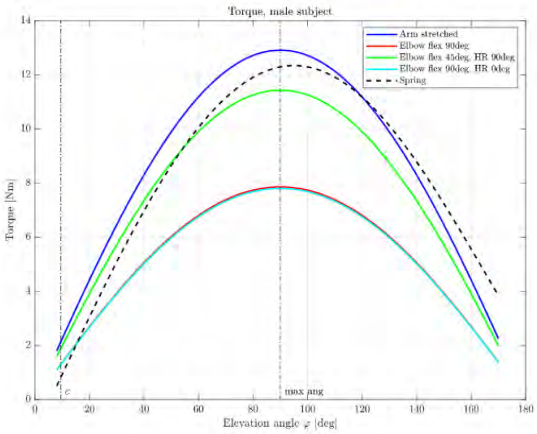

Figure 1 : Torque profiles at different elevation angles and possible use cases

CONCLUSIONS

From this preliminary study, it emerged that the new design was able to provide adequate support torque to help the subject during overhead tasks. Furthermore, the first prototype was able to reduce the metabolic cost of the task. Further studies will be required to assess the impact of the device on the muscular strategy and the effective energy expenditure over more subjects.

WALKING WITH EXOSKELETONS: ESTABLISHING BIOMECHANICAL METRICS FOR QUANTIFYING ASSISTED-GAIT FAMILIARIZATION

Giorgos Marinou[1], Lizeth Sloot[1], Katja Mombaur[2]
[1]Institute of Computer Engineering (ZITI), Heidelberg University, Heidelberg, Germany
[2]Department of Systems Design Engineering and Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, Canada
Email: giorgos.marinou@ziti.uni-heidelberg.de

INTRODUCTION

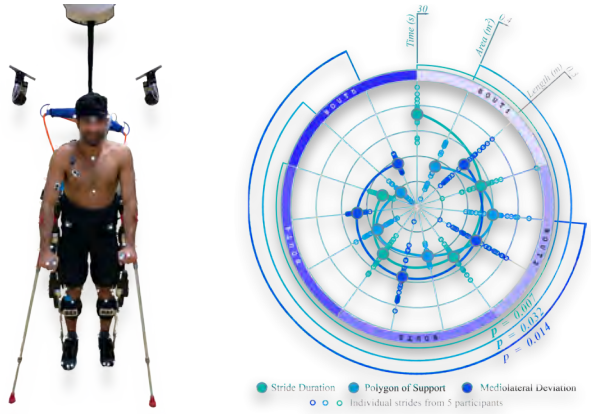
Walking with exoskeletons has gradually evolved over the past two decades, from experimental setups to home use, establishing exoskeletons as well-facilitated devices for rehabilitated and assisted walking. Biomechanical evaluation of exoskeletons is a fundamental part of testing hardware and software modifications, but it can be quite challenging and inefficient since different users demonstrate different familiarization patterns and time windows. This study summarizes and extends previous work [1] on deriving and establishing a set of familiarization criteria based on biomechanical metrics, in order to *quantify the familiarization process* of young healthy adults walking with a lower-limb exoskeleton. Hence, the proposed method aims to improve exoskeleton-testing efficiency and accuracy of biomechanical measurements and data collection.

METHODS

Five able-bodied young male adults of 29.4 ± 4.9 years, 26 ± 1.4 BMI, walked with the lower-limb exoskeleton TWIN [2] over five bouts with a manual control mode and five more with a more automatic mode. Motion and muscle activity data were simultaneously collected using the Qualisys camera system (feet and sternum markers) and the Noraxon surface electromyography (EMG) system (triceps, biceps brachii, tibialis anterior and gastrocnemious medialis). Three spatiotemporal ((1) *stride duration*, (2) *mediolateral deviation from a straight path* and (3) *polygon of support*) and (4) *muscle activity* metrics are proposed as familiarization indicators, detailed in Marinou et al. [1]. Familiarization is defined as the reduction in magnitude of each of these four quantities. To assess an effect over time, Friedman's one-way analysis of variance (ANOVA) test was conducted separately for each mode (5 bouts), and a posthoc analysis was performed with a multiple comparisons test on the ten bout pairs with a significance value of $p < 0.05$. Results are reported in terms of median and interquartile range.

RESULTS

There were no significant changes in muscle activity for any of the examined arm or leg muscles, over both walking modes. Stride duration, mediolateral deviation, and polygon of support metrics indicated that participants start to show signs of familiarization to the exoskeleton after several walking bouts, and only in the automatic walking mode, as summarised in Figure 1. Stride duration decreased over bout 1 to 5 by 2.05 [2.61] s (average decrease: 16.9%, $p = 0.007$). Comparably, mediolateral deviations from straight-line walking decreased over time. There was an improved ability to walk in a straight-line path during the 5 bouts in the automatic mode, with a 63.8 [32.2] mm or 51.7% ($p = 0.014$) improvement between bout 1 and 5. The polygon of support area decreased similarly since participants did not show considerable changes during the first 5 bouts with the manual mode but the support area did decrease over bouts 2 to 5 of the automatic mode, by 0.0202 [0.0505] with an average decrease of 30.6% (p = 0.0316).



(A) (B)

Figure 1: (A) Experimental setup with exoskeleton and participant, (B) Summarized spatiotemporal metrics (1 - 3) results for automatic mode: large markers indicate median values and small markers individual participant values per stride. p-values reported concentrically.

CONCLUSIONS

Three biomechanical metrics have been established as familiarization indicators for lower-limb exoskeleton-assisted gait. Familiarization took place between bouts six and ten with the automatic walking mode. The presented approach of quantifying a user's familiarization allows to distinguish when familiarization begins and when we can start collecting meaningful data to evaluate these devices. Ongoing work to be included in conference presentation involves instrumented crutches and insoles that measure these metrics without the need of bulky laboratory equipment.

INTRODUCTION

The use of wearable exoskeletal devices can enhance locomotor performance in various fields [1–4], but the added mass of such devices can cause a metabolic increase that needs to be overcome [3,5]. Previous studies have examined the effects of added mass, in forms such as shoes [6] , backpacks [7], and more. Notably, previous studies that have examined running metabolic power while loading the lower extreme have had very small sample sizes [8] or have not examined female runners and shank loading [9]. The present study aims to quantify the effects of adding mass to the thighs, shanks, and feet on the metabolic power required for running, using load magnitudes based on previous exoskeleton mass distributions. Furthermore, this study tests both women and men to determine any differences in effects between the sexes and develops numerical models to predict the effect of added mass on metabolic power for future assistive device design.

METHODS

Fifteen participants (7 females and 8 males) completed treadmill running trials ($3\ m \bullet s^{-1}$) normally and with lead mass (0.3–1.35 kg) attached bilaterally to the thighs, shanks, or feet. Using indirect colometry, metabolic power was measured and used to quantify the direct change and the relative changes due to added mass using linear models.

RESULTS AND DISCUSSION

For every kilogram of added mass per leg, gross metabolic power increased by approximately 16% (feet) and 11% (shanks) for females, which was slightly greater than the 11% and 8% increases for males, respectively. For thigh loading, metabolic power increased by 4% per 1000 g in both sexes (Figure 1). In the development of metabolic prediction equations, we found correction coefficients for Epstein-87 equations that were originally developed to predict a range of walking and running conditions with backpack weight (speed, incline, added mass, and terrain) [10]. The correction coefficients are a 9.8% addition for feet and a 6.4% addition for shanks per 1 kg compared to metabolic power calculated with the equations. This improved the prediction on walking and running with added mass on the lower extreme (compare [2,5]).

CONCLUSIONS

Adding mass more distally on the leg increases the metabolic cost of running to a greater degree. For the same absolute added mass on the feet or shanks, the metabolic rate increases more in females.

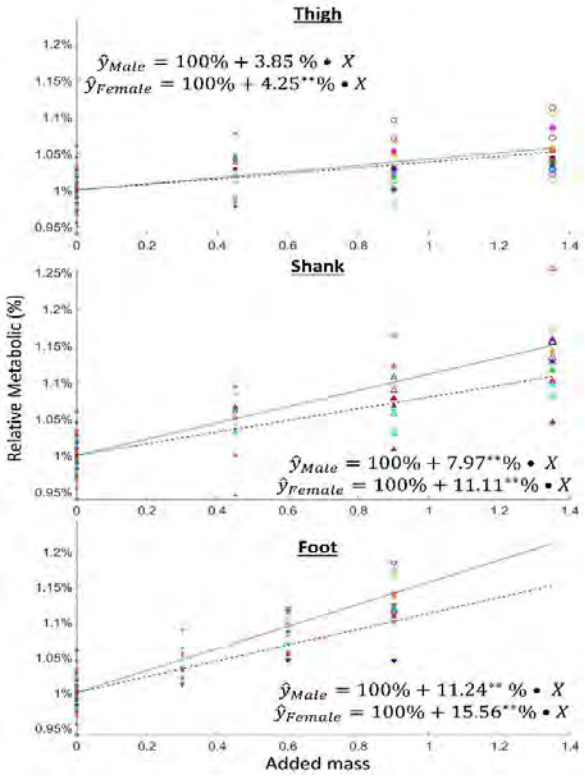

Figure 1 Relative increase in metabolic power due to added mass, as a function of the added mass at each location; female model = ... ; male model = – – –; ** = $p < .01$; * = $p < .05$.

INTRODUCTION

Residual force depression (rFD) is the loss of force following shortening of an activated muscle compared to the corresponding isometric contraction at the same final muscle length [1, 2]. In human, muscle contraction at a fixed joint angle is typically accompanied by fascicle shortening due to the compliant nature of the muscle-tendon unit (MTU), thereby causing rFD [3]. However, active shortening of muscle fascicles during fixed-end contraction of MTU occurs instantaneously with muscle activation, which is distinctly different from the classical way of rFD measurement whereby steady-state isometric force is achieved before any active shortening. As the rFD is thought to be caused by stress-induced inhibition of cross bridge formation [4], and is strongly associated with the work done [1], the rFD resulting from activation of compliant MTU may be lower than the classical rFD for the same amount of active shortening due to the rising active force, rather than the steadily high active force, during the early phase of muscle contraction. The purpose of this study was to determine the effect of timing of active shortening on the amount of rFD. We hypothesised that rFD is lower for active shortening that occurs instantaneously with muscle activation than for shortening that occurs following the attainment of steady-state active force.

METHODS

Intact tibialis anterior MTU of 8-10 week-old male C57/BL6 mice (N = 7) was set at resting length of ~10mm, and stretched by 3 mm (L1), 3.5 mm (L2) and 4 mm (L3) by a miniature dynamometer to lengths corresponding to the descending limb of the active force-length curve [5]. The MTU was activated isometrically by electrical stimulation of the sciatic nerve for 1.13s upon reaching the target length. For trials involving active shortening, MTU was stretched by 0.15 mm longer than the target length and activated. Active shortening of 0.15 mm at 0.5 mm/s was applied either instantaneously upon activation (INST) or delayed by 500ms following activation (DELAY). The MTU was allowed to recover at the resting length for 3 min between trials. The average steady-state force following active shortening was compared with that of the reference isometric contraction (ISO, Fig. 1A). The work done during active shortening was also calculated.

RESULTS AND DISCUSSION

MTUs stretched to L1 length had active force comparable to passive force, but the active forces of MTUs stretched to L2 and L3 lengths were lower than the passive force. Under this test protocol, activation-induced muscle shortening was minimised [5]. Force depression of the DELAY group was 5–9 %, and was significantly greater than the 1–5% force depression of the INST group (Fig. 1B). However, the work done during active shortening for the DELAY group was significantly lower than for the INST group at L2 and L3 lengths (Fig. 1C), which is against the general understanding of the positive correlation between work done and rFD [1]. We speculated that the manner in which rFD developed may be altered under high passive force seen at these MTU lengths.

CONCLUSIONS

We concluded that rFD depended on the timing of active shortening. rFD was lower in the INST group than in the DELAY group. However, the driving factor for this behaviour cannot be explained by work done during active shortening.

INTRODUCTION

The forefoot strike pattern (FFS) was always reported to be more economical and widely used by elite runners. The underlying reason includes the FFS allows greater storage and return of elastic energy from ankle tendons [1]. The previous studies verified this and reported the medial gastrocnemius (MG) contracted more slowly in FFS than in rearfoot strike pattern (RFS), which could be more energy-saving. Thus, gait retraining (GR) was highly recommended. However, few studies focused on the effects of GR at the MG-tendon unit (MTU) level. Thus, the aim of this study was to explore the effects of GR on MTU behaviour and mechanical properties.

METHODS

Twenty-four habitual RFS male runners were recruited and randomly divided into GR group and control group (CON). The participants in GR group were asked progressively transit to run with FFS in FiveFingers and those in CON were asked to keep their original running habits for 12 weeks. During tests, participants were asked to run at 9 km/h with traditional running shoes. An ultrasound system, motion capture system, and instrumented treadmill were used to capture the ultrasound image of MG, marker positions, and ground reaction forces (GRF) in real-time during running. The MG/MTU behaviour and mechanical properties were calculated. A 2x2 two-way repeated measures ANOVA was to analyze and the significance level α was 0.05.

RESULTS AND DISCUSSION

After 12 weeks, 10 participants in each group completed the training with nobody injured and eight in GR group transmitted to Non-RFS. These results illustrated the GR was safe and effective to transit foot strike pattern.

There was a significant interaction effect in the second peak GRF. Post hoc analysis revealed a significant increase after training in the GR group (Table 1).

There were no interactions but main time effects in MG fascicle shortening length and peak fascicle velocity. Specifically, both were significantly lower after 12 weeks (Figure 1). It was reported that the MG fascicle shortening length and peak fascicle velocity were negatively related to running economy [2], implying the MG could contract in a more efficient way after GR and long-term running.

Significant interaction effects were observed in MG force and MTU lengthening length. Post hoc analysis revealed significant increases in MG force in both groups and a significant increase in MTU lengthening length in GR group after training (Figure 1). It was inferred that the MG tendon was more compliant to make fuller use of stretch-shortening cycle, acting as compensation for MG to reduce higher force after GR.

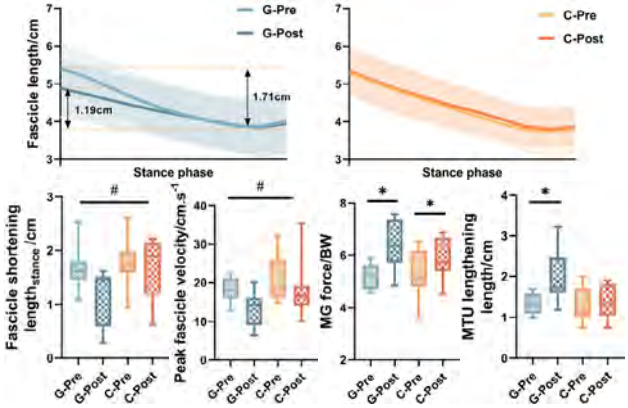

Figure 1 The effect of gait retraining on meidal gastrocnemius-tendon unit (MTU) behaviour and mechanical properties.
Note: G= gait retraining group, C= control group, *=significant difference, #=significant time main effect

CONCLUSIONS

The GR was safe and effective to transit FSP. After 12 weeks, the MTU lengthening length were greater in GR group, indicating GR helps enhance the elastic energy storage ability of MTU. Meanwhile, the MG fascicle shortening length and peak fascicle contractive velocity reduced after training but generated higher force in both groups, implying the MG could contract more efficiently after GR and long-term running.

INTRODUCTION

Knowledge of muscle architecture and moment arms is crucial for understanding the functional morphology of the musculoskeletal system [1]. Traditionally, moment arms were measured in vitro. However, for the complex shoulder mechanism, it is difficult to determine the biomechanical effects of shoulder muscles on glenohumeral joint stablity and range of motion from cadaver measurements alone. This study investigates the feasibility of using magnetic resonance imaging (MRI) to quantify muscle volumes and moment arms of human rotator cuff muscles in vivo.

METHODS

Twelve healthy subjects (six males, six females; age 33 ± 6 years; height 170 ± 6 cm; weight 69 ± 10 kg; values are mean ± SD) with no symptoms or recent history of shoulder pathology were included in this study. mDixon anatomical scans of the right shoulders were acquired with a 3T MRI scanner (Philips Ingenia CX). Rotator cuff muscles were manually segmented on all slices of mDixon water images to create 3D surface models, from which muscle volumes were calculated. The glenohumeral joint centre of rotation was determined by fitting a sphere to the articular surface of the humeral head. A third-order polynomial curve was fit on each rotator cuff tendon in 3D to represent the muscle line of action. The moment arm was then estimated as the smallest perpendicular distance between the line of action and the centre of the fitted sphere (i.e., the centre of rotation).

RESULTS AND DISCUSSION

Muscle volumes and moment arms from this study were in good agreement with previously published [2] MRI-based measurements obtained in vivo (Table 1), suggesting our measurements were broadly accurate. Also, the variation in volumes between muscles is comparable with that reported by Juul-Kristensen et al. [2]. Minor differences in our values and those reported by Juul-Kristensen and colleagues could be attributed to inaccuracies in manual segmentation, differences in methods used to estimate centres of rotation and muscle lines of action, and differences in anatomical characteristics of participants between studies.

CONCLUSIONS

This study demonstrates the feasibility of using MRI to quantify the muscle sizes and moment arms of human rotator cuff muscles in vivo and provides preliminary evidence of validity. This study adds to the larger study conducted by Juul-Kristensen et al. [2] by measuring the properties of infraspinatus and teres minor separately. We also quantified moment arms in 3D, which overcomes limitations associated with 2D approaches [3].

These measurements could be used to explore skeletal muscle structure-function relationships non-invasively and to develop realistic computational models of the human shoulder for clinical and surgical applications.

We are currently working on complementing the dataset with other muscle architectural parameters (fibre length, physiological cross-sectional area and pennation angle) from diffusion tensor imaging data.

CORRELATIONS BETWEEN ACHILLES TENDON MOMENT ARM AND PLANTARFLEXOR MUSCLE ARCHITECTURE

Logan K. Faux-Dugan and Stephen J. Piazza
Dept. of Kinesiology, The Pennsylvania State University, University Park, PA, USA.
Email: fauxdugan@psu.edu

INTRODUCTION

Because sufficient plantarflexor muscle moment is essential for locomotor function, its direct determinants are parameters of great interest in understanding the mechanics of locomotion. This moment is primarily the product of the Achilles tendon force and the plantarflexor moment arm of the Achilles tendon (ATMA), but the production of plantarflexor moment is complex because ATMA determines muscle length change and shortening velocity per unit change in ankle angle. A large moment arm has the potential to increase sarcomere shortening velocity and thus decrease force generating capacity during concentric contractions [1]. If, however, resting fascicle length scales with moment arm, then sarcomere operating range and force-generating capacity may be preserved [2].

Similarly, if muscles with larger physiological cross-sectional area (PCSA) also possess shorter moment arms, it might result in moment generating capacity being consistent across individuals. These relationships between ATMA and plantarflexor muscle architecture are thus important for understanding the roles played by muscles in producing locomotion. The purpose of this study was to investigate the relationship between ATMA and the architecture (fascicle length and PCSA) of the plantarflexor muscles lateral and medial gastrocnemius (LG and MG) in a young healthy population. We hypothesized that ATMA would correlate positively with fascicle length and negatively with PCSA in both muscles.

METHODS

Sixteen healthy young adults (9M/7F, age 27.64 ± 5.13 y, height 1.75 ± 0.03 m, mass 76.29 ± 4.36 kg) were recruited as participants in the study. Techniques integrating ultrasonography (US) and video-based motion analysis were used to quantify the architecture of LG and MG as well as the ATMA in each subject's right leg. With the participant in a prone position, transverse-plane 2D US images of the calf were collected in multiple sweeps. These images were used to create 3D models of LG and MG in Stradwin software from which muscle volumes were estimated. With the subject standing, static sagittal-plane US images were collected and analysed to estimate pennation angles and fascicle lengths. PCSA was computed by dividing the product of muscle volume and pennation angle by fascicle length. As the subject performed calf raises, markers on the foot and shank were tracked along with markers on an ultrasound probe placed over the Achilles tendon near the ankle [3]. Marker locations were processed to locate the ankle axis of rotation from the measured movement, while simultaneously locating the Achilles tendon from the US images. ATMA was estimated as component of the ankle moment due to a unit tendon force directed along the joint axis [3]. ATMAs reported below are those occurring when the ankle was in neutral position.

RESULTS AND DISCUSSION

For LG, a moderate significant correlation was found between ATMA and fascicle length (R = 0.53; p = 0.033) but no significant correlation between ATMA and PCSA (R = 0.38; p = 0.142) (Fig. 1). For MG, however, the opposite was found: A moderate significant correlation between ATMA and PCSA (R = 0.50; p = 0.048) and no significant correlation between ATMA and fascicle length (R = 0.37; p = 0.164).

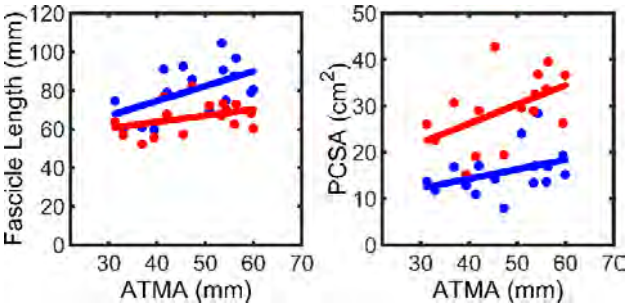

Figure 1 Correlations between ATMA and fascicle length (*left*) and PCSA (*right*). Results are shown for LG (*blue*) and MG (*red*).

CONCLUSIONS

These findings suggest that LG, a muscle with longer fascicles and smaller PCSA, is well suited for maintenance of force generation throughout the range of motion across individuals. But MG, a muscle with a larger PCSA and shorter fascicles, is more suited for static moment generation, and those individuals with the greatest force-generating capacity also benefit from having the best leverage in terms of their ATMA. Similar positive correlations between muscle size and moment arm have previously been attributed to muscle belly bulging altering the tendon line of action [4].

ACKNOWLEDGMENT

We wish to thank Rebecca Gonzalez for her assistance with the data collection.

INTRODUCTION

Hamstring strains are the most common non-contact injuries, accounting for 37% of all muscle injuries in sports [1]. Although, eccentric Nordic hamstring exercise (NHE) induces hypertrophic adaptations in the hamstring muscle group, the training favourably develops biceps femoris short head and semitendinosus muscles [2]. However, the pattern of hypertrophy in different regions for different hamstring muscles is still unknown. Therefore, we aim to investigate the regional hamstring hypertrophic adaptations in response to 9 weeks of eccentric NHE training.

METHODS

Five recreationally active subjects (3 females, 2 males, 26.4±3.3 yrs., out of 10 recruited) completed a 9-week eccentric NHE intervention totalling 867 repetitions. Thigh region of all subjects were scanned in a 3.T MR scanner, (GE Healthcare) using IDEAL IQ (TR/TE=13.3/6.3ms, no. of echoes=6, flip angle 5°, matrix=252×252, FOV= 22.5-45cm, slice thickness= 6mm) before and after the intervention. Hamstring muscles, biceps femoris short head (BFSH), biceps femoris long head (BFLH), semitendinosus (ST), and semimembranosus (SM) were segmented in 3D Slicer blinded to pre/post intervention status. To keep measurements consistent across all subjects, hamstring volumes were measured from points of origin till the first appearance of patella on the MR slice. The hamstrings were divided into three equal regions: proximal, central, and distal. For each muscle, total and regional volumes were compared before and after the intervention using two-tailed paired sample T-test.

RESULTS AND DISCUSSION

The preliminary results showed that NHE increased overall hamstring volume in preferential order of ST (~22%, p=0.021), BFSH (~21%, p=0.027) BFLH, (~10%, p=0.001), and SM (~4%, 0.001). Regionally, NHE intervention increased BFSH volume mainly in central (~11%, p=0.006) and distal (~29%, p=0.035) regions (Fig. 1A). BFLH showed significant hypertrophy only in the distal (~10%, p=0.008) region (Fig. 1B). For ST, the increase in volume was significant only in the central region (~27%, p=0.015) (Fig. 1C). SM did not show any significant region-specific volume changes (Fig. 1D). Along with another study that showed increase in muscle fascicle length in the distal region of BFLH [5], our pilot results give novel insights into possible course of manifestation of these heterogeneous muscle adaptations.

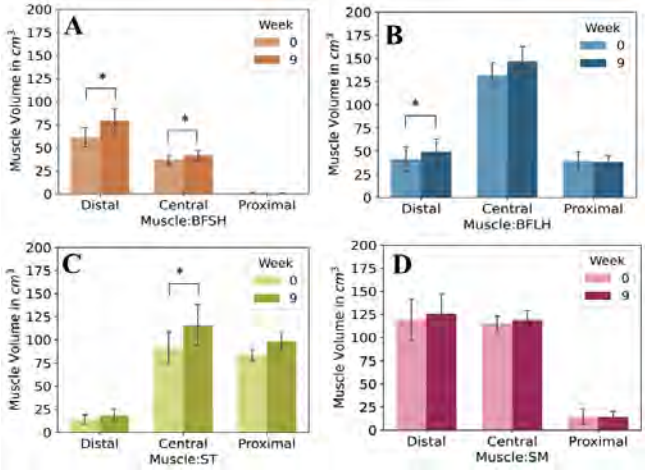

Figure 1. Hamstring muscle volume changes following 9-week eccentric NHE training program. Region-specific (distal, central, and proximal) muscle volumes for A) BFSH, B) BFLH, C) ST, D) and SM. * indicate statistically significant changes (p<0.05).

CONCLUSIONS

Overall, our results indicate that hamstring muscle adaptations to eccentric NHE are non-uniform and are muscle and region-specific.

INTRODUCTION

The role of obesity in the development of metabolic and cardiovascular diseases is well acknowledged and has been clinically examined. In contrast, little is still known on the effect of obesity on the musculoskeletal system , and diagnostic tools for monitoring changes in skeletal muscles are still poorly explored. Ultrasound imaging is a promising, non-invasive diagnostic tool to estimate muscle quality and fibrosis through echointensity (EI). However, subcutaneous fat between the utlrasound and the muscle region can result in reduced EI and therefore in overestimated muscle quality in individuals with obesity. Previous studies have tried to account for this confounding effect by applying pressure over the muscle in order to deform the layer of fat [1]. Here, we i) present an equation to correct for the independent effect of subcutaneous fat on ultrasound estimates of muscle quality, and ii) compare, for a sample of healthy adults with varying body composition, the differences between this newly developed correcting factor and the one available in the literature based on pressure [1].

METHODS

The independent effect of fat thickness on EI was verified using exogeneous layers of pork fat over the muscles in 10 participants. The regression between fat thickness and echointensity was verified and the slopes were averaged across individuals. Later, the rectus femoris and tibialis anterior EI were evaluated in 14 subjects ranging from lean to obese. Sonograms were obtained with a depth of 40 mm; general gain of 60 dB and TGC neutral. Focus position was adjusted to the muscle region of interest (ROI) [2]. EI was determined as the mean value of a gray-scale histogram function and was corrected for the confounding effect of subcutaneous fat using the correction factor developed by us and the one previously available in the literature.

RESULTS AND DISCUSSION

There is a significant error in the raw estimates of muscle quality (Table 1).

The analysis of the independent effect of fat resulted in the following correction equation: $EI_{corrected} = EI_{measured} + 39.2297 \times (adipose\ thickness\ in\ cm)$. Compared to the estimates corrected with the current equation, we observe a bias in muscle quality estimates using a pressure-based correction to account for the effect of subcutaneous fat thickness (Figure 1).

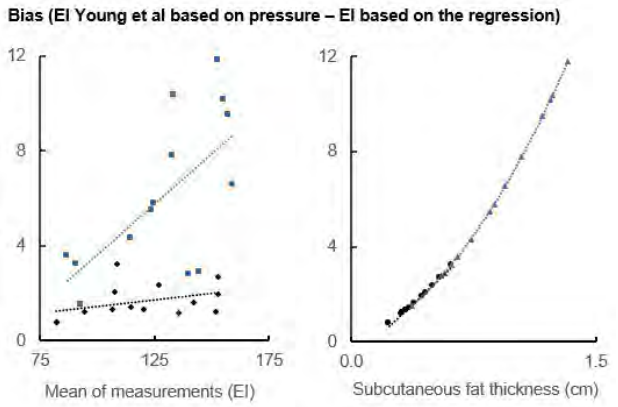

Figure 1 Left: bias in EI estimates corrected based on pressure applied on the probe (Young et al [1]) compared to estimates corrected by the independent effect of fat. Data for the TA are shown in black, and for RF, in blue. Right: Bias increases with increasing fat thickness.

CONCLUSIONS

EI estimates of muscle quality are significantly affected by the thickness of the subcutaneous fat. Using pressure to try to correct for the confounding effect of subcutaneous fat may introduce bias and lead to erroneous estimates of muscle quality in individuals with obesity. Here, we present an equation that was developed experimentally through the analysis of the independent effect of fat and suggest its use in future studies.

INTRODUCTION

Aseptic loosening is often associated with adverse periprosthetic bone remodelling owing to stress/strain shielding. An earlier study proposed a thermodynamic-based model that could incorporate the coupling between the mechanical loading and biochemical reactions involved in bone adaptation [1]. Earlier studies which implemented the mechanobiochemical model in the intact and implanted femur ignored the anisotropic nature of bone and were limited to femur [1, 2]. The objectives of the study were to develop an improved mathematical framework orthotropic bone adaptation of a hemipelvis based on mechanobiochemical model and to compare the predictions with the orthotropic-strain-based bone adaptation.

METHODS

The patient-specific 3-D finite element (FE) models of intact and implanted hemipelvises were developed [3]. The newly developed framework considered thermodynamic-based bone adaptation along with the orthotropic material property determination based on the strains along the principal directions. The standard law of mass action was modified as Eqn. 1, to achieve the coupling between biochemical affinity of the reactions and the mechanical stimulus [1].

$$r_\alpha = k_{+\alpha} \prod_{i=1}^{n} [N_i]^{v_{\alpha i}} - k_{-\alpha} \prod_{i=1}^{n} [N_i]^{v'_{\alpha i}} + l_{\alpha v} d_{(1)} \quad (1)$$

Where r_α and A_α represents the rate and affinity of the α^{th} biochemical reaction (α = 1 to 5), l and k represents the phenomenological and reaction rate coefficients, respectively, $d_{(1)}$ represents the rate of dilatation (rate of volume variation). $v_{\alpha i}$ and $v'_{\alpha i}$ are the stoichiometric coefficients of the mixture of N_i entering and leaving the α^{th} reaction, respectively [1].

RESULTS AND DISCUSSION

The changes in bone density distribution, after equilibrium in bone remodeling, corresponding to orthotropic strain-based model (Figure 1b) and orthotropic MBC model (Figure 1c) were compared. The orthotropic strain-based model predicted an appreciable bone resorption (~75%) in the region of interest (ROI) 1, whereas the orthotropic MBC model predicted a slightly lesser reduction in average bone density (~50%) in the ROI 1. The sectional plots of figures 1b and 1c indicates similar high bone resorption (75-85%) predictions by both the models. However, orthotropic MBC model estimated more volume of bone elements (10-20%) to experience bone resorption. Similar bone apposition was observed near the acetabular rim (Figure 1) in the bone remodeling predictions of orthotropic strain-based model and the orthotropic MBC model. Despite the similarities within the bone density distributions (section 1-1, 2-2 of Figure 1 b, c) between the orthotropic strain based model and orthotropic MBC model, a clear distinction could be observed in the evolutionary bone density predictions.

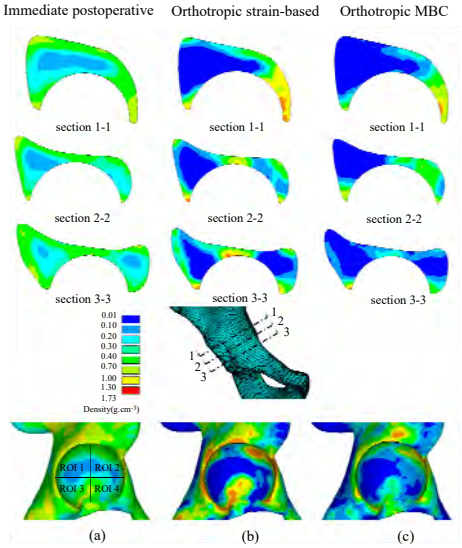

Figure 1: Changes in bone density distribution owing to implantation, sectional and lateral views: (a) immediate postoperative; (b) predicted by orthotropic strain-based model; (c) predicted by orthotropic MBC model.

CONCLUSIONS

The predictions of the orthotropic MBC model were agreed qualitatively with that of the orthotropic strain-based model. This novel framework of orthotropic MBC model implicitly incorporates the biochemical stimulus and the mechanical stimulus along with a detailed description of the bone anisotropy.

INTRODUCTION

Personalized biomechanical models of the foot may assist in understanding form function relationships through techniques such as finite element (FE) analysis [1]. Foot geometric characteristics are usually obtained from medical images, which are considered the gold standard, primarily from computed tomography (CT) and magnetic resonance imaging (MRI). However, personalizing a foot and ankle joint model is highly time-consuming in terms of medical image collection and data processing. Statistical shape modelling (SSM) can represent a range of expected, evidence-based variations in a population and be used to intelligently scale a model to a subject with minimal information [2]. This study aimed to develop and validate a framework to rebuild a 3D foot including internal bones using SSM based on skin measurements.

METHODS

The 3D foot surface shape of 50 participants (age: 24.0±3.8 yrs; height: 1.75±0.06 m; mass: 67.6±7.8 kg) was scanned using an Easy-Foot-Scan machine to train a SSM following ethical approval. Model-based shape reconstruction was performed to generate foot surface geometry using a principal component analysis (PCA). Following this, free-form deformation (FFD) was performed to reconstruct internal bone meshes [3]. The pipeline for personalized foot model generation using surface-based SSM is shown in Figure 1. The model accuracy was established by comparing three reconstructed foot models (age: 24.3±2.5 yrs; height: 1.75±0.03 m; mass: 66.0±2.0 kg) to corresponding skin and bone geometries that were manually segmented and not part of the original training set.

RESULTS AND DISCUSSION

We used the top ten principal components representing 85% of the population variation. For prediction validation, the average Dice similarity coefficient (DSC), Hausdorff distance, and root mean square (RMS) error were 0.84±0.03, 1.83±0.10 mm, and 2.36±0.12 mm for bones, and 0.92±0.01, 2.2±0.19 mm, and 2.95±0.23 mm for the encapsulated tissue, respectively.

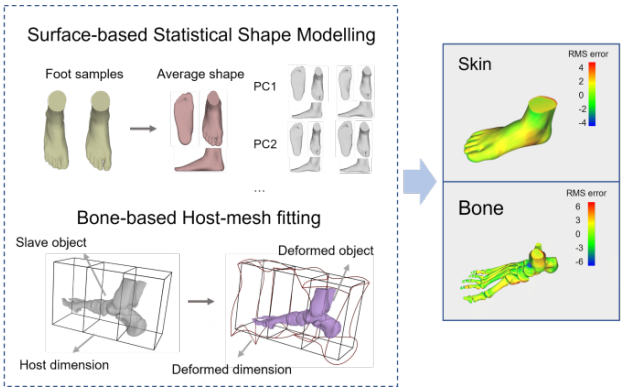

Figure 1 Illustration of the pipeline for 3D personalized foot model generation.

This study developed a personalized foot model reconstruction pipeline through a foot surface scan. Specifically, a PCA-based SSM coupled with FFD was used to rebuild the encapsulated skin and inner bones. We found that a 3D personalized foot model can be reconstructed using rapid surface scanning with minimal error. This approach eliminates the cost of medical imaging for reconstructing bone geometries and is time-saving. The proposed pipeline is an effective technique to rapidly personalize foot geometries for FE modelling and rigid body modelling such as with OpenSIM. This in turn will lead to more informed predictions with models especially in pathology.

CONCLUSIONS

This study presents a subject-specific foot model via SSM generation of the foot surface and bone reconstruction based on free-form deformation. The proposed workflow makes it possible to accurately generate foot models informed by population anatomy, which can be used in future anatomical and mechanical simulation investigations.

INTRODUCTION

Lateral ankle sprain is one of the most common injuries during physical activities in the lower limb [1]. Previous studies have shown that 36% of lower limb injuries are associated with strains and sprains-related injuries, which often develop into chronic ankle instability (CAI). Hallux movement relates to foot function and posture, such as foot flat [2, 3], which is one cause of CAI. Previous research indicates that different walking speeds are associated with significant biomechanical changes in the movement pattern [4]; however, there are still inconclusive findings in relation to deficits in hallux movement as a functional activity, such as level walking at different speeds in individuals with CAI. Therefore, we aimed to explore hallux movement in CAI patients and healthy controls during walking at different speeds.

METHODS

We recruited 18 participants in both healthy and CAI groups (9 female and 9 male) with age- and BMI-matched. The participants of both groups are between 18-25 years old. Participants in the CAI group have suffered from ankle sprains for at least two episodes with recurrent ankle sprain within one year and did not have other lower-limb injuries over six months, and Cumberland Ankle Instability Tool (CAIT) score less than 21.5 scores. The healthy group did not have an ankle sprain, and other injuries in the lower limb within one year [5]. A Vicon Motion Analysis System (12 optoelectronic cameras) with Plug-in-Gait (PiG) and the Oxford Foot Model (OFM) were used to capture hallux kinematics in barefoot conditions during level-walking at fast speed (FS) (140 bpm), self-selected (NS), and slow speed (SS) (80bpm) during the stance phase. Comparisons were used between groups by using independent t-tests ($p<0.05$) and one-Dimensional Statistical Parametric Mapping (SPM-1D).

RESULTS AND DISCUSSION

Significant differences in hallux kinematics were found between the groups during level-walking at their FS, NS, and SS. Increases in hallux dorsiflexion were found in CAI group during mid-stance (MS) to terminal stance (TS) at FS and SS (mean difference (MD) 10.68 ° ; p=0.031, MD 10.01 ° ; p=0.003, respectively), and pre-swing (PS) at FS, NS, and SS (MD 8.67 ° ; p = 0.042,MD 6.79 ° ;p=0.049,MD 7.31 ° ;p=0.043, respectively), Then, CAI group showed increased hallux varus during MS at FS (MD -3.44 ° ; p=0.047), MS to TS at SS (MD -3.74 ° ; p=0.013) and PS at FS, NS, and SS (MD -3.44 ° ; p= 0.046, MD -3.45 ° ; p=0.049, MD -3.29 ° ; p= 0.048, respectively) when compared to the healthy group.

A previous study shows that increased hallux dorsiflexion is related to a decrease foot arch high, which can lead to foot flat problem [3]. In our study, the CAI group showed an increase hallux dorsiflexion and varus at three walking speeds, which relates to the hallux varus position. Nevertheless, Hallux Varus is related to foot intrinsic and extrinsic muscle imbalance such as flexor and extensor hallucis brevis and longus (FHB, EHB, FHL, EHL), abductor hallucis brevis and adductor hallucis[6]. More importantly, a recent study showed that EHL would be a pivotal muscle to improving CAI problems due to intramuscular angle change[7]. Consequently, an increase in hallux dorsiflexion and varus will cause CAI injury.

CONCLUSIONS

At different walking speeds, individuals with CAI may employ compensatory motor strategy in the hallux movement to adapt their functional movements by increased hallux dorsiflexion and varus during mid-stance to terminal stance (FS, SS) and pre-swing (FS, NS, and SS). These alterations in forefoot biomechanics during level walking may lead to structural adaptions, such as Hallux Varus, and flat foot deficits. Furthermore, these above changes in foot structures may be potential precursors to contribute to the recurrence rate of re-injury.

INTRODUCTION

Different modes of mechanical loading lead to various adaptations in the mechanics of the Achilles tendon (AT) [1]. Despite these adaptations, AT is a common site of musculoskeletal conditions, usually due to sports activities [2,3]. Although AT has been frequently studied, knowledge of its' biomechanical organization and properties remains incomplete. Therefore, we exploratively investigated the internal AT displacement and passive AT shear wave velocity (SWV) of athletes. The aim was to investigate whether previous physical exercise, lower limb injury history, or individual characteristics influence internal AT displacement and AT SWV.

METHODS

A total of 131 athletes (48 men, 83 women; 19.5±3.8 years) from basketball (27), football (31), gymnastics (25), track and field (21) and ice hockey (27) were recruited from a local Sports academy. All subjects competed at the national level and actively trained in their sports. The study was approved by ethics committee and participants provided a signed informed consent.

Internal AT displacement was measured with cine B-mode ultrasonography and quantified offline using 2D speckle tracking [4]. Mean displacement (mm) was extracted for the overall tendon and for the anterior and posterior halves of the tendon. Maximum non-uniformity (mm), calculated as maximum-minimum displacement within the tendon cross-section, was also extracted. Shear wave elastography was used to measure resting AT SWV (m/s) from three distal locations longitudinally. SWV was extracted with a custom software (ElastoGUI). Participation in sport within two days before assessments, history of lower limb injuries, sport specialisation and leg dominance were asked. Significance of mean differences was tested using paired and independent samples *t* tests, and associations between outcome variables were tested using Pearson's correlation coefficient.

RESULTS AND DISCUSSION

Athletes without prior exercise exhibited greater AT non-uniformity (Figure 1) and mean displacement of the anterior half of the tendon, and lower SWV of the proximal AT measurement site (mean difference [95%CI]:1.768 mm [0.621–2.916], p=0.003; 1.556 mm [0.236–2.875], p=0.021; -0.887 m/s [-1.589- -0.185], p=0.014, respectively).

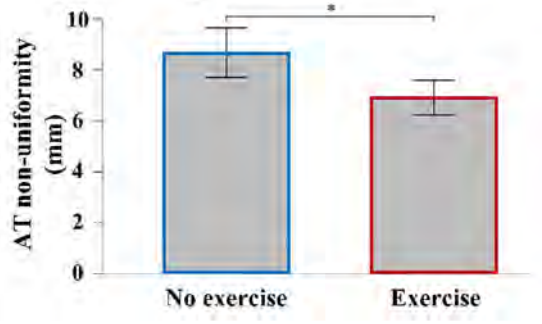

Figure 1. AT non-uniformity of athletes with or without exercise within two days before assessment.

Injury history or sex did not affect any of the outcomes measured. Sports differences were observed in men, with smaller AT mean displacement in basketball players compared to gymnasts (-3.741 mm [-6.938- -0.543], p=0.042), with the difference localizing in the anterior half of the tendon (-5.051 mm [-9.044- -1.058], p=0.022). The dominant leg showed a greater AT mean displacement in the posterior half of the tendon in gymnasts (1.2 mm [0.009–2.4], p=0.048), and in contrast, the displacement was greater for the non-dominant side (0.9 mm [0.05–1.8], p=0.039) in football players. In ice hockey players AT non-uniformity and SWV of the proximal AT measurement site were greater on the dominant side (1.2 mm [0.2–2.2], p=0.022; 0.8 m/s [0.1–1.5], p=0.031).

CONCLUSIONS

The internal displacement of the Achilles tendon was smaller if exercise was performed within two days before the assessment. This may reflect the necessary time course of tendon recovery in healthy individuals. The results suggest multifaceted differences in mechanical properties of Achilles tendon regarding sport-specific loading and leg dominance.

Determining Torque-Angle Relationships of Human Toe Flexors

Samuel J Wisdish[1], Hannah Rice[1,2] Matthew A Ellison[1], and Dominic J Farris [1]

INTRODUCTION

We rely on the foot's muscles during tasks of movement, with the plantar intrisnic muscles (PIMs) actively facilitating propulsion during gait [1]. Weakness or atrophy of foot musculature is associated with reduced mobility, and strengthening of these muscles may help mitigate age-related mobility declines [2]. Understanding the force-generating capacity of the toe flexor muscles may therefore be a key to understanding healthy foot function. We aimed to establish toe flexion torque-angle relationships and improve *in-vivo* estimations of the parameters governing force production.

METHODS

Separate isometric hallux (HFT) and lesser digit (LDFT) flexion torque-angle data were twice collected from nine participants (age 28 ± 5 years) using a custom setup. Torque of twitch response to transcutaneous supramaximal stimuli applied at two tibial nerve sites (medial malleolus – MM; and popliteal fossa – PF) distinguished PIM, and PIM+extrinsic active contributions from passive contributions throughout MTP joint range, in four conditions (HFT_{MM}, $LDFT_{MM}$, HFT_{PF}, $LDFT_{PF}$). 3D kinematics were processed in OpenSim 4.3 using a multi-segment foot model. Active and passive torque-angle curves were computed within Matlab (Mathworks) using physiologically appropriate models [3] for each participant with curve coefficients of maximum torque (T_{max}), optimum angle (Θ_{opt}), passive stiffness (k) and slack angle (Θ_{slack}).

RESULTS AND DISCUSSION

HFT and LDFT torque-angle relationships and their coefficients showed good-excellent inter-day reliability (Table 1.). Greatest T_{max} occurred when innervating both the hallux flexors (3.04 ± 0.76 Nm) and lesser digit flexors (3.17 ± 1.05 Nm) from the PF. For all conditions T_{max} occurred at MTP joint angles (Θ_{opt}) that would be typically observed during the propulsive phase of gait (HFT_{PF} = 48 ± 14.6°; $LDFT_{PF}$ = 42.9 ± 14.9°) (Figure 1C), which suggests they may be optimised to contribute to propulsion. Furthermore, the peak total torque generated at the MTP joint was dominated by active, not passive, torques (Figure 1. A and B). Passive MTP joint torques are assumed largely to be generated by the plantar fascia (Figure 1. Panel A & B), and our results therefore question the functional importance of the windlass mechanism.

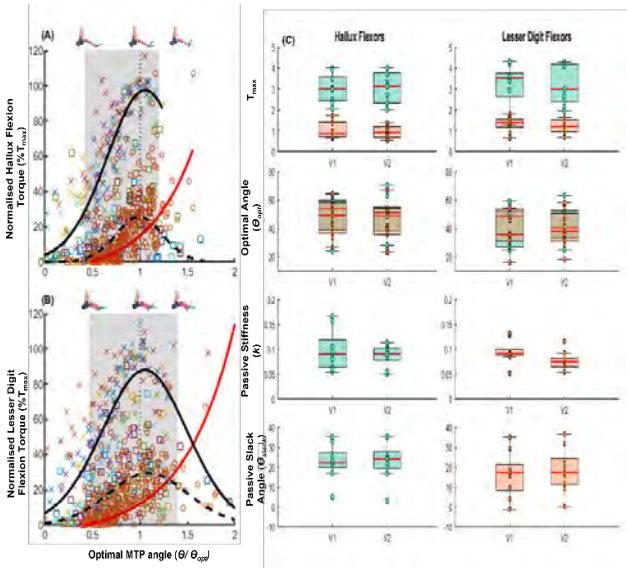

Figure 1. Comparison of mean toe flexor torque-angle relationships and coefficients. (A) and (B) plot mean normalised hallux flexor (A) and lesser digit flexor (B) torque-angle relationships from PIM only (dashed black), PIM + extrinsic (solid black) and passive torque (red) about the respective MTP joints. The shaded grey area represents typical range of MTP joint during propulsive phase of gait. (C) plots torque-angle relationship curve coefficients across Visit 1 & Visit 2 for each contraction condition (PIM only = orange; PIM + extrinsic = green).

CONCLUSIONS

Optimal force-generating angles of human toe flexors appears to be aligned with the typical MTP joint kinematics during propulsion, and are dominated by active muscle contraction. This may have implications for further understanding how active muscle contributions determine the foot's mechanical function in tasks such as walking.

Individual rocker shoe parameters that reduce plantar peak pressure

Thomas Johnson[1], Frederico Klein[1], Juha M. Hijmans[2], Fredrik Olsson[1], Elena M. Gutierrez-Farewik[1,3]

Introduction

Diabetes is an insulin deficient condition that is growing in many parts of the world (WHO [1]). One of the most common co-morbidities associated with diabetes is the loss of peripheral sensation. Increase in plantar pressure under the foot [2] contributes to development of diabetic foot ulcers (DFU), which can lead to amputation. Rocker shoes, or shoes with a curved midsole have been shown to decrease plantar pressure especially in the forefoot [3]. The aim of this study is to investigate the influence of a range of rocker shoe parameters in plantar pressure, with the specific goal of reducing to or maintaining peak pressure (PP) at all points of less than 200 kPa.

Methods

In this randomised crossover-controlled trial, twenty-four different rocker shoe conditions were tested on thirty-six able-bodied participants. Longitudinal bending stiffness (rigid (r) and flexible (f)), rocker radius (rr) - 60% and 70% of shoe length from heel, apex position (ap) - 55%, 60% and 65% of shoe length, and apex angle (aa) - 65° and 85° from the shoe longitudinal axis (from the heel to the 2nd toe) all varied in the different experimental shoe conditions. In-shoe plantar pressure insoles (Novel Pedar) were used to measure PP during ca. 12-15 gait cycles at 2 different speeds on a treadmill, with all shoe configurations and with participants' own everyday shoes (control). The speeds were height-, age- and gender-normalised preferrable walking speed [4], and slow walking (mean preferrable walking speed – 1 standard deviation). Sensors were grouped into 7 masks deemed clinically relevant to the development of DFU.

Results and Discussion

Stiffness, ap and rr all showed significant effects on the reduction of PP ($p<0.001$) in the forefoot. At the heel all rocker conditions lead to increased pressure relative to control ($p<0.001$). Stance phase was shown to be shorter in rocker shoes when compared to control.

Rocker shoes are effective in reducing PP distally [3] wherein a range of ap and rr can significantly reduce pressure in clinically relevant areas such as the hallux and the medial forefoot. However, all rocker conditions caused an increase in PP above the threshold value (200 kPa) at the heel in early stance phase. Increased PP at the heel may be associated with spatiotemporal gait changes in rocker shoes such as reduced double stance phase.

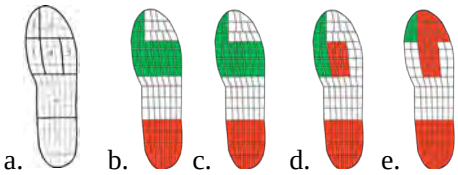

Figure 1. a. *Custom masks. Experimental rocker shoes compared to control, significant increase (green) and decrease (red).* ***b.*** *f- and* ***c.*** *r/ap55/aa65/rr60.* ***d.*** *f- and* ***e.*** *r/ap65/aa85/rr70*

Conclusion

Going forward it may be important to compensate for heightened pressure under the heel with some pressure redistributive material insole or midsole. These results indicate the importance of an individualised approach to the prescription of rocker shoes to reduce pressure at specific plantar areas of the foot.

INTRODUCTION

In motion analysis, kinematic signals are calculated from optical or inertial data to visually represent movement between joint segments. Despite ISB recommendations aiming to standardise the reporting of these signals [1], a lack of consensus around joint coordinate frame definitions remains. The influence of local segment frame position and orientation on the characteristics of kinematic signals has been shown to be a major limitation [2,3]. For consistent interpretation of joint motion to be possible, differences in frame alignments must therefore be addressed. Here, we assess the REference FRame Alignment MEthod (REFRAME) [3] on the knee kinematics of a cohort of 10 healthy subjects, investigating the method's ability to enable kinematic signal convergence in six degrees of freedom, despite the use of different frame definitions.

METHODS

REFRAME reorientates and repositions local segment frames such that the associated kinematic signals fulfil certain optimisation criteria. Here, *in vivo* knee kinematics captured using a moving videofluoroscope were used to validate REFRAME. While a common approach was used to define the tibial frame, three different femoral coordinate frames were defined using the following variations of the flexion/extension axis: cylindrical axis (CA), functional flexion axis (FFA), and transepicondylar axis (TEA) [2]. Flexion/extension, ab/adduction, and int/external rotation, as well as anteroposterior, mediolateral and proximodistal translation were calculated over five stair descent trials for 10 healthy subjects [4]. REFRAME then optimised the obtained kinematic signals to realign local frames such that root-mean-square errors (RMSEs) vs. 0 for ab/adduction and int/external rotation, as well as variances for all three translations, were minimised.

RESULTS AND DISCUSSION

Frame transformations induced by REFRAME led to noticeable changes in the magnitude and characteristics of the kinematic signals. In addition to evident convergence of the optimised signals (Fig. 1), pairwise comparisons of signals coming from different definitions led to a decrease in mean RMSE from 3.24mm±2.50mm to 0.24mm±0.05mm for translations, and from 2.62°±2.07° to 0.10°±0.16° for rotations. Changes in the orientation and position of local frames resulting from the implementation of REFRAME led to convergence of kinematic signals that originated from the same underlying movement but were calculated using different flexion/extension axis approaches.

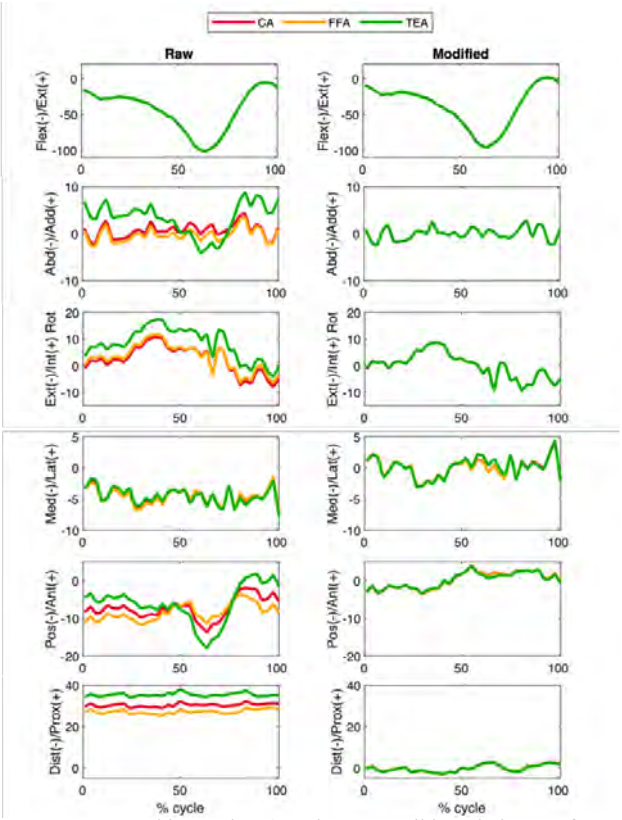

Figure 1 Knee kinematics (rotations [°]: tibia relative to femur; translations [mm]: femur relative to tibia) during a sample subject stair descent trial, using three different primary axes, before (raw) and after (modified) REFRAME. (CA and FFA partially covered by TEA)

CONCLUSIONS

REFRAME can enable the consistent interpretation and comparison of joint kinematics derived using different approaches.

Is Peak Anterior Foot Position Related to Anterior Foot Position at Initial Contact during Gait Training with Visual Feedback?

INTRODUCTION

Providing relevant and easy to interpret feedback stimuli is key for gait training paradigms utilizing augmented feedback. Anterior foot position at initial contact relative to the body (AFP_{IC}) provides insight into the severity of impairments in patient populations such as cerebral palsy (CP) [1], and hence could be a strong basis for a feedback retraining cue. During normative gait, the furthest anterior foot position (AFP_{Peak}) occurs simultaneously or close to initial contact, indicated by the "reversal" of the foot anterior/posterior velocity measured via motion capture [2]. AFP_{Peak} can be estimated purely through segmental kinematics as measured from wearable inertial measurement unit (IMU) orientations and does not require detection of initial contact which can be technically challenging, especially in pathological gait. We previously reported that a participant with CP responded to AFP_{Peak} feedback with increased knee extension at initial contact as anticipated [3]. In the current study we compared the relationships between AFP_{Peak} and AFP_{IC} during baseline (BAS) walking and AFP_{Peak} feedback exposure, to gain further insight into the adaptations to this visual cue.

METHODS

Results are presented from four participants (13.8 ± 5.1 yrs) diagnosed with CP and exhibiting increased knee flexion angle at initial contact. In all testing, participants walked on a treadmill at a self-selected speed with synchronized collection of lower extremity kinematics from four IMUs (60 Hz) and 3-dimensional motion capture (120 Hz). Participants first walked for one minute to obtain BAS gait kinematics. Participants then walked for six minutes with visual feedback followed by 3 minutes of rest, repeated three times. During feedback trials, a kinematic model utilizing 3D IMU orientations and segment lengths for the more involved side thigh and shank calculated relative foot position, displayed real-time as a red dot moving vertically [3]. The display incorporated scoring zones and awarded points in ascending order based on AFP_{Peak} for each step.

RESULTS AND DISCUSSION

During BAS, all participants displayed a strong correlation between AFP_{Peak} and AFP_{IC} (Figure 1). This supports the notion that, during gait, AFP_{Peak} could be considered a surrogate assessment of AFP_{IC}. When feedback was introduced, the observed correlations were maintained overall for 3 of the 4 subjects. Subject 2, however, displayed decoupling of the relationship. This subject adopted an unusual gait adaptation in which the time delay between the occurrence of AFP_{Peak} and initial contact was increased almost six-fold (Fig. 1). We observed adaptations including greater increases in AFP_{IC} among subjects 1, 3, and 4 (+13.5% - 853.2%) compared to subject 2 (+4.1%).

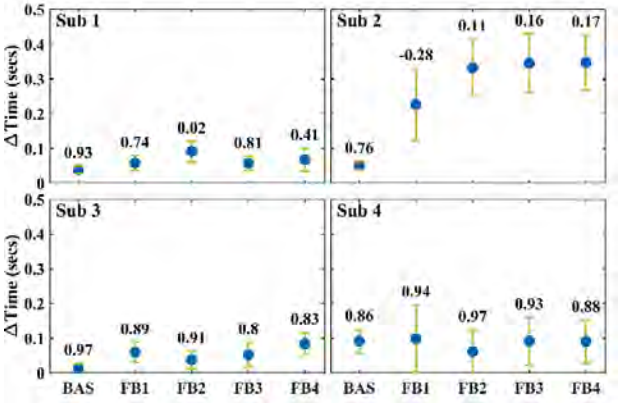

Figure 1. Time delays between AFP_{Peak} and AFP_{IC} (mean and S.D. bars) and AFP_{Peak}/AFP_{IC} correlation coefficients (numbers above S.D. bars) for baseline (BAS) and feedback (FB) trials.

CONCLUSIONS

With exceptions for some trials, three out of four subjects maintained high correlations between AFP_{Peak} and AFP_{IC} from BAS into AFP_{Peak} exposure. Hence, this feedback stimulus shows potential for gait training in paediatric CP when the intention is to target adaptations at initial contact. In this way, feedback systems such as this one can rely on IMU orientation only and avoid the need to detect foot contact in real-time. However, some individuals may respond to this feedback with unintended gait patterns in which AFP_{Peak} significantly precedes initial contact. For these circumstances, additional cueing from clinical staff may be adopted to model the type of adaptation to AFP_{Peak} visual feedback.

INTRODUCTION

The use of biomechanical data to inform clinical decision making in orthopaedics has been rare, largely due to practical limitations in obtaining motion capture data. Traditional marker-based motion capture systems are resource- and time-intensive with significant data collection burden for patients. Markerless motion capture technology using computer vision and machine learning approaches to obtain biomechanical data from standard video images offers significant advantages for ease of data collection, but must demonstrate the ability to produce relevant outcome metrics in a clinical population. The objectives of our pilot study were to (1) determine the feasibility of using markerless motion capture technology to record kinematics during a variety of tasks in an orthopaedic population recruited directly from clinic visits and (2) to compare gait waveform data collected on a severe knee osteoarthritis (OA) population to a control group, to replaced knee joints, and to historical marker-based data for similar groups.

METHODS

Orthopaedic patients with knee OA were recruited from an orthopaedic assessment clinic after referral to an orthopaedic surgeon for total knee arthroplasty. Participants wore the clothes and shoes they had worn that day. Severe OA patients (n=77) performed functional tasks during markerless motion capture: timed up-and-go (TUG), stair ascent and descent, quiet standing (balance), walking at self-selected speed, and fast walking. Previous knee replacements in the contralateral leg were analyzed separately (n=17). A control group consisted of members of the community over 50 years of age (n=29). Markerless motion capture was performed using 8 commercially available video cameras (Sony RX0-II) recorded at 60 Hz and processed using Theia3D (Theia Markerless Inc.). Historical data using a marker-based motion capture system for severe OA post-knee replacement, and control subjects were obtained from a previous publication [1].

RESULTS AND DISCUSSION

The markerless severe OA group was 56% female with mean age 69 years (SD 8). Kinematic data from the markerless system was calculated for all participants for all completed tasks with no discernable tracking issues. The markerless control group (59% female, mean age 58 years) had a self-selected walking speed of 1.3 m/s compared to 0.9 m/s for the severe OA group. Joint angle waveform data captured with the markerless system show similar patterns to historical data collected with marker-based motion capture for severe OA, post-knee replacement, and control groups (Figure 1).

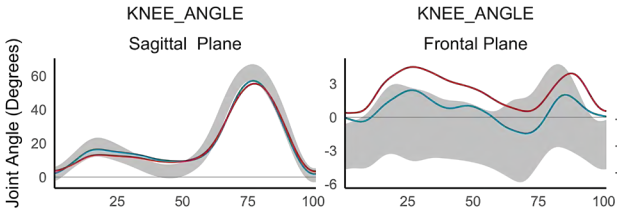

Figure 1 Joint kinematics from markerless motion capture in a cohort of severe knee OA patients (red) and post-total knee replacement (blue). Shaded regions represent +/- 1 standard deviation from age-matched control group means. Knee flexion in the sagittal plane and knee adduction angles in the frontal plane exhibit similar waveform pattern and magnitude characteristics as compared to historical maker-based data, specificially reduced flexion angles and greater varus alignment in the severe OA group. Replaced knees are closer to asymptomatic patterns.

CONCLUSIONS

This study demonstrates feasibility of using markerless motion capture for an orthopaedic population directly from a clinic visit with no restrictions on clothing. Kinematic data from markerless motion capture exhibited expected kinematic deviations based on historical marker-based gait data on similar populations. The ease of data collection and the standardized calculation of biomechanical metrics have important implications for clinical implementation as well as longitudinal and multi-centre studies.

INTRODUCTION

Spinal fixation for spinal deformity in adults corrects the alignment of the spine, both in static positions and during gait. However, mechanical complications occur in approximately 30% of cases postoperatively; sagittal malalignment is one of these factors. Gait characteristics are closely related to spinal alignment. Therefore, identifying gait characteristics in older adults with the progression of sagittal malalignment after spinal fixation aids decision-making in postoperative rehabilitation. Herein, we compared the gait characteristics of patients with and without sagittal malalignment after spinal fixation.

METHODS

Ninety-four patients (mean age: 74 years) who underwent spinal fixation from the thoracic to the pelvis were assessed by three-dimensional gait analysis six months postoperatively and by radiographic spinal alignment six months and one year postoperatively. Patients whose sagittal vertical axis (SVA) was > 0 at six months and increased from six months to one year postoperatively were defined as the sagittal malalignment group; the others were defined as the non-sagittal malalignment group. Inverse probability of treatment weighting (IPTW) was performed to adjust the covariates of the patients with and without sagittal malalignment. The covariates included were spinopelvic or radiographic parameters such as SVA, thoracic kyphosis, pelvic tilt, proximal junctional angle, lumbar lordosis, age, sex, knee extension strength, and ankle plantar flexion strength. To determine the characteristics of the individuals with the progression of sagittal malalignment, gait characteristics were compared using a generalized linear model between groups after IPTW. Then the coefficient of determination was calculated between the gait characteristics, which showed significant differences between groups, and other gait characteristics to reveal the gait pattern of the patients with the progression of spinal malalignment. Analyses were conducted using R software (version 4.0.3). $P < 0.05$ denoted statistical significance.

RESULTS AND DISCUSSION

The maximum trunk flexion angle during the gait cycle was significantly larger and the trailing limb angle (TLA) was smaller in patients with sagittal malalignment than those in patients without sagittal malalignment (Table 1, Figure 1). In patients with sagittal malalignment, the maximum trunk flexion angle was positively correlated with the maximum distance between C7 and the center of mass (COM) during the gait cycle ($r^2 = 0.61$, $p < 0.001$) and negatively correlated with TLA ($r^2 = 0.23$, $p < 0.001$), step length ($r^2 = 0.28$, $p < 0.001$), and hip extension angle at toe-off ($r^2 = 0.16$, $p = 0.01$). The results suggested that, despite adjusted radiographic parameters, patients who walked with trunk flexion and reduced step length may receive mechanical load by increasing the C7-COM distance.

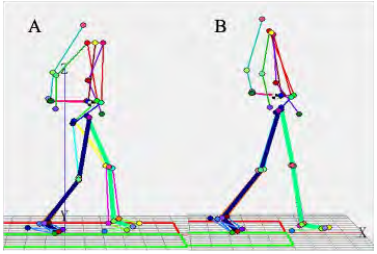

Figure 1 Gait pattern in patients with (A) and without (B) sagittal malalignment.

CONCLUSIONS

Although spinal alignment is corrected by spinal fixation, patients who cannot keep the trunk upright during gait may experience progression of sagittal malalignment. A rehabilitation strategy after spinal fixation aimed at keeping the trunk upright and carrying the lower limb posteriorly can effectively prevent the progression of sagittal malalignment.

Table 1: Comparison of gait characteristics of patients with and without sagittal malalignment.

INTRODUCTION

Gait disturbance is commonly associated with disorders in the central nervous system such as stroke and spinal cord injury. Although there are reports on the effectiveness of robot-assisted gait training for these patients, they are often reported with clinical assessment, but not with biomechanical analysis of the gait changes. For this reason we aim to characterize the changes in gait control and lower limb muscle activity in these patients after robotic intervention, in terms of segmental coordination of the limbs and lower limb muscle synergies, by comparing between pre and post gait training using a bioelectrically controlled robot suit HAL (Hybrid Assistive Limb, Cyberdyne, Japan.), and between HAL and control groups, among patients with gait impairment due to stroke or spinal cord disorder.

METHODS

30 patients with disorders in the central nervous system (11: acute phase after stroke, 15: myelopathy and 4: spinal cord injury) underwent HAL treatment of 9-10 training sessions. 9 post stroke patients underwent conventional gait training of the same number of sessions. All-In-One walking trainer (Ropox A/S, Denmark) was used together. The training using HAL consisted 20 min of walking activity in a 25 m oval course at a comfortable pace using a single or double legged HAL to support the lower limb movement. Neuromuscular activity of the hip flexor, hip extensor, knee flexor, and knee extensor muscles of the affected side was detected through surface electrodes and processed to mechanically assist the patients' gait. Gait and lower limb muscle activity during 10m walking test was recorded using an optical motion capture (VICON, UK) and a wireless electromyography system (Trigno Lab, Delsys, USA).

RESULTS AND DISCUSSION

10m walking speed and the range of joint motion improved after the HAL sessions in both stroke and myelopathy patients [1,2]. As well, covariation analysis of sagittal elevation angle of the limb segments (thigh, shank, foot) showed closer to healthy segmental coordination after HAL, in terms of planarity and loop shape, in both stroke and myelopathy patients [2,3].

Muscle activity analysis showed improvement of symmetry of the lower limb muscle synergies in the stroke patients after HAL training [4], and when compared to the control group, improvement of timing synergies was observed in the HAL group [5]. A case analysis of a myelopathy patient suggested involvement of greater number of lower limb muscle synergies during HAL gait training [6].

Patients with complete paraplegia due to spinal cord injury used upper limbs to control HAL during training based on the symmetric coordination of upper and lower limbs during human gait. The patients showed activation of some of the lower limb muscles during and after HAL gait training [7].

Since HAL assists the lower limb joint motion by sensing the relevant neuro-muscular activity [8], we consider that actual achievement of the motion, and hence sensation of the motion, intended by the central nervous system during the robot-assisted gait training, helped to change the central nervous system's control of gait.

CONCLUSIONS

In this study, we analysed gait coordination changes after gait training using HAL in stroke patients and in patients with spinal cord disorders. The analyses showed improvement of coordinated control of the limbs and the muscles. The effect of HAL on the coordinated gait control by the central nervous system is discussed.

EFFECTS OF POSTERIOR SPINAL FUSION SURGERY ON GAIT BIOMECHANICS IN PATIENTS WITH ADOLESCENT IDIOPATHIC SCOLIOSIS

Manish Gupta[1], Bhavuk Garg[1], Nishank Mehta[1], Rajesh Malhotra[1]
[1]Department of Orthopaedics, All India Institute of Medical Sciences, New Delhi, India
Email: manishgupta1307@gmail.com

INTRODUCTION

Scoliosis is a complex multidimensional spinal deformity which affects spinal anatomy, quality of movement and walking, and trunk symmetry. Posterior spinal fusion (PSF) is usually performed to stop curve progression, to reduce back pain and to restore asymmetric upper body [1]. Previous studies indicate that, there is an alteration of gait patterns in patients with Scoliosis and this gait pattern is substantially altered after surgical intervention. In India, these deformities are often neglected and present at a very late and much more deformed state (mean cobb angle $\geq 60^0$). So, we have planned a study to investigate the effects of posterior spinal fusion surgery on spatio-temporal, kinematics, kinetics and Electromyography (EMG) in severe Adolescent Idiopathic Scoliosis (AIS) patients during gait.

METHODS

This clinical prospective study after written informed consent included 60 AIS subjects and 20 healthy controls (mean age 16.3 Years) diagnosed with thoraco-lumbar/lumbar AIS (cobb angle MT 78.62 ± 8.10, TL/L 60.52 ± 7.42). Spatio-temporal parameters, kinematics, kinetics, & EMG were evaluated preoperatively and after 1 Year of surgery for AIS subjects and one time for healthy controls using instrumented 3D gait analysis (BTS, Italy) (Figure-1). Student T test, & two way annova were performed to find significant differences between pre and post operative AIS and healthy controls.

RESULTS AND DISCUSSION

Gait speed, cadence, step length were improved significantly after 1 Year of surgery. Trunk tiklt range, pelvis tilt range, gait profile score (GPS) and gait deviation index (GDI), were not changed significantly postoperatively. No significant changes in mean angle of spine flex extension, Peak during loading and propulsion, EMG activity of Erector spiane & gluteus medius were observed postoperatively (Table-1). A comprehensive study involving long-term post-operative follow-up is needed to draw decisive conclusions regarding alteration in gait of scoliosis patients postoperatively.

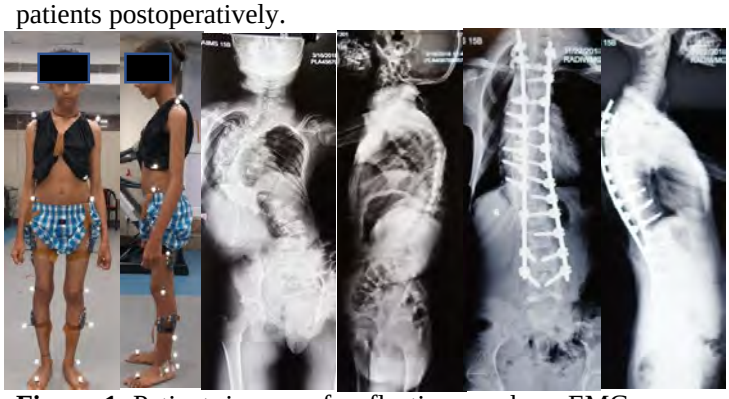

Figure-1 Patient image of reflective marker, EMG placement and pre & post operative x ray of AIS subject

CONCLUSIONS

The results of our study suggested that Surgical intervention did not cause any significant changes in the upper and lower limb kinematics during gait, despite of large part of spinal fusion. Postoperative significant improvements in spatio-temporal parameters explain the well functioning in daily life of subjects with Adolescent Idiopathic Scoliosis.

THREE-DIMENSIONAL VECTOR ANALYSIS OF GROUND REACTION FORCE MOMENT ARMS: CONCEPTUAL CONSIDERATIONS AND EXPERIMENTAL VERIFICATION

Shinichi Kawamoto, Momoko Nagai-Tanima, Tomoki Aoyama
Department of Human Health Science, Graduate School of Medicine, Kyoto University, Japan.
Email: kawamoto.shinichi.26m@st.kyoto-u.ac.jp

INTRODUCTION

Various geometric algorithms are used in the calculation of three-dimensional moment arms (3D-MA) in vivo. Inappropriate use of vector equations for 3D-MA in the context of purpose may occur without comprehension of its meaning. This research attempted to classify various research publications for 3D-MA and identify geometrical differences among the algorithms theoretically and experimentally.

METHODS

3D-MA were classified geometrically into three major categories and renamed based on conceptual considerations. The vector equations of the algorithms were collectively reinterpreted using 3D vector analysis. Additionally, these vector algorithms were verified experimentally. The moment arms of the ground reaction force about the knee in a deep squat position were determined in 31 healthy subjects using an optoelectronic motion capture system. MA with a fixed axis were calculated in four algorithms including three 3D-MA and one two-dimensional (2D-) MA.

RESULTS AND DISCUSSION

3D-MA were classified by definition: MA about a Point, Conversion MA, and Medical MA (Table 1). Figure 1 represents a schematic showing various 3D vectors, 3D-MA, and mutual relationships. Medical MA [1] is:

$$d_3(=d_4)=\overrightarrow{CG}\cdot\frac{\hat{\mathbb{F}}\times\hat{\mathbb{u}}}{|\hat{\mathbb{F}}\times\hat{\mathbb{u}}|}\ (=\mathbb{B}\cdot(\hat{\mathbb{A}}\times\hat{\mathbb{u}})) \quad (1)$$

Where $\cdot$ denotes dot product and $\times$ denotes cross product of vectors. Conversion MA [2] is:

$$d_3\sin\alpha=\overrightarrow{CG}\cdot(\hat{\mathbb{F}}\times\hat{\mathbb{u}}) \quad (2)$$

where α denotes twist angle between the line of action and the axis of rotation. To keep the moment-force relation universal in 3D also, the Medical MA algorithm imposes a component resolution on the force side, whereas the Conversion MA algorithm does on the MA side. MA about a point [3,4] is:

$$d_1=|\mathbb{P}\times\hat{\mathbb{F}}| \quad (3)$$

$$\text{or}\ \ d_2=|\mathbb{P}-(\mathbb{P}\cdot\hat{\mathbb{A}})\hat{\mathbb{A}}| \quad (4)$$

The following inequality holds geometrically as long as the identical axis (whether fixed or moving) is in use:

$$d_3\sin\alpha\le d_3(=d_4)\le d_1,d_2 \quad (5)$$

Regarding verification, Conversion MA was 2% shorter ($P<0.001$), 2D-MA was 10% shorter ($P<0.001$), whereas MA about a point was 3% longer ($P<0.001$) than Medical MA, which agreed with the geometrical deduction.

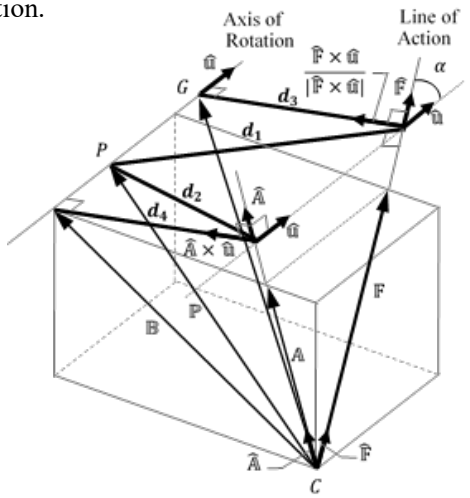

Figure 1 Schematic showing the vectors and the moment arms in three dimensions. d_1, d_2: Moment arm about a point, d_3, d_4: Medical moment arm, C: the origin of force, G: the foot of the perpendicular from the line of action to the axis of rotation, P: the joint center, $\mathbb{F}$: the force vector, $\hat{\mathbb{F}}$: the unit force vector, $\hat{\mathbb{u}}$: the unit vector along the line of action, $\mathbb{A}$: the projection of $\mathbb{F}$ into the plane perpendicular to the axis of rotation, $\hat{\mathbb{A}}$: the unit vector of $\mathbb{A}$, $\mathbb{B}$: the vector from C to the point perpendicular to the axis of rotation, $\mathbb{P}$: the vector from C to the joint center.

CONCLUSIONS

For the three-dimensional moment arm, there exist three major groups of definitions with discrete values, therefore researchers should choose the appropriate one to match concepts with individual purposes.

Table 1: Geometrical classification of three-dimensional moment arms

Classification name	Definition	Concept
Moment arm about a point	Perpendicular distance from a joint center to the line of action	Applicable to ball-and-socket joint
Conversion moment arm	Perpendicular distance between the axis to the line of action multiplied by the sine of the angle between these two lines	Coefficient converting scalar force into scalar moment
Medical moment arm	Perpendicular (shortest) distance between the axis of rotation and the line of action	Focusing solely on force component which contributes to rotation

AUTOMATED GENERATION OF PATIENT-SPECIFIC INTERVERTEBRAL DISC FEM MODELS BASED ON CT IMAGES

INTRODUCTION

Patient-specific numerical models of the spine offer a great potential for analyzing personalized biomechanics and may help to find individual back pain treatments. [1] Automated segmentation pipelines are used for modelling bony tissue like vertebrae, but the automated model creation of soft tissue, such as intervertebral discs (IVD), still includes time-consuming manual steps. We implemented an algorithm that uses patient-specific CT images to interpolate IVDs between adjacent vertebrae and generates FEM-ready, meshed volume bodies.

METHODS

An automated image segmentation based on artificial intelligence [2] was used to segment and register vertebrae from a CT image. A projection method then determined the endplates of the 3D vertebrae, which were supplemented by IVD border points using interpolated polynomials (Figure **1**). That done, two distinct approaches were investigated to create a 3D volume mesh: surface-based and volume-based. As surface-based approaches, a Ball-Pivoting algorithm (1) and a Poisson surface reconstruction (2) were implemented using different parameters. The resulting 3D surface mesh was subjected to three different smoothing methods: Laplace, HC and Taubin. Subsequently, the mesh was converted to a 3D volume mesh using surface reconstruction techniques. Instead of generating a 3D surface of the IVD border point cloud, volume-based approaches filled the inside of the IVD with a point cloud volume. To create an FEM model, it was further processed with a 3D Delaunay triangulation (3) and voxel-based methods (4). The most promising approaches were determined by evaluating and comparing mesh quality measures. The resulting meshes were smoothed using Laplace, HC and Taubin algorithms with varying parameters to determine the most suitable one. A python script was implemented to convert the final model into an Abaqus input format. For validation, the geometry of the automatically created bodies was compared to respective, manually segmented disc models. To allow comparability, smoothing steps were temporarily undone for the algorithms' validation.

RESULTS AND DISCUSSION

The surface-based Poisson reconstruction method (b) with a linear fit and a depth parameter of 10 proved to be most accurate in creating a 3D volume mesh of the IVD. With α=1, the 3D Delauney triangulation (3) resulted a marginally lower overall mesh quality and a lower geometric consistency. The Ball-Pivoting algorithm (1) resulted in bad mesh quality. Voxel-based methods (4) failed to represent the original IVD geometry in this study, but the straightforward use of hex elements could be advantageous in future studies.

For the surface-based Poisson reconstruction (2), Taubin smoothing resulted in the least change of geometry using a parameter combination of n=200/ λ=0.9 or n=1000/ λ=0.5. Comparison of the manually segmented geometries and the automatically created IVDs of (2) showed good agreement. To sum up, the implemented algorithm successfully created 3D volume models of intervertebral discs based on the segmentation of vertebrae in CT images.

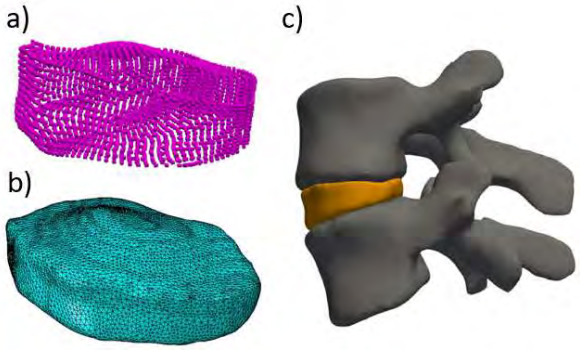

Figure 1 a) IVD border point cloud. b) 3D volume mesh after smoothing was applied. c) Integrated model of a functional spinal unit containing one IVD and two vertebrae.

CONCLUSIONS

The proposed algorithm generates FEM models of the IVD with decent quality. It contributes to the automated implementation of patient-specific spine models by reducing manual intervention and improving efficiency.

BACKPACK CARRYING: A COMPARISON BETWEEN MARKER-BASED AND MARKERLESS SYSTEMS

Heredia-Jimenez, J[1]

[1] Department of Physical Education and Sports. Human Behaviour & Motion Analysis Lab (HubemaLab), University of Granada. Spain
Email: herediaj@ugr.es

INTRODUCTION

3D analysis can be performed utilising marker-based capture systems that are considered the gold standard method for movement analysis [1]. The occlusion of reflective markers on the back and pelvis preclude the use of traditional marker-sets during gait analysis when the subject is carrying equipment on their back (i.e. backpacks or exoskeletons)[2]. An alternative that can solve back occlusion and the limitations of marker-based systems is markerless technology. The aim of this study is to compare the trunk-pelvis models between marker-based and markerless systems while carrying a backpack.

METHODS

16 healthy adults (9 males) participated in this study. The average (SD) age was 35.4 (10) years, their height was 1.71 (0.09) m and weight was 67.2 (12.3) kg. Participants walked at a self-selected walking speed in two randomized experimental conditions: loadless walking and walking with a 10 kg-backpack. The trials were recorded with two different motion capture systems (marked-based (Qualisys AB, Sweden) and markerless (Theia, Canada)). The marker set model used was previously validated in backpack carriage studies [3]. An SPM-1 dimension Anova [4]. was used to compare between systems and conditions.

RESULTS AND DISCUSSION

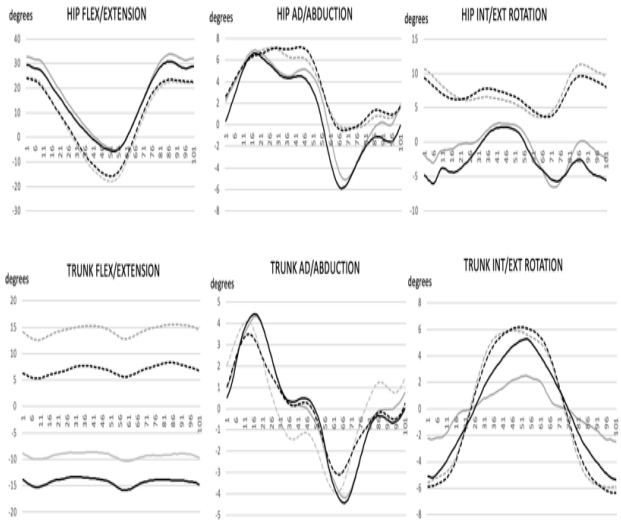

Figure 1. Comparison of kinematic waveforms under four experimental conditions. Black solid: loadless markerbased- black dotted: loadless markerless; grey solid: backpack markerbased, grey dotted: backpack markerless

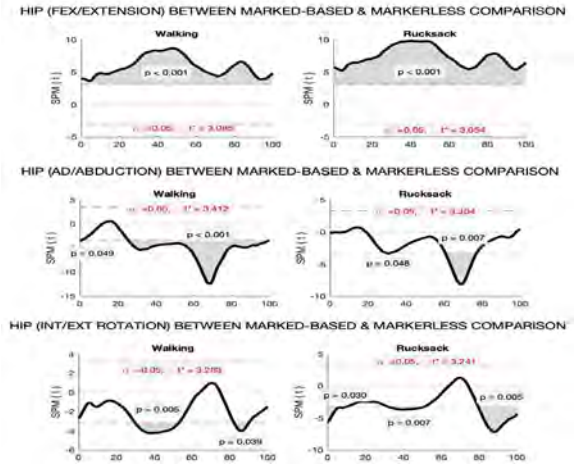

Figure 1. Hip kinematics with marker-based and markerless systems compared during loadless and backpack conditions.

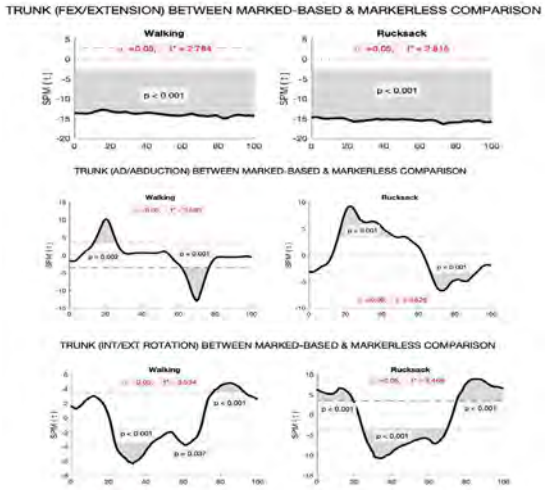

Figure 2. Trunk kinematics with marker-based and markerless systems compared during loadless and backpack conditions.

CONCLUSIONS

Kinematics of the sagittal plane did show an offset between marker-based and markerless models and partial significant differences during the gait cycle in the frontal and transverse planes across both conditions (loadless and rucksack). The markerless model showed an overestimation of the thorax angle and underestimation of the hip angle in the sagittal plane compared to the Hubemalab marker-based model. For this reason, the author advises to take into consideration the offset between different models.

ADAPTIVE P-SPLINES FOR CHALLENGING FILTERING PROBLEMS IN BIOMECHANICS

Andrew J. Pohl[1], Matthew R. Schofield[2], W. Brent Edwards[1], Reed Ferber[1]

INTRODUCTION

For signals with rapidly changing derivatives, such as those involving impacts, determining a filter cutoff frequency [1], or smoothing penalty [2], able to capture signal peaks during periods of rapid change while also removing noise from less volatile regions is problematic without over smoothing the peaks or under smoothing periods of low volatility. A potential solution is an adaptive p-spline [3] where the amount of penalization of spline coefficients is allowed to vary across the time domain of the signal. It is hypothesized that an adaptive p-spline will outperform traditional filtering and non adaptive approaches.

METHODS

Adaptive p-splines extend standard p-splines and are best understood as a hierarchical statistical model. Observations y_t for recorded samples $t = 1,\dots T$ are modelled via a spline of order d.

$$y_t = [\boldsymbol{B}\boldsymbol{\theta}]_t + \varepsilon_t \qquad (1)$$

where $\boldsymbol{B}$ is a $T \times (K+d)$ B-spline basis matrix defined over K equally spaced interior knot points spanning the range of observed times and ε_t is additive white noise. We let $K = 100$ and consider quintic splines $(d = 5)$. A p-spline is achieved via incorporation of a penalty on the integrated second derivative of the modelled function. With equally spaced knots this is approximated by a random walk prior on the second finite difference of spline coefficients $\boldsymbol{\theta}$ with variance of the random walk τ^2 determining the smoothness of the fit:

$$\theta_k = 2\theta_{k-1} - \theta_{k-2} + \upsilon_k, \qquad \upsilon_k \sim \mathrm{N}(0,\tau^2) \qquad (2)$$

Adaptive p-splines allow τ^2 to vary over the time domain. We examine two candidate models: one in which variation in τ^2 is described by an AR(1) process $(\mathrm{APS_{AR}})$ and when the variation in τ^2 is described by a cubic B-Spline $(\mathrm{APS_{cubic}})$. We choose the Dowling dataset[1] as a benchmark, which describes the angular displacement and acceleration of a rigid body impacting a barrier. The percentage root mean squared difference (RMSD) for each model when estimating the angular acceleration from the noisy angular displacement signal was computed and compared to that obtained from a Butterworth filtering approach with cutoff frequency determined via an autocorrelation procedure [1]. Bayesian inference with regularizing priors was used to estimate coefficients for each adaptive p-spline model.

RESULTS

A standard p-spline approach outperformed Butterworth filtering and was further improved when the degree of penalization was allowed to vary (Table 1). Acceleration estimates from each approach are outlined in Fig. 1 A Butterworth filter does a poor job when estimating peaks in acceleration and periods where the rigid body is stationary (0.35-0.6s) both of which are well described by an adaptive p-spline with the acceleration peak at impact best described by via the $\mathrm{APS_{AR}}$ model.

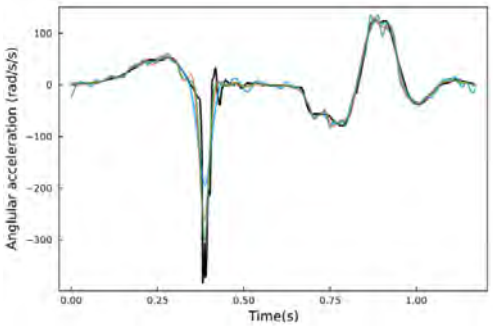

Figure 1: Estimated angular acceleration derived after Butterworth filtering (blue), $\mathrm{APS_{cubic}}$ (orange) and $\mathrm{APS_{AR}}$ (green). Ground truth acceleration in black.

CONCLUSIONS

When examining signals with rapidly changing derivatives adaptive p-splines outperform traditional filtering and non-adaptive spline methods. Biomechanists should consider adaptive p-splines especially if features such as the magnitude of impact peaks, loading rates or periods of negligible acceleration are of interest.

SHAPE OPTIMIZATION OF DENTAL IMPLANT THREAD GEOMETRY

Andi Isra Mahyuddin[1], Satrio Wicaksono[1], Hakim Dwi Ananda[1], Pramudita Satria Palar[1] and Tatacipta Dirgantara[1]

[1] Faculty of Mechanical and Aerospace Engineering, Institut Teknologi Bandung, Bandung, Indonesia.
Email: aim@itb.ac.id

INTRODUCTION

Denture implantation is a popular remedy to overcome the adverse impacts of tooth loss. However, mechanical failures such as fixture fractures are still reported [1]. To the best of our knowledge, existing dental implant-related studies focused on evaluating commercially available implant components or optimizing the geometry for volume reduction. In this study, optimization of the fixture thread geometry was performed to obtain a better thread geometry that produces a better stress distribution on the mandibular bone.

METHODS

Twenty fixture samples with different thread angle combinations were generated using the Latin hypercube sampling method. Each sample satisfies four boundary conditions including $55.68° \leq \theta_1 \leq 90°$, $55.68° \leq \theta_2 \leq 90°$, $\theta_1 \geq \tan^{-1}(\frac{0.63tan\theta_2}{0.43\tan\theta_2 - 0.63})$, and $\theta_2 \geq \tan^{-1}(\frac{0.63tan\theta_1}{0.43\tan\theta_1 - 0.63})$, which is derived according to Figure 1 by keeping the value of D and T constant, 0.63 and 0.43 mm, respectively.

Finite element analysis using Ansys ® was implemented to compare the performance of each sample. The simulated 3D model consists of four components: first molar tooth prosthesis, sectioned cortical and trabecular bone, and implant assembly. Interactions between each component were assumed to be perfectly fit and osseointegrated. Furthermore, each component was assumed to have isotropic, linear elastic, and homogeneous behavior. Zirconia and Ti-6Al-4V were chosen to represent the prosthesis and implant. Around 140000 tetrahedral elements were used for discretization. The type of simulation was static structural. Fixed supports on the mandible mesial and distal sides were defined for the boundary condition, and an axial load of 720N was defined on the enamel surface as the loading condition.

RESULTS AND DISCUSSION

The averaged maximum and minimum principal stresses in cortical and trabecular bone produced by each sample are shown in Figure 2. In cortical bone, the safe maximum principal stress was found in only four samples and the safe minimum principal stress in only six. In trabecular bone, the safe minimum principal stress was found in all samples. However, the safe maximum principal stress was only in two samples. Sample with $\theta_1 = 58.38°$ and $\theta_2 = 72.88°$ was the only one that produced a safe maximum and minimum principal stress on both cortical and trabecular bone.

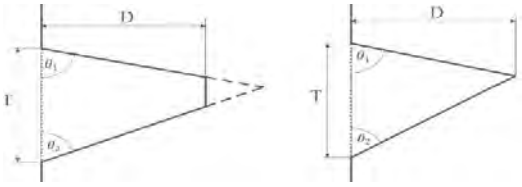

Figure 1 Simplified cross-section of fixture thread.

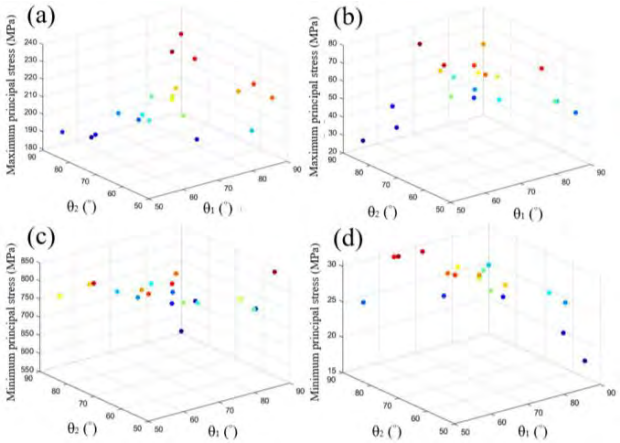

Figure 2 Produced maximum principal stress: (a) cortical, (b) trabecular; Produced minimum principal stress: (c) cortical, (b) trabecular.

The best sample is equivalent to the commercially available reversed buttress thread [2]. The other samples that performed well were equivalent to square, buttress, and V-shaped thread.

CONCLUSIONS

The optimization of the fixture thread angle generated using the Latin hypercube sampling method and assessed using finite element analysis reveals that the sample equivalent to reversed buttress thread is the best. Future studies will consider more geometric parameters, tooth regions, and loading cases.

Thermal assessment of an ankle-foot orthosis for varied climatic conditions

Nishit C. Pachpande[1] and Ganesh M. Bapat [1]
[1] Department of Mechanical Engineering, BITS Pilani K.K. Birla Goa Campus, Goa, India.
Email: ganeshm@goa.bits-pilani.ac.in

INTRODUCTION

An Ankle-Foot Orthosis (AFO) is a commonly prescribed wearable orthotic device to assist patients with neuromuscular disorders during walking. However, recent studies show that the patient compliance with AFOs is often poor [1], mainly due to improper fit, discomfort issues and resulting skin problems. An orthosis limits the contact of the skin with air which in turn restricts the convective and radiative heat transfer from the limb. Hence, we hypothesize that similar to lower-limb prosthesis wearers, lower-limb orthosis users also experience thermal discomfort. This thermal discomfort and sweating can potentially cause health issues like skin irritation, skin maceration, bacterial infections, and unpleasant odour [2]. Therefore, the aim of this research is to investigate the temperature distribution in an AFO-limb assembly for varied climatic conditions using a generic, 3D finite element (FE) model of a lower leg braced with an AFO.

METHODS

A simplified CAD model of the lower leg was developed using SolidWorks software, with the shank modelled as a solid cylinder and the foot as a triangular wedge. The cylindrical shank was concentrically divided into layers of skin, fat, muscle, and bone. The solid-ankle AFO was modelled using thermoplastic with an Ethaflex cushion. The AFO-limb assembly was imported in ANSYS Mechanical 18.1 for the FE simulations. The sweep meshing method was used on the cylindrical shank, with Hex20 elements on the shank and Tet10 elements on the orthosis and foot. The mesh size (0.005 mm) was finalized using a mesh convergence study. The FE model was validated using boundary conditions similar to previous studies [3] and then further applied considering temperate and tropical climatic conditions. Metabolic volumetric heat generation values for muscle, skin, fat and foot were referred from [4] for resting condition. Convection and radiation boundary conditions were applied to the exposed skin and outer orthosis shell. The ambient temperature for temperate climate (typical in Europe and North America) was considered to be average 20 ºC while for the tropical region (typical in South-East Asia) was considered to be average 42 ºC. and fat was 36.67 ºC. For skin, temperature was set to 30ºC and 36ºC, corresponding to ambient temperatures of 20ºC, and 42ºC respectively [5].

RESULTS AND DISCUSSION

The temperature distribution on the skin of the anterior and posterior portion of the leg was recorded after 1 and 2 hours of wearing the AFO under varied climatic conditions (Table 1). Thermoplastic AFO keeps posterior skin covered with AFO hotter in temperate climate and cooler in tropical climate as compared to anterior skin exposed to ambient weather conditions. Figure 1 shows the temperature contours after wearing the orthosis for 2 hours in two climatic conditions.

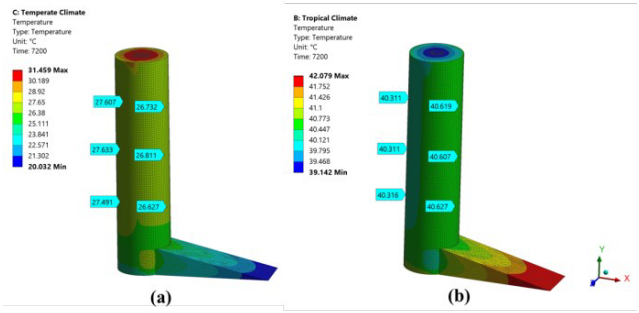

Figure 1: Skin surface temperature contours in (a) temperate and (b) tropical climatic conditions after 2 hours of no activity

CONCLUSIONS

The FE analysis showed that the temperature variation of the skin was found to be dependent on the climatic conditions and resting time duration. Thermoplastic AFO shell acts as insulator obstructing the heat transfer. These findings provide insights to design and select appropriate liner materials for an orthosis considering varied climatic conditions. The study suggests the need for designing AFOs that allow better heat transfer to improve the comfort of the wearer. Future studies need to be conducted considering perspiration mode of heat transfer.

GAIT ANALYSIS AND ENERGETICS OF A NOVEL PASSIVE DYNAMIC CUSTOM FOOT AND ANKLE ORTHOSIS IN A POPULATION OF FOOT-DROP PATIENTS

Paolo Caravaggi[1], Giulia Rogati[1], Alessandro Zomparelli[2], Franco Cevolini[3], Luca Zamagni[1], Massimiliano Baleani[1], Roberta Fognani[1], Luca Boriani[1], Alberto Arceri[1], Maurizio Ortolani[1], Lisa Berti[1], and Alberto Leardini[1]

INTRODUCTION

Ankle-foot Orthoses (AFOs) are orthopedic devices commonly prescribed to support the foot during the swing phase of gait in individuals with foot-drop. Off-the-shelf AFOs are a cost-effective option and widely utilized, but they may not adequately address the variations in foot and leg morphology and the degree of deficit present in each individual. As such, custom-made AFOs are often necessary. The purpose of this study was to to evaluate the kinematic and energetic characteristics of a new passive-dynamic, custom-made AFO in a sample of 10 individuals with foot-drop.

METHODS

Ten unilateral foot-drop patients were enrolled in the study (8M, 2F; age 65 ± 11 years). Custom AFOs were designed and modelled as to match the shape of the foot and leg of each patient in weightbearing. AFOs were produced via selective-laser-sintering of a fiberglass-reinforced polyamide powder (Windform GT®, CRP Technology). Patients were fitted with skin-markers according to a validated lower-limb kinematic protocol [1]. Five walking trials were recorded for each patient in each of the three conditions: wearing the custom AFO; wearing a standard Codivilla spring, and shod (no-AFO). Temporal profiles of hip, knee and ankle joints rotations were calculated via the joint coordinate system [2]. sEMG was used to detect activation of the gastrocnemius and tibialis anterior muscles in the affected and non-affected limb. Three reflective markers were attached to the posterior aspect of the custom AFO to measure the relative flexion-extension motion of the calf-shell with respect to the foot plate. The angle/resisting-moment relationship established for each AFO using an ad-hoc experimental setup [3] were used to estimate the work done by the custom AFO during the stance phase. Friedman test was used to detect statistically significant differences in kinematics and spatio-temporal parameters between shod and the two AFO conditions.

RESULTS AND DISCUSSION

Patients walked at faster normalized gait speed (%height/s) wearing the custom AFO (53.9±12.6) with respect to the Codivilla (53.4±14.0) and shod (51.0±13.5) conditions ($p<0.05$). All patients showed larger ankle dorsiflexion in the swing phase wearing the AFOs with respect to the no-AFO condition (Figure). In terms of energetics, negative work is done at midstance to flex the calf-shell of the custom AFO, which is released to the ankle in the push-off phase. Custom AFOs were rated significantly more comfortable than the Codivilla spring.

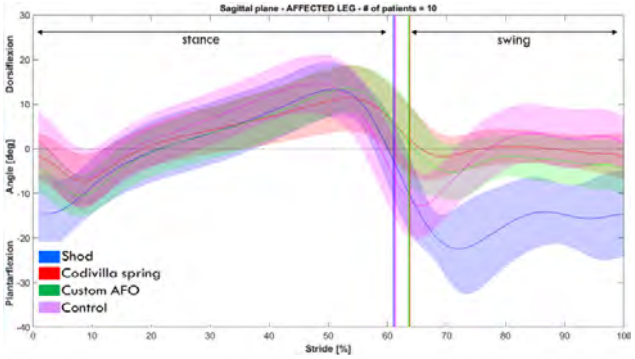

Figure 1 Inter-subject mean (±1SD bands) sagittal-plane rotations of the ankle joint during normalized gait duration in the control population, and in the foot-drop patients in the three conditions: shod (no-AFO); wearing the Codivilla spring and wearing the custom AFO.

CONCLUSIONS

Patients suffering from foot-drop and with other foot postural and morphological alterations or ailments, are usually not fully satisfied with standard AFOs. According to the outcome of this study, a passive-dynamic custom AFO, designed to comply with the shape of the leg and foot in weightbearing, provides foot-drop patients with better comfort and results in improved functional parameters with respect to a widely used standard AFO.

INTRODUCTION

Cycling is a low impact activity that is becoming increasingly popular amongst amputees [1] and can benefit the recovery process, aside from just being a step towards regaining the ability to walk [2]. However, the study of amputee cycling can be complicated, given that depending on the nature of the procedure, amputations are carried out at different levels, making it difficult to generalise the results. Therefore, the objective of this study is to evaluate the use of custom-made orthoses as an option to simulate and investigate the biomechanics of cycling by transtibial amputees. This was carried out by comparing the range of movement (ROM) during the use of orthoses that simulate amputee cycling, to data presented in the paper "The Biomechanics of Cycling with Transtibial Prosthesis: A Case Study of a Professional Cyclist" by Koutny et al. [3], which collected biomechanics data for the cycling movement of a professional amputee cyclist.

METHODS

Female (n = 5; age: 22–29 years; height:157–164 cm) and male (n = 3; age: 20–24 years; height: 164–183 cm) able-bodied participants were recruited, and custom-made orthoses for cycling (Arizono Orthopaedic Supplies Co. Ltd., Fukuoka, Japan) were manufactured to fit the right leg of each participant, in order to prevent direct contact between the biological foot and the pedal.

For the biomechanics assessment of the cycling practice, participants cycled on an AeroBike 75XL (Konami, Japan) ergometer. Trials lasted 1 minute each, which consisted of cycling at different cadences, 40 rpm and 50 rpm, under two different resistance settings, 40 W and 60 W respectively, which are compatible with recreational cycling. Conditions were set as intact cycling (IC) and simulated amputee cycling (SAC).

The assessment of ROM was accomplished through capturing video footage, using a Panasonic HC-300M (Panasonic, Japan) camera, placed at the right side of the participant. The participants were fitted with seven auto-adhesive markers, placed at anatomical landmarks on the right side of the body to enable motion tracking.

RESULTS AND DISCUSSION

IC and SAC conditions for this study were measured on the same participant, while the participant in the comparable case study had his biomechanical data compared to a control study [4], carried out at similar professional loads and cadences with 6 participants; data for all of which are shown in Table 1. Minimum knee angles showed a decrease of 22° ± 1.0°, similarly, maximum knee angles also showed a decrease of 13° ± 0.5° between intact and simulated amputee cycling under both loads in the present study, and between the intact and amputee cycling in the comparative data. ROM presented an increase of 8° ± 1.1° between intact and simulated or amputee conditions for all comparable data.

Table 1: ROM for the knee for the present and comparative studies.

	MIN	MAX	ROM
IC 60W	45°	118°	73°
SAC 60W	24°	105°	81°
Increase	**-21°**	**-13°**	**8°**
IC 40W	49°	119°	70°
SAC 40W	26°	106°	80°
Increase	**-23°**	**-13°**	**10°**
Control Study*	46°	112°	66°
Amputated Limb*	24°	98°	74°
Increase	**-22°**	**-14°**	**8°**

* Data for the comparative studies.

CONCLUSIONS

Minimum and maximum knee angles decreased, while ROM showed increase between the intact cycling conditions, and the comparable amputee or simulated amputee cycling conditions. The evaluation presented here indicates a possible successful emulation of prosthetic conditions for the practice of cycling through the use of orthoses. However, future studies should collect more data, for more amputee cyclists at more appropriate recreational levels.

INTRODUCTION

Foot musculoskeletal disorders are usually treated with plantar customized insoles (CI), which provide healing aid by direct mechanical effects on the lower extremities [1]. Tipically CI are designed and produced based on plaster casting and vacuum forming techniques, with a high level of the subjective knowledge required by practitioners and lab technicians. Lately, the CI design benefited from computer aided technologies; however the subjectivity has not been removed yet [2]. However, the success of these two approaches is based on the need to let the patient try the CI prior to purchasing it [2]. This work describes a new methodology for the design and the check of the effectiveness of CI finite element modeling (FEM) combined with gait analysis and 3D printing.

METHODS

A healthy subject with flatfoot was used as a case study and proof of the methodology. The foot geometry was acquired with a 3D scanner (Structure 3D), in unloaded position, to scale a previously developed foot FEM (Abaqus) [3]. Plantar pressure data and foot-floor angle were acquired respectively by pressure insoles (PedarX, Novel) and a markerless technique [4] while the subject was walking at self-selected speed at the manufacturer site. An stl surface was generated from pressure data and processed through Blender, Simplify 3D and PrusaSlicer: three insoles with different infills or inserts were designed and one was 3D printed (Bioflex, straight filling, 90% infill, 3D-DELTA WASP-4070). The shapes of the designed insoles were included in the FEM and tested by FEM simulation with the subject-specific loads (from the plantar pressures) and kinematics acquired during gait [3] as boundary conditions. The results of the simulations with and without the three insoles were validated through the comparison with the experimental plantar pressure data. Simulated pressures and internal stresses in the plantar soft tissues were compared across the three insoles.

RESULTS

Table 1 shows no considerable difference between peak Von Mises stresses obtained with the Cad Cam and straight infill insoles, in correspondence of the heel plantar aspect of the foot, even though a higher peak pressure was recorded (Figure 1).

Table 1: Pressure and Von Mises stresses on the foot with the

PI	Peak Pressure	Peak Von Mises
Cad Cam solid infill	144 kPa	227 kPa
Straight infill with 2 inserts honeycomb	209 kPa	230 kPa
Infill 15% Full honeycomb	734 kPa	450 kPa

3 PIs: peak values. Infill 15% Full honeycomb

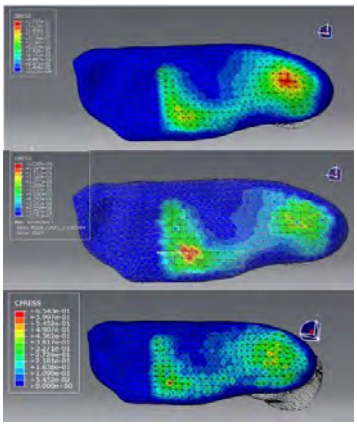

Figure 1: Simulated plantar pressures with the three CIs. From the top: Cad Cam, Straight infill with 2 inserts honeycomb and Infill 15% Full honeycomb.

CONCLUSIONS

The proposed method can be used to predict the effect of the CI before its production, and to use the simulated pressure and internal stress for its optimization. This approach can overcome the limit of the traditional long trial-and-error procedures as well as removing the subjectivity associated with the technician. Future developments will include trying different filling materials, slicing, inserts, and filling distribution.

INTRODUCTION

Posterior tibial plateau fracture is an uncommon injury with 28.8% of all tibial plateau fracture cases [1]. A concomitant posterior cruciate ligament (PCL) avulsion fracture might also appear as a result of high-energy injuries such as dashboard injuries from motorcycle accidents in which a posterior directed force is applied to the proximal tibia when the knee is flexed [2, 3].
Common implant designs used for treating posterior tibial plateau fracture are T-shaped buttres plate and dual plate [4], while toothed plate and hollow lag screw have been stated as reliable approach for treating PCL avulsion fracture [5]. However, there remains a lack of an optimal fixation design for posterior tibial plateau fracture along with concomitant PCL avulsion fracture.
Therefore, the purpose of this study is to analyze the stability provided by newly designed plate for treating such fractures, by using finite element analysis (FEA).

METHODS

The 3-dimensional (3D) tibia was obtained from scanning a synthetic tibia using 3D scanner, followed by geometry cleaning. The cortical and cancellous bone were prepared based on rough measurement of CT scan image of bone, thus representing the heterogeneity of the bone better [6]. The plate and screws were prepared using computer aided design software. The PCL avulsion fracture was designed in similar fashion with average anatomic PCL tibial insertion [7].
FEA software was utilized for pre-processing where mesh generation, material properties, and boundary conditions were set. Absolute displacement and von Mises stress were interpreted in post-processing software to evaluate the stability of novel design implant.

RESULTS AND DISCUSSION

Figure 1 showed the results of simulation, where smooth transition of displacement over the fracture border indicates greater mechanical stability [8]. The displacement value happened on the tibial plateau region was 0.04 to 0.08 mm. This result was lower than the assumed failure displacement threshold of 3 mm [4]. The maximum von Mises stress were around 63 MPa, happening in the most distal screw. The value is below its destruction value of 2800 MPa [6], implying the implant would not fail within the given the loading condition representing a person in standing mode [4].
Such convincing stability provided by the implant can be caused by the novel part of the plate which lies in its screw positioning, where it has a subarticular raft construct with a compression screw placed through the pre-contoured proximal end.
This can give more stability from the superior side of PCL avulsion fracture compared to screw placed independently of a buttress plate.

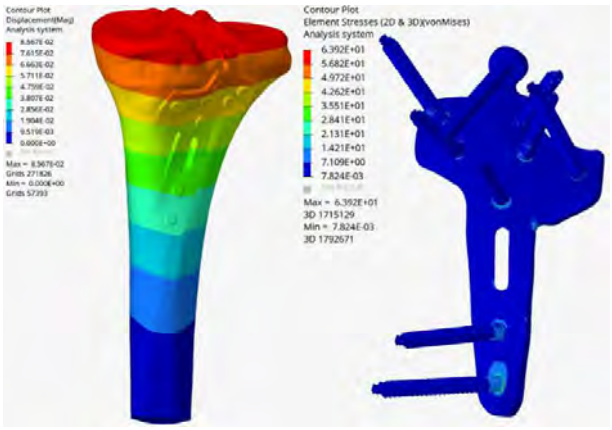

Figure 1 Absolute displacement (left) and stress distribution on the implant (right) of novel design implant

CONCLUSIONS

This study investigated the stability provided by the novel design implant. Additionally, the model used in this study considers the heterogeneity of the bone. With the satisfactory result of stress and displacement distribution, it is implied that this implant might give promising stability, thus making it safe to be used in treating posterior tibial plateau fracture, especially the one with concomitant PCL avulsion fracture.

INTRODUCTION

Cardiovascular diseases are the first cause of death worldwide and, in particular, atherosclerosis affects 50% of cardiopathic patients [1]. Mechanical characterization of atherosclerotic arteries is crucial for accurate risk assessment of heart attack. However, existing methods have a common issue: a long waiting time incompatible with today's hospital day care exams [2]. The presented study explores a methodoloy to provide an accurate real-time estimation of mechanical properties of atherosclerotic coronary ateries.

METHODS

An Artificial Neural Network (ANN) has been developed to accurately estimate Young's moduli of necrotic core (E_core) and fibrotic tissue (E_plaque). First, we built a large and idealized database by conducting Finite Element Analyses (FEA) of 540 2D idealized geometries of atherosclerotic coronary arteries with varying stenosis ratios (SR), fibrous cap thickness and core thickness. A statistical analysis to pre-process the data and determine the most influential variables was performed to select the inputs for the ANN. The ANN was based on Multilayer Perceptron (MLP) architecture and was trained and tested using the developed database. Then, the ANN was applied to a realistic database, previously build throughout FEA. To improve the predictions, the ANN was fine-tuned using the transfer-learning technique, where the last four layers were re-trained using the realistic dataset.

RESULTS AND DISCUSSION

The statistical analysis showed a quadratic pattern in the behaviour between the candidate variables and the response variables. The most influential variables in the prediction of Young's moduli of the necrotic core and plaque were the SR (%), and the strains of the core and the fibrous cap with an accuracy of 92.8% and 97.67% respectively. The ANN trained with the large and idealized database presented relative errors in the prediction of E_core and E_plaque lower than 4% both during the training and the testing step. However, when applied to a realistic dataset, the ANN struggled to accurately predict the mechanical properties. To improve its performance, a fine-tuning process was performed, utilizing the 50% of the realistic dataset to re-train the last four layers of the ANN. The result was a relative error lower than 3% both in E_core and E_plaque when predicting the remaining 50% of the realistic dataset.

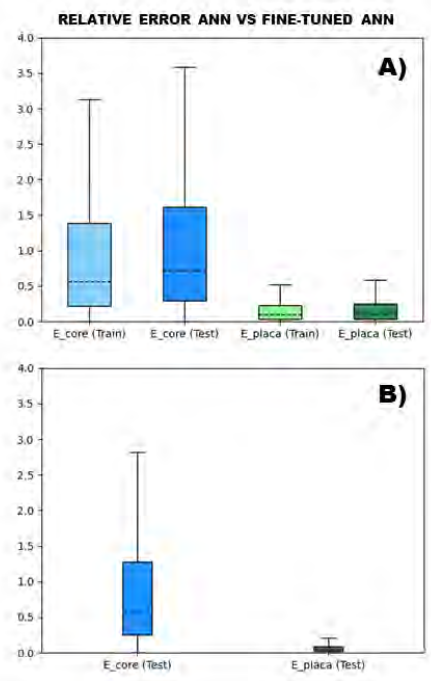

Figure 1 Relative error in the predictions of E_core and E_plaque. A) Original ANN. B) Fine-tuned ANN.

CONCLUSIONS

This study provides a novel perspective on the estimation of material properties in coronary arteries through a large and representative database that takes into account different core sizes, fibrous cap thicknesses, and stenosis ratio values. The promising achieved results set a path for the application of neural networks in the estimation of mechanical properties of patient-specific coronary arteries.

INTRODUCTION

Cardiac tissue presents a complex mechanical response that is essential to understand to develop innovative therapies for cardiac pathologies. It is widely accepted that cardiac tissue presents an orthotropic behaviour, undergoing diverse loading conditions during cardiac cycle [1,2]. Hence, to ensure a complete three-dimensional characterization, considering different loading scenarios is required. Following this line, several mechanical tests were performed into porcine specimens. We considered two groups of animals of two different ages to assess the influence of age on the mechanical response of cardiac tissue.

METHODS

Porcine left ventricular transmural biopsy specimens were obtained from 12 white pigs. 7 animals were used at 3 months of age (3MA) and the rest at 6 months of age (6MA), when they had already doubled their weight. Following the experimental procedures observed at the literature [1-3], cyclic biaxial extension tests, triaxial shear tests and confined compression testing were performed at different areas of the left ventricle free wall (LVFW). Two different types of confined compression tests were made, the first one allowed the fluid to flow out of the sample and the other did not. The former allows to assess the permeability of the tissue and the latter its compressibility. Biaxial samples were obtained at the medial anterior (MA) region of the LVFW for 3MA and at the apical anterior (AA) region of the LVFW for 6MA. Shear samples as well as compression samples were obtained at the medial posterior (MP) region of the LVFW. All samples were obtained following the cardiac tissue muscular fiber directions. A total of 33 biaxial tests, 104 shear tests and 67 compression tests were performed.

RESULTS AND DISCUSSION

Mean results are shown for every test (Figure 1). Biaxial and shear results show an hyperelastic and orthotropic behaviour consistent to the literature, with a stiffer response at fiber direction. At both tests, we observe a more rigid response for the 6MA animals, suggesting that the stiffness of cardiac tissue increases with animal age. We also observe a more isotropic response at the biaxial results of 6MA. However, this may be due to regional differences between MA and AA areas, as fiber alignment is weaker at AA region. Confined compression results show a compressible response, with a 10% volume reduction. No significant differences were obtained at confined compression without fluid output and greater values of pressure were obtained at 6MA respect to 3MA when fluid output was allowed. This suggests that tissue compressibility remains the same, but its permeability decreases with animal age.

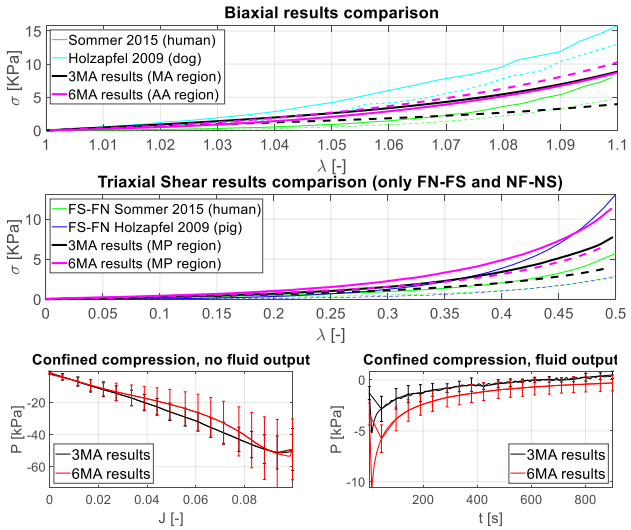

Figure 1. Results from biaxial (top), shear (middle) and confined compression tests (bottom). For biaxial and shear results, continuous line represents fiber direction and dotted line normal to fiber direction

CONCLUSIONS

A complete three dimensional characterization including biaxial, triaxial shear and confined compression tests has been performed at porcine cardiac tissue considering animals of two different ages. We obtained a compressible, hyperelastic and orthotropic behaviour, which is consistent to literature. Our results suggest that the behaviour of cardiac tissue becomes stiffer with increasing age of the animal, as well as experiencing a reduction in its permeability.

INTRODUCTION

Total hip arthroplasty (THA) is well known as a highly successful procedure and can significantly improve quality of life and restore mobility for people with severe hip pain and disability [1]. However, as with any surgical procedure, there are still risks and potential complications [1]. Dual mobility THA has been recently applied clinically, as one of several alternatives to overcome the risks and potential complications [2]. However, a little information is available on bio-mechanical efficiency of dual mobility THA. Therefore, the aim of the current study is to evaluate the bio-mechanical efficiency of dual mobility THA, particular in squat motion.

METHODS

Full body musculoskeletal models with/without a traditional or dual mobility THA were developed based on a musculoskeletal model in AnyBody Managed Model Repository (AMS version 7.4.0., Anybody Technology Aalborg, Denmark) provided by the AnyBody Research Group (Figure 1). To evaluate the biomechanical efficiency of dual mobility THA, squat motion was applied to the full body musculoskeletal models. Then 10 – 100° hip flexion and no rotation ankle flexion were applied to the models. Validation of the full body musculoskeletal models were performed by comparing the joint reaction forces computed by the models with them reported by Layton et al. [1].

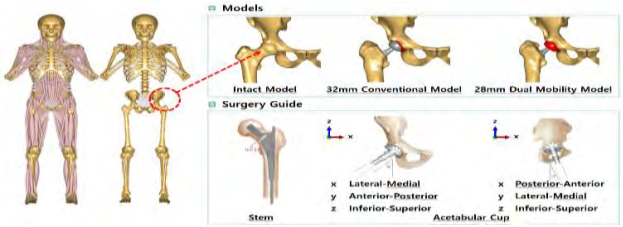

Figure 1. Full body musculoskeletal models: A) without THA, b) with traditional THA (considered a 32mm head size of femoral component, c) with dual mobility THA (considered a 28mm head size of femoral component and a 36mm mobile linear thickness)

RESULTS AND DISCUSSION

The results of the validation showed a reliability level of approximately 82% compared with them reported by Layton et al. [1] and Koyanagi et al. [3]. The joint reaction forces showed similar tendency in all full body musculoskeletal models with/without a traditional or dual mobility THA during the squat motion (Figure 2). However, full body musculoskeletal model with dual mobility THA showed no dislocation of the femoral head for hyper-flexion of the hip joint, relative to the model with a traditional THA. The major muscle forces surrounding the hip, knee and ankle joints were similar in all models with/without a traditional or dual mobility THA (Figure 3).

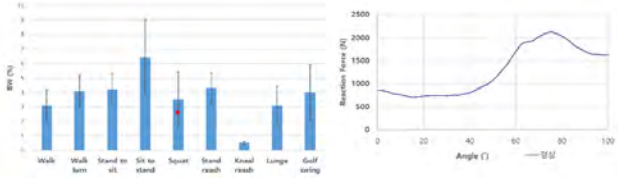

Figure 2. Validation of Joint reaction forces during the squat motion in the conditions

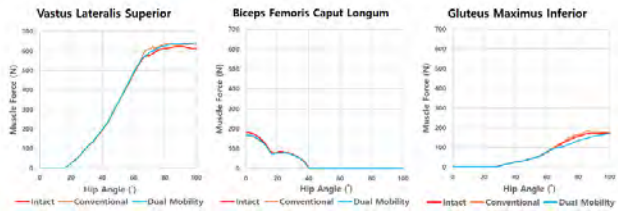

Figure 3. Muscle forces in a) vastus lateralis superior, b) biceps femoris caput longum, c) gluteus maximus interior for the squat motion in the conditions with/without a traditional or dual mobility THA

CONCLUSIONS

In conclusion, Dual mobility THA may have an effective benefit in maintaining biomechanical stability in terms of reducing the risk of dislocation. However, it is necessary to conduct additionally comprehensive research considering various biomechanical and clinical conditions.

INTRODUCTION

Lower limb prosthesis must meet the core requirements including tensile strength, density, corrosion resistance, shear strength, flexibility, durability, and cost efficiency. These considerations depend on the nature of the material being used including foot design, and applied manufacturing process [1]. This study proposed three common materials to manufacture the prosthetic foot; including Acrylonitrile Butadiene Styrene (ABS), Polyethylene Terephthalate Polyester (PETG), Polylactic Acid (PLA), High Density Polyethylene (HDPE) and, Polypropylene (PP). The proposed materials are intended to have high mechanical properties and suitable for this application. Also, to compare these materials to select the best material for manufacturing prosthetic legs. Mechanical properties of materials proposed for use in the manufacture of prosthetic legs were tested.

METHODS

In testing the mechanical properties of the five materials, specimens were made for each material in accordance with the ASTM guidelines in accordance with the tests to be carried out, for tensile tests using a guide ASTM D638 Type 1 [2], for bending tests using a guide ASTM D790 [3] and for impact tests using ASTM D256 [4] guidelines (Figure 1).

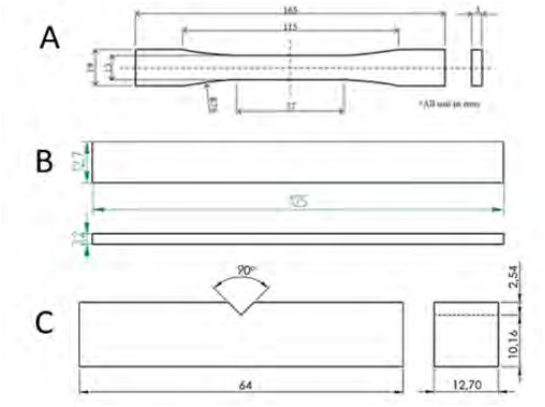

Figure 1. Dimension specimens **(A)** ASTM D638 Type1, **(B)** ASTM D790, **(C)** ASTM D256-03

RESULTS AND DISCUSSION

The results of testing the mechanical properties of the polymer material showed better mechanical properties with HDPE than the other polymer materials used in this study with the results of tensile strength 33.55 MPa. Bending test having a compression strength of 83.74 MPa and impact test have impact value 0.0777 j/mm² (Table1).

Table 1: Mechanical properties polymer materials.

Material	Tensile Strength (MPa)	Compression Strength (MPa)	value impact (J/mm2)
ABS	31,147	108,90	0,0150
PLA	20,357	65,63	0,0037
PETG	23,867	83,57	0,0030
HDPE	33,553	132,93	0,0777
PP	33,040	101,77	0,0137

CONCLUSIONS

The tensile, bending, and impact tests performed on the five types of polymer materials revealed that HDPE materials had the best resistance to tensile, pressure, and sudden loading/shock compared to the other types of polymer materials used in this research. As a result, it was determined that HDPE is the best choice for the manufacture of prosthetic legs due to its high mechanical properties and light weight compared to prosthetic legs made from other polymeric materials such as ABS, PETG, PLA, and PP.

INTRODUCTION

Knee osteoarthritis (KOA) is commonly diagnosed by pain and radiographic findings, but these may not be present in the early stages [1,2]. Alternatively, tissue response to mechanical loading has been suggested as a potential biomarker for early OA [2]. Recently, a magnetic resonance imaging (MRI) stress test was proposed to measure cartilage creep [3]. However, the accuracy of this approach has not been tested. Therefore, this study aimed to develop and test a fast-imaging sequence to quantify *ex vivo* creep and recovery response and compare it to a classical mechanical test performed in a controlled environment.

METHODS

A 4.5% weight/volume agarose plug (9 mm diameter) was prepared and underwent unconfined creep and recovery test using MRI and classical mechanical testing. For the MRI test the sample was loaded in a custom-made MRI-compatible device within a knee coil. Sagittal plane images were generated using a multiphase FIESTA sequence (FOV: 12 cm; resolution: 160x200; slice thickness: 4 mm; flip angle: 45°; TR: 4.3 ms; TE: 1.8 ms) with a 3T scanner sampling at 1.62 Hz. After 5 minutes of preloading (0.01N), the initial thickness was determined from reference images. Subsequently, a compression creep load (0.982N) and recovery load (0.01N) were applied, and both imaged for 5 minutes, respectively. Thickness changes were manually segmented from selected MRI images in both phases, and a power fit was performed separately in each phase. Finally, the sample underwent an identical loading scenario using a DMA850 sampling at 3Hz.

RESULTS AND DISCUSSION

Mechanically loading the sample resulted in a time-dependent creep and recovery response (Figure 1), but differences were observed between the response. The initial elastic contribution showed great agreement, but the creep strain was overestimated with the MRI (Table 1). Strain calculations based on sub-millimetre changes of voxels are highly sensitive, and one voxel difference would result in an average error of 3.47%. Thus, accounting for partial volume artifacts and limited spatial resolution is necessary for accurate estimations.

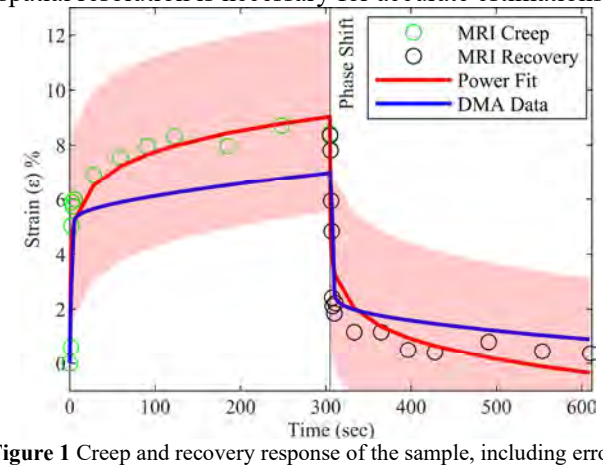

Figure 1 Creep and recovery response of the sample, including error estimates of one voxel.

CONCLUSIONS

The agarose gel sample showed a time-dependent creep and recovery behaviour during compressive loading, indicating that fast imaging MRI sequences may pose as a tool to determine *in vivo* creep and recovery response. Nevertheless, future work is needed to validate the accuracy and reliability of this approach.

INTRODUCTION

Artery palpation is a standard method to touch and feel cardiovascular functionality. Modern science assesses three parameters such as rate, amplitude, and rhythm in general. In ancient science, radial artery palpation is used for disease diagnosis. In both cases, the force field transmitted to the fingertip from the artery is a crucial factor. The palpation involves fingertip interaction with the forces from the arterial wall. The current work studies the force distribution with a constant force palpation at a single location on the arteries with various elastic moduli.

METHODS

The pressure distribution across the curvature due to palpation on the artery is investigated using fluid-structure interaction (FSI) modeling in COMSOL 5.5 to a non-pulsatile and pulsatile flow. The constriction of palpated arteries is assumed at both sides of the artery. The non-pulsatile flow is with a velocity inlet of 0.23m/sec and 80 mm Hg outlet condition for 1 second in 100-time steps. The study includes three elastic arteries($E = 0.3MPa, 0.6MPa, 0.9MPa$) with corresponding intima-media thickness ($0.4mm, 0.45mm, 0.5mm$) as shown in Figure 1.

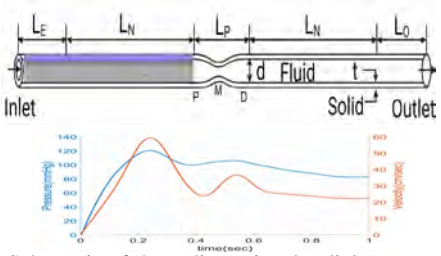

Figure 1: Schematic of three-dimensional radial artery model with the velocity and pressure boundary conditions [1] at the inlet and outlet

RESULTS AND DISCUSSION

A higher elasticity zone captures high-frequency components in the pulse, whereas a lower elasticity zone captures very low frequency. The intermediate elastic zone between them captures the low-frequency component of the pulse as evident from the root locus plot 2. Along the length of the artery, the distal (D) sites on the artery contain very low-frequency components of pressure pulse whereas proximal (P) sites on the artery contain high-frequency components of the pulse. The palpation amplifies the deviations in the pulse profile and in the spectral distribution of the pulse waves at P, and D locations for various arteries during pulsatile flow. The palpation can make the artery operate in passive or active modes [2] to result in pressure change along the length of the artery.

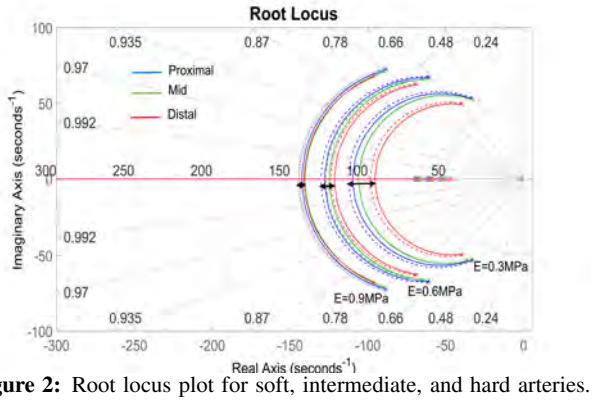

Figure 2: Root locus plot for soft, intermediate, and hard arteries. The solid line is during palpation, and the dashed line is without palpation).

CONCLUSIONS

The palpation aids in separating the powers under various frequency bands in the spatial domain within one single pulse in the pulsatile response of the artery. The step response shows the spatial filtering property of the Gaussian loading that acts as a Gaussian Space Filter. The experimental validation of this study will be analyzed further in the future.

Deformable headform design choices: An evaluation of brain simulant stiffness influence on intracranial displacements and strain

Sheng Xu[1], Jean-Jacques Demiannay[1], Simon Ouellet[2], Austin Azar[2], Oren Petel[1]
[1] Department of Mechanical and Aerospace Engineering, Carleton University, Ottawa, ON, Canada, K1S 5B6

INTRODUCTION

Deformable polymeric headforms are being developed as new tool for helmet performance evaluation [1]. These headforms often contain elastomeric brain tissue simulants to model the response of the human head to impact and/or blast wave loading events. Sylgard 527 has been commonly used to represent brain tissue, but has been shown to be stiffer than brain tissue under quasi-static conditions [2]. However, brain tissue has presented a strong strain-rate dependence, making it stiffer than Sylgard 527 at strain rates relevant to mild traumatic brain injury (i.e., 10^2-10^3 s^{-1}) [3]. This difference will cause elevated intracranial strain measurements in these deformable headforms. In the present work, we investigate different brain tissue simulant formulations that possess varied stiffness properties to determine their strain response for comparison to cadaveric datasets.

METHODS

The tunable stiffness of brain simulants was achieved by mixing two commercially available polydimethylsiloxan (PDMS), Sylgard 527 and Sylgard 184, with different ratios, from soft to stiff, which were pure 527, 40:1, 20:1 and 10:1. The brain simulants with differnet stiffness were used to prepare four different deformable closed headforms, based on the BIPED Mk2 [1]. These headforms were subjected to a series of impacts from a linear impactor at speeds ranging from 2.5 m/s to 4.5 m/s. Two impactor caps were used in testing, a 75 mm vinyl nitrile end cap and a Neoprene rubber end cap. Numerous radiopaque markers were embedded within the same parasagittal plane of the headform brains. Marker motions were tracked using a high-speed X-ray imaging system (5,000 fps). A digitial image correlation analysis was used to calculate the displacement and intracranial strain fields within the headform.

RESULTS

A direct comparison of the resultant displacements of a single point in the frontal region across brain simulant formulations is shown in Figure 1a, for the same impact conditions (4.5 m/s). This comparison showed that the stiffer material, had a greater resistance to motion, lower strains, and a shorter response time. The 95th percentile true strain response in the same frontal region shows that increasing tissue simulant stiffness changed both the peak strain and strain patterns during the impact (Figure 1b).

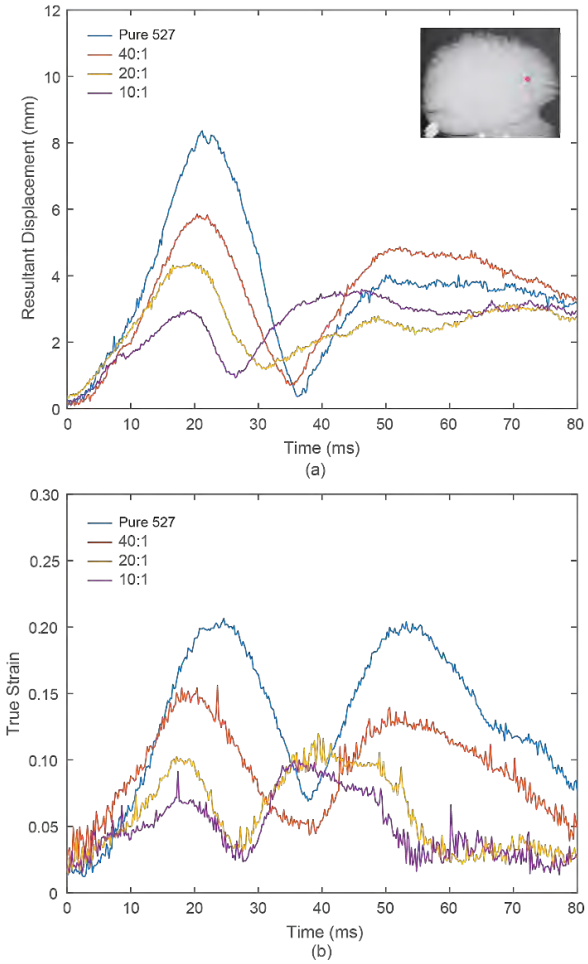

Figure 1 The response comparison of different brain simulants formations in frontal region at impact velocity 4.5 m/s. (a) Resultant Displacement at a single point; (b) 95th percentile true strain.

CONCLUSIONS

The investigation of several brain simulant formations demonstrated that stiffness of the brain simulants can be used to optimize brain simulant selection. This approach could also improve the biofidelity of future headform design through a validation with cadaveric data.

INTRODUCTION

Pulmonary contusion is a prevalent injury related to thoracic trauma events, however it currently lacks both reliable mechanistic understanding and predictive criteria [1]. Finite element (FE) models have have been used to study the response of the body to blunt-impact trauma, in which the lungs are often assumed both homogeneous and isotropic, almagamating the alveoli and bronchi structures into a monolithic mass. These models typically predict peak strains at the surface of the impact site, which is qualitatively validated against tissue damage imparted on the surface of animal surrogate lungs [2]. We have shown that these approximations are unable to resolve local maxima in the dynamic strain fields that occur within the interbronchial regions [3]. This suggests that the current finite models may be underestimating and mislocating strain-induced injuries, such as contusion.

METHODS

Fixed porcine lungs, preserved using a Bioflex process to maintain tissue flexibility (NASCO, Fort Atkinson, WI), were instrumented with a 2D array of elastomeric radiopaque markers outlining the surfaces of the lung parenchyma in the plane of the tertiary bronchi. Additional radiopaque markers, encapsulated within flexible heat shrink tubing, were inserted within the tertiary bronchi. The instrumented lungs were suspended from a custom impact fixture and inflated to a physiologic expiratory pressure. A pneumatic cannon was used to launch a 53.5 g plastic sphere towards the lungs at speeds ranging from 7.1-14.60 m/s, inducing a direct deformation of the lung surface characteristic of thoracic trauma. The dynamic deformation of the lungs was captured using a high-speed x-ray imaging system at 7500 fps, and the displacements of the markers were used to quantify the trans-lobe, interbronchial, and superficial parenchymal true strains through the definition of quadrilateral elements (Fig. 1). Strain fields measured in fresh porcine lung specimens were also compared to the severity of resultant regional tissue damage to validate strain as a mechanism of injury.

RESULTS AND DISCUSSION

The difference in peak strains measured in the parenchymal surface elements and within overlapping trans-lobe elements are consistent with the results seen in current isotropic FE models, whereby peak strain is observed at the surface of the impact site. However, when the interbronchial strains in regions adjacent to the surface elements are considered, the effect of the inhomogeneity of the bronchial structures is evident. Due to the increased stiffness, the bronchi are displaced upon impact, generating localized measures of maximum principal, minimum principal, and maximum shear true strains (MPS, mPS and MSS) that exceed both the trans-lobe and surface strains (Fig. 1).

CONCLUSIONS

These results show that the inclusion of the bronchial structures is necessary in biofidelic lung models. Furthermore, model validation efforts relying on measures of physical tissue damage should not be limited to surface pulmonary contusion and must be expanded to include regions adjacent to inhomogeneities such as the bronchial network.

INTRODUCTION

ACL rupture or injury frequently occurs in the early phase of single–legged landing from a jump toward the front, back, left, and right directions and is due to the knee valgus during the landing. Knee and hip flexor displacement are reduced during lateral landing rather than forward landing [1]. However, no studies have investigated which lower limb joint movements are associated with the knee valgus. This study aims to investigate which joints in the lower limb are involved in the knee valgus that occurs after single–legged drop landing (SLDL) from multiple directions.

METHODS

Ten male students with no previous ACL injury or rupture performed the SLDL from a 30 cm height box with each leg. We instructed the subjects to drop from the box to a Force–platform (Sports Sensing inc., 1000Hz) placed in the frontal direction (0 degrees) and at 30, 60, and 90 degrees lateral to the landing leg, and to land with the entire sole of the foot. The subjects' whole-body kinematics was captured by four high-speed cameras (For-A inc. and Ditect inc., 250 fps), and the coordinated reflective markers attached on the body were digitized (Dipp-Motion V/3D, Ditect inc.). The coordinates were used to calculate joint angles in lower limbs using the Euler method. We calculated the touchdown angle and the angular displacement up to the time when the vertical ground reaction force (Fz) reached its maximum value after landing. We calculated the correlation coefficient (CC) between these variables and the knee valgus/varus angular displacement in each landing task. These angles were further converted to principal component (PC) scores using PC analysis up to the fifth PC, where the cumulative contribution ratio first reached 0.8 or greater. Then we extracted the labels of the angles constituting the PC scores using factor loadings.

RESULTS AND DISCUSSION

We found individual difference in the mean and standard deviation value of angular displacement of knee valgus/varus. Meanwhile, we found high CC values between knee valgus/varus displacement and several kinematic variables, for example, hip internal rotation (Fig.1). Table 1 shows the main variables, factor loadings, and PC scores of the 1st PC for the dominant and non–dominant leg obtained by PCA. These scores included the knee valgus/varus and hip internal rotation shown in Figure 1 for both legs, indicating that an increase in the PC score not only means an increase in the valgus and internal rotation but also means that the joint displacements in both directions are related. These findings suggest that inhibiting knee valgus after landing, which is a risk factor for ACL injury, requires decreasing internal rotation of the hip joint after landing, and furthermore, utilizing the muscular strength of the external rotation muscles, gluteus maximus and six deep external rotators, that antagonize the internal rotation may reduce the risk of this injury.

Table 1. PC scores, factor loadings and contribution rate obtained from PC1.

	Dominant leg 1st PC		Non–dominant leg 1st PC	
Factor loadings	Knee Valgus/Varus	0.929	Knee Internal/External rotation	0.864
	Anke Spination/Pronation	0.894	Knee Valgus/Varus	0.834
	Hip Internal/External rotation	-0.876	Hip Internal/External rotation	-0.809
	Knee Internal/External rotation	0.866	Hip Abduction/Adduction	0.785
	Knee Flexion/Extension (Touchdown)	-0.816	Hip Flexion/Extension	0.745
Contribution rate	0.396		0.375	

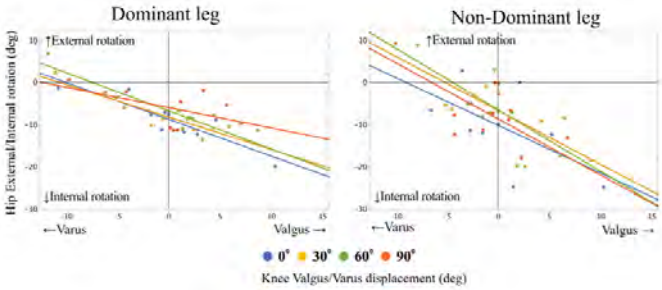

Figure 1. Scatter plot of knee valgus and hip internal rotation displacements.

CONCLUSIONS

Correlation analysis and PCA of the kinematic variables revealed that hip internal rotation and other movements related to the knee valgus movement that occurs after a SLDL are involved. This suggests that the external rotator muscles at the hip can be an important muscle in inhibiting the external rotation.

VINYL SPORTS FLOOR CUSHIONING THICKNESS AFFECTS SHOE-SURFACE TRACTION IN FUTSAL BUT NOT MECHANICALLY EVALUATED ANKLE INVERSION MOMENT

INTRODUCTION

Point elastic artificial sports flooring is largely preferred by Futsal players, who also complete futsal-specific agility course faster on this surface, compared to hardwood flooring [1]. These artificial floors come in various designs with varying levels of shock absorption, and it is believed that the improvements found in performance might be due to the higher traction [1], which could be facilitated by a greater local deformation of the floor against the shoe sole [2]. Excessive traction might also come with a downside, as greater horizontal forces would arguably lead to increases in lower extremity joint loading, and a potentially increased risk of ankle sprain injury [3].

It is still unknown, however, whether shoe-surface friction is actually affected by the thickness of the underlying cushioning layer under artificial sports floors, and whether a further thickening would lead to further increases in traction – and whether this would be reflected by an increase in inversion moment.

METHODS

In this mechanical study, three different thicknesses of Taraflex™ indoor sports floor (Gerflor, Villeurbanne, France) was tested. All conditions had similar 2.1 mm vinyl top layer (Shore A: 91.0±0.9) but varied in thickness (0mm, 4.9mm, 9.8mm) of the underlying cushioning layer (Shore A: 26.0±0.6).

The additional floor was installed onto a force platform (AMTI OR6-7-1000, Watertown MA, USA) prior to calibrations, and the varying heights were adjusted for.

A Puma futsal shoe (Invicto II, Puma GmbH, Herzogenaurach, Germany; outsole Shore A: 72.2±1.2) was attached onto an artificial foot at the end of a custom build enlarged British pendulum, that was fixated to the floor above the force plate.

Ten trials were recorded for each floor condition using eight infrared highspeed cameras sampling at 500 Hz (Oqus 300+, Qualisys AB, Gothenburg, Sweden) to capture the kinematics of 13 retroreflective markers via Qualisys Track Manager (v. 2021.2). Force plate data was sampled at 1000 Hz. Both kinematic and kinetic data was filtered at 35 Hz using a 4th-order low-pass Butterworth filter. Early contact friction coefficient and mechanical ankle joint kinetics was analysed in Visual 3D v6 (C-Motion Inc., Maryland, USA) between 10 and 200 N in vertical ground reaction force.

RESULTS AND DISCUSSION

The coefficient of friction (COF) was similar at initial contact and decreased as the normal force increased. At the 200N cut-off, the 9.8 mm cushioning layer had a 6% and 3.5% higher COF than the zero and 4.9 mm cushioning thicknesses, respectively (Table 1).

Table 1 Friction coefficient (COF) at 10N and 200N normal force.

Cushioning thickness	COF at 10N (SD)	COF at 200N (SD)
0.0 mm	0.90 (0.02)	0.83 (0.01)
4.9 mm	0.90 (0.02)	0.85 (0.00)
9.8 mm	0.92 (0.02)	0.88 (0.01)

To our surprise, there was no measurable difference in mechanical inversion moment about the ankle joint (Figure 1), despite the increase in COF with the added cushioning layers.

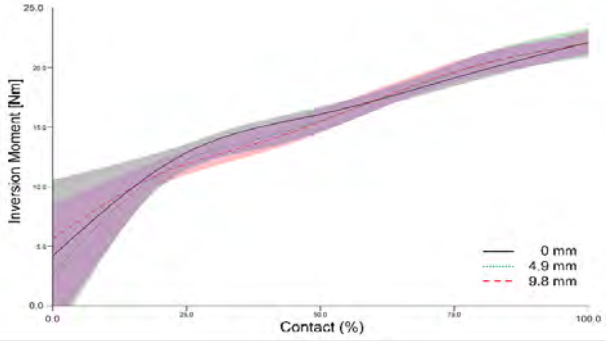

Figure 1 Inversion moment between 10 and 200 N normal force.

The change in thickness as the surfaces would compress was not adjusted for, which might affect the centre of pressure – and the inversion moment calculated.

CONCLUSIONS

The thickness of the cushioning layer under indoor vinyl sports floors affects mechanical impact friction in futsal. However, this is not reflected by a similar increase in mechanical joint moments.

IN VIVO INVESTIGATION OF MICROSTRUCTURAL BRAIN CHANGES FOLLOWING FOOTBALL HEADING

Hugh McCloskey[1,2], Rhosslyn Adams[1], Carolyn McNabb[2], Megan Barnes-Wood[1], Bethany Keenan[1,2], John Evans[2], Derek Jones[2], Peter Theobald[1]

INTRODUCTION

Repeated football heading may be a cause of the increasing incidence of neurodegenerative disease in former elite players [1]. Correlating head impact exposure and disease incidence is hindered by conclusive diagnosis relying on post-mortem examination. An alternative route to predict injury risk correlates head kinematic data to metrics including head and rotational injury risk (HIC, RIC respectively). These are, however, intended for single, high-magnitude collisions and so prevent meaningful investigation of cause-and-effect. This pre-post study increases the sensitivity of such comparisons, investigating whether repeated heading causes changes in microstructural neuroanatomy and assesses whether changes correlate with injury scores.

METHODS

Six male university-level footballers (21 – 23 years) volunteered for a baseline brain scan (t = 0 hrs), using a 3 Tesla Connectom MRI scanner (Siemens), capable of gradient strengths of 300mT/m. Scans followed a high angular resolution diffusion imaging (HARDI) protocol. Participants then performed 10 headers, with controlled deliveries and instructions to attempt neck flexion-extension only (t = 2hrs). All wore personalised, instrumented mouthguards to capture head kinematics in 6 degrees of freedom (SWA; Swansea, UK). HIC and RIC scores were calculated for each header. A follow-up HARDI scan (t = 24 hrs) then allowed derivation of change in mean diffusivity (MD), for 50 white matter tracts (derived using TractSeg) in each participant. Increased MD has been shown to correspond to increased water content, edema and inflammation [2]. A linear mixed-effects model was then used to assess the effect of peak HIC and RIC on changes in MD.

RESULTS

Peak HIC [mean = 33.17, ± 14.52] was not significantly associated with any change in MD. Peak RIC [mean = 1230440, ± 724713.7] was significantly correlated with MD increase in the left inferior fronto-occipital fascicle (IFO) This is consistent with observations of acute traumatic brain injury in other sports [3]. However this result became non-significant after correction for multiple comparisons (Figure 1, Table 1).

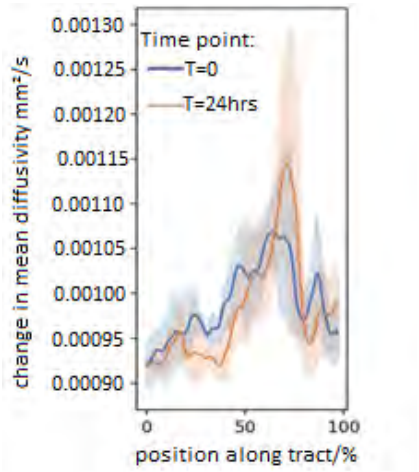

Figure 1: Group mean MD along the IFO left tract at T=0 and T=24.

CONCLUSIONS

Peak RIC scores initially appeared to correlate significant to an increase in MD in the IFO. This became non-significant after corrections for multiple comparisons.

INTRODUCTION

Synthetic turf holds a distinct advantage over natural grass, due to the ability to alter the different components of artificial turf. While changes in sport surface components can alter performance [1], insight into how these changes in performance are achieved is absent. Therefore, the purpose of this study was to investigate the biomechanical differences on artificial turf associated with changes in athletic agility performance.

METHODS

Eighteen University grid-iron football players (nine speed players and seven power players) performed three modified football specific movements (agility drill, vcut, 3 cone drill) on three artificial turf surfaces: i) Control, commonly installed artificial turf surface for sporting activities, ii) Shockpad (SP), identical to the Control, except for the addition of an underlying shockpad, iii) Low Faceweight (LW), with identical infill composition to the Control, but reduced carpet area density. These surfaces have previously been shown to alter agility performance [1]. All surfaces were installed in the lab over a force platform (2400Hz) to quantify utilized traction while using a motion capture system (240Hz) to quantify changes in the lower extremity movement patterns of the athletes. Data was compared between the different surfaces using a repeated measures ANOVA (α=0.10) with within participant factors of surface and between participants factors of player position.

RESULTS AND DISCUSSION

During all movements there was a significant effect of surface on utilized traction at take-off (vcut, p=0.061; agility, p=0.058; cone, p=0.005) and the frontal plane ankle angle (vcut, p=0.076; agility, p=0.002; cone, p=0.011) with players utilizing a lower amount of traction and having a lower peak frontal plane ankle angle on the low traction surface (LW). During the agility drill and vcut movement, a significant effect of surface was seen for the peak frontal plane rearfoot-floor angle (vcut, p<0.001; agility, p<0.001), with players having a flatter foot orientation on the high traction surfaces (Control and SP).

CONCLUSIONS

When on a high traction surface football players have a flatter foot orientation, which may increase cleat engagement and allow players to generate a greater utilized traction at take-off. Players additionally increase their ankle angle to maintain upper body orientation while increasing shoe-surface interaction.

ACKNOWLEDGEMENTS

Football cleats were provided by Nike and the surfaces were provided by FieldTurf. Funding for this study was provided by a National Football League (NFL) grant.

Exploring the acute neuromuscular effect of accentuated eccentric loading during unconstrained vertical jump with different loading locations on the body

INTRODUCTION

Accentuated eccentric loading (AEL) is an exercise where additional load is added to the body during the eccentric phase of a movement and then immediately decoupled during the concentric phase. It has been suggested that applying AEL during countermovement jump may increase jump height and power output [1, 2]. However, there is conflicting evidence for this effect [3, 4], and it remains unclear whether this increased performance is due to mechanical reasons, such as increased energy stored in the tendon, or just a more effective movement coordination strategy. This study aimed to examine how applying AEL loads at different locations on the body impacts the jump height and power output of a maximal countermovement jump.

METHODS

We collected data from 2 healthy adult participants, but ongoing data collection aims to collect 13 participants (aged 18-45). In session 1, the participant selected a preferred countermovement depth (CMD) for non-weighted condition and practiced AEL jumps (20% body mass) to the same depth with two different conditions (loading from pelvis and trunk). Each jump was performed on a customised pulley system with an electromagnet attached, which allowed adding weights during the jump and automatically releasing weights at the bottom of the countermovement. We monitored and controlled CMD in these conditions using a linear potentiometer transducer via a waist belt (GymAware, Kinetic Performance Technology, Canberra, Australia) to provide instant feedback after each jump. Two more conditions were used without CMD constraint: AEL from hand-held dumbbells (20% body mass) and free countermovement jump without arm swing. In session 2, the participant performed three successful maximal jumps for each condition. We randomized the order for conditions with and without constrained CMD. Two AMTI force plates were used to collect ground reaction forces synchronously with 8 high speed video cameras (FLIR) through a 3D motion capture system (Vicon). Markerless motion analysis software (Theia Markerless) was used to analyse whole body three-dimensional kinematics, including the location of the body centre of mass. Surface EMG of 8 lower limb muscles were also collected. Only the trial with the highest jump height for each condition was analysed.

RESULTS AND DISCUSSION

We found decreased jump height with AEL conditions in pelvis and trunk loading compared to non-AEL conditions. CMD was constrained in pelvis and trunk loading conditions (<3 cm difference), and hence the hip and knee angles at the bottom of the jump did not differ meaningfully between AEL and non-AEL conditions. However, both participants increased jump height with AEL in dumbbell loading. The mechanism for increased jump height requires more consideration, as kinematics and CMD varied substantially despite both participants improving jump height. Data are reported in Table 1.

CONCLUSIONS

Our preliminary data suggests that when CMD was constrained (<3 cm between conditions), AEL did not increase maximal jump height. However, when CMD was not constrained and AEL was loaded from both hands, participant increased jump height. This performance-enhancing effect could be explained by adopting a deeper squat depth or through shifts in the position of the centre of pressure related to arm movement, but further investigation is needed.

INTRODUCTION

55% of athletes who have had an ACL reconstruction (ACLR) return to competitive levels of sports [1]. 30% of these athletes suffer another ACL injury in the contralateral or ipsilateral limb within 24 months of return-to-sport (RTS) which may eventually result in knee osteoarthritis within ten years [1]. One of the potential risks for a repeat ACL injury is sagittal plane knee loading abnormalities [2]. Individuals with ACLR avoid loading the surgical knee by shifting the load to the ipsilateral hip [2]. It is known there is a significant association between ACL injury and a history of prior ankle sprains [3]. However, little is known about how a history of ankle sprains impacts sagittal plane joint loading biomechanics during simple bilateral and more complex unilateral tasks at RTS in individuals with ACLR. Therefore, the purpose of this study was to evaluate if sagittal plane loading biomechanics between lower extremity joints (i.e., ankle, knee, hip) changes across tasks at RTS in individuals with ACLR with a history of ankle sprains (ACLR-AS) compared to individuals with ACLR and healthy controls.

METHODS

Thirty-nine athletes, who were matched by sex, height, weight, and limb dominance, performed five trials of double-limb squats (DLS) and then single-limb squats (SLS) followed by a 30-second rest between trials and 1-minute rest between tasks. The kinematics and ground reaction force data were recorded at 120 Hz (Qualisys) and 1200 Hz (AMTI), respectively. In order to assess the integrated biomechanics of the lower extremity joints during squatting, energy absorption contribution (EAC) from separate joints was used. EAC was computed by averaging the middle three trials' negative joint work during the decelerating phase of DLS and SLS relative to total EAC. This negative joint work represents the muscle-tendon unit at individual joints and was normalized by athletes' height and weight. Athletes' surgical limbs were identified as the limb with ACLR and ACLR-AS, and healthy controls were given a surgical limb based on matched athletes. Nonsurgical limbs were defined as contralateral to the surgical limb. 3 (group) × 3 (joints) × 2 (tasks) repeated measures analysis of variance were conducted to examine differences between groups and within joints and tasks in EAC during DLS and SLS in the surgical limb. Alpha was set a priori at 0.05.

RESULTS AND DISCUSSION

Significant group × joints × task interactions were found in the surgical limb ($F_{4,72}$=7.543; P=.011). Tukey post hoc comparisons revealed ACLR-AS and ACLR groups displayed greater EAC at the hip (ACLR-AS: 38.91±3.09%, P=.01; ACLR: 44.09±3.09%, P<.001) and lower EAC at the knee (ACLR-AS: 38.91±3.09%, P=.010; ACLR: 44.09±3.09%, P<.001) during SLS compared to healthy controls (Hip: 28.13 ± 3.09%; Knee: 56.58±2.82%). All three groups significantly loaded the knee the most, followed by the hip and ankle during DLS (P-range:<.001-.038) and SLS (P-range: .009-.038), with the exception of the ACLR group, which displayed a load-sharing strategy between the hip (44.09±3.06%) and knee (41.70±2.82%) during SLS.

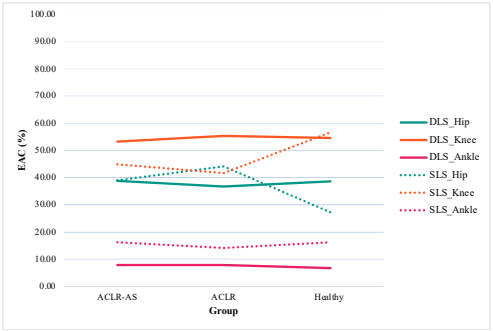

Figure 1 Significant interactions of Group by Joints by Task for EAC in the Surgical Limb

CONCLUSIONS

Group differences in loading biomechanics depended on joints and tasks. The ACLR-AS and ACLR group increased loading at the hip during more complex SLS in the surgical limb compared to healthy controls at RTS. The sagittal plane joint loading biomechanics used by the ACLR-AS and ACLR groups did not differ based on a history of ankle sprains. To comprehend load-sharing strategies employed by the ACLR group, further research on proprioceptive characteristics and potential deficits, in the case of ACLR, especially at the knee joint, may be required to better understand mechanisms that may explain differences in loading biomechanics.

INTRODUCTION

Over 60% of practitioners in sport and exercise science use mobile appications to collect data [1]. Mobile applications are an appealing and affordable alternative to laboratory systems. These applications are useful in field-settings to inform practice when valid and reliable. The Calf Raise application (CR_{app}) was developed to facilitate testing of the triceps surae (i.e., calf) muscles in a clinical or field-based context. Given that these muscles are key for many sport-related activities, included maximal-effort accelerated sprints, testing calf muscle function is likely to inform on athletic ability. We aimed to establish the validity and reliability of the CR_{app} in a cohort of Rugby Union players, and explore the potential association between 10-m sprint times and calf muscle strength-endurance and power metrics.

METHODS

Cohorts of professional male Rugby Union players participated in the validity (n = 20; 35% backs), test-retest reliability (n = 18, 61% backs), or correlation (n = 16, 63% backs) portions of this project. In all studies, players completed three single-leg tests once on both legs: (1) bodyweight power; (2) 35 kg weighted power; and (3) endurance. The CR_{app} was used to track the vertical displacement of a marker placed below the lateral malleolus using computer-vision algorithms. The vertical displacement was used to extract peak power from the power tests and total repetitions, peak height, total displacement, and total work from the endurance test. Three-dimensional motion capture and force plates were used to extract the same metrics for validation purposes. Players were tested twice a week apart to assess test-retest reliability. The 10-m sprint times of players were tested 3-4 days after calf muscle testing using single-beam timing lights in the correlation study.

Two-way mixed effects single measurement intraclass correlation coefficients ($ICC_{3,1}$) and typical errors expressed as coefficient of variations (CV) with 95% confidence intervals (CI) were calculated to quantify relative and absolute concurrent validity and test-retest reliability. Relative validity and reliability were considered *fair*, *good*, and *excellent* when ICC values reached 0.40, 0.75, and 0.90, and *poor* when <0.40. Absolute validity and reliability were deemed acceptable when CV was < 10%. Pearson correlations and 95% CI between sprint times (average and best trial) and calf muscle metrics were computed using estimates based on Fisher's z transformation with bias adjustment. Correlations were considered *small*, *moderate*, and *large* when reaching 0.10, 0.30, and 0.50, and *trivial* when <0.10. Statistical significance was set to $p < 0.05$.

RESULTS AND DISCUSSION

The relative validity of CR_{app} metrics was *good* to *excellent* and absolute validity of CR_{app} metrics was acceptable compared to 3D motion capture and force plate data (ICC 0.84–1.00, CV ≤ 6.6%). Test-retest reliability of CR_{app} metrics was *good* with acceptable retest errors (ICC 0.83–0.88, CV≤ 9.8%) across metrics.

There were *large* significant correlations between 10-m average sprint times and calf muscle bodyweight power, weighted power, and total displacement and total work during endurance testing ($|r|$ = 0.51–0.63). There were *large* significant correlations between 10-m best sprint times and calf muscle weighted power, and total displacement, total work, and peak height during endurance testing ($|r|$ = 0.50–0.53).

CONCLUSIONS

The metrics from the calf muscle testing procedures extracted using the CR_{app} were valid and reliable in male Rugby Union players. These metrics were largely correlated to their 10-m sprint times, an indicator of their acceleration ability. Other than being used as a performance indicator and monitoring tool, the CR_{app} may prove useful in injury prevention efforts, rehabilitation, and return-to-play decision making for calf muscle and Achilles tendon injury, a prevalent concern in Rugby Union players.

ACKNOWLEDGEMENTS

Two authors (KHL and CBS) are developers of the free-to-use CR_{app}. A researcher (TN) not related to app development collected all data.

INTRODUCTION

Muscle fatigue is described as a reduction of maximal force or power that the involved muscles can produce, and it can develop gradually after onset of sustained physical activity. Among all the muscle in the lower limbs, hamstring injury is often associated as a risk factor leading to hamstring strain during sports activities. Dry needling (DN) has been a common intervention for the treatment of muscle fatigue because it induce immediate analgesia of the myofascial trigger point without hyperaesthesia for patients with myofascial pain. Variables describing the movement of the centre of pressure (COP) are useful for the evaluation of balance behaviors such as body postural sway. The purpose of the current study was to investigate the effect of dry needling on standing balance in terms of COP sway variables.

METHODS

Nine young and healthy subjects from Hualien community aged from 20-35 years old participated in the current study. In a gait laboratory, each subject was guided to perform static balance test, namely standing with feet close up with eyes closed for 60 seconds before and after induced muscle fatigue exercise (Control and Fatigue Conditions) and after dry needling therapy for fatigue (DN Condition). The induced muscle fatigue exercise is defined as fifty active flexion of the knee with resistance of the therabands while prone on the treatment bed. The dry needling therapy was delivered by an experienced and qualified Chinese medicine doctor (Keng Chang Kuo) using disposable sterilized stainless steel needles. The dry needles were located at myofascial trigger points of the biceps femoris, semitendinosus and semimembranosus muscles. Each trigger point was needled with 1 minute of fast in-out cone-shaped technique. The time-varying COP positions were calculated from the ground reaction force data using the forceplate. The sway area of the COP (ACOP) was described by an equivalent ellipse covering 95% of the samples along each axis obtained by principal component analysis. The ratio of the lengths of the major axis and minor axis was also calculated to describe the distribution of the COP positions. A one-way analysis of variance with block design of each subject was used to compare the differences of ACOP and ratio of axis lengths between conditions.

RESULTS AND DISCUSSION

There were no significant differences of ACOP between Control and Fatigue Conditions. After dry needling therapy for fatigue (DN), the subjects showed greater ACOP compared with those in Control and Fatigue Conditions. Moreover, there were no significant differences of ratio of axis lengths between conditions.

Hamstring fatigue might not affect the strategy of co-contraction of knee extensor and flexor muscles for maintenance static standing balance. However, relaxation of the hamstring muscle using dry needling therapy may cause greater posture sway (i.e. ACOP) of the body during quiet standing. Dry needling may be an effective treatment for relaxation of the muscle leading to compromise the strategy of co-contraction of the agonist and antagonist muscles for static balance control. Moreover, no significant differences of the ratio of axis lengths between conditions indicates that fatigue or dry needle therapy might not affect the unity of posture sway during standing.

CONCLUSIONS

Dry needling may be an effective treatment for relaxation of the muscle leading to compromise the strategy of co-contraction of the agonist and antagonist muscles. It is suggested that dry needling therapy might not suitable for decreasing posture sway of static balance control.

INTRODUCTION

The tennis forehand drive is the first technique usually learned by beginners [1] and is considered the second most important technique in tennis just behind the serve [2]. Given that ball velocity depends highly on the velocity of the racket head, many researchers have attempted to determine the most efficient mechanics for higher racket velocity [3]. Based on the method developed in previous studies [4], researchers have identified the upper limb rotations that most contribute to the racket head velocity between different type of forehand shots [5]. Despite the importance of the latter studies comparing different techniques, no study used this method to compare the contributions of upper limb rotations to the racket head velocity between different levels of expertise. Thus, the aim of this study was to compare the contributions of the upper limb segments rotations to the racket head velocity in the tennis forehand drive between intermediate (INT) and high-performance (HP) tennis players.

METHODS

Twenty-seven tennis players Participated in this study, 12 intermediate and 15 high-performance. The tennis forehand strokes were performed inside the laboratory (Figure 1). Athletes were asked to hit the ball like in a real situation. Kinematic data were collected at 240Hz with an optical system with fifteen infrared high-speed cameras using the Qualisys Track Manager (version 2.17, Qualisys AB, Gothenburg, Sweden) software. The contribution of the upper limb segment's rotations to the racket head velocity was calculated using the method developed in a previous study [4].

RESULTS AND DISCUSSION

The results showed significant differences between INT and HP tennis players (Table 1) in the contribution of the shoulder (representing the contribution of the trunk and lower limbs) to the racket head velocity. No other significant differences were found between both levels. The results of this study differ from a previous study [5] which referred the internal rotation of the upper arm as the most important rotation to the racket head velocity.

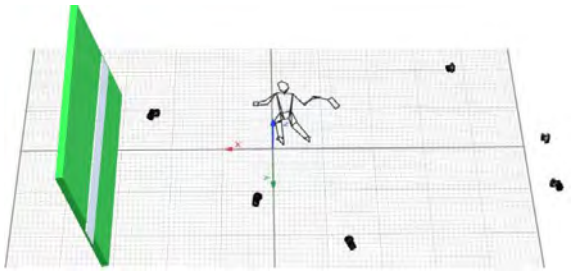

Figure 1 Laboratory test environment with fifteen infrared high-speed cameras during forehand drive performance.

CONCLUSIONS

The horizontal shoulder velocity represents a key factor that might distinguish intermediate from high-performance tennis players. Tennis coaches and athletes should focus in developing higher velocities of the shoulder to achieve a higher performance.

INTRODUCTION

At the University of Exeter, UK we are adressing a range of research topics to further understand static and dynamic balance control in healthy and clinical populations using our state-of-the-art VSimulators facility. VSimulators has a 3.7 m^2 platform, that can be programmed to move precisely in 6 degrees of freedom with an amplitude of up to 4cm, where frequency of motion can range between 0.4 and 40 Hz. The floor of the platform is covered with an array of 9 AMTI force plates (Fig. 1a), the area is surrounded by a Motive motion capture system. In addition, VSimulators is integrated with 9 virtual reality headsets and we have synchronised add ons; FNIRS, EMG, IMUs, eye tracking, and gas analysis technologies.
Here we demonstrate the system through a study which aims to identify critical frequencies of floor motion that results in transitions in balance control stratergy. Previous work in this area has focussed on large amplitudes of platform motion (9-23 cm at 0-3 Hz) in the anterio-posterior (AP) direction, and defined ankle to hip dominant strategies with transition from in-phase to anti-phase centre of pressure-centre of mass (COP-COM) relation occuring at around 0.5 Hz [1-3]. Here we use smaller amplitude platform motion reflective of real life to investigate how the postural system regulates hip, knee and ankle strategies to govern the COP-COM coordination.

METHODS

Nine young healthy participants stood on the VSimulators platform as it sinusoidally translated in the AP direction. Platform frequency was linearly scaled from 0.4 Hz to 6 Hz and then back down to 0.4 Hz with amplitude of 2 mm peak, resulting in platform acceleration between 0 to 2.5 m/s^2 (Fig. 1c). Full body motion capture and force plate data were collected. Using a 4-segment model, hip, knee and ankle joint torques were calculated via inverse dynamic analysis. Coordination between the joint torques, and COP-COM relative motion were quantified by vector coding. Ankle, knee and hip postural strategies were defined based on the phase relationship between hip-knee and knee-ankle joint torque couples [4].

RESULTS AND DISCUSSION

There was a significant effect of platform frequency on knee-ankle torque and COP-COM phase relationship. At frequencies below 2.27 Hz, an ankle strategy was used (in-phase knee-ankle torque), which resulted in in-phase COP-COM motion with the COP being dominant. As the frequency of the platform increased beyond 2.27 Hz, COM motion became dominant. At this point, a knee strategy was used, which involved anti-phase knee-ankle torque and allowed the COP to regain dominance over the COM.

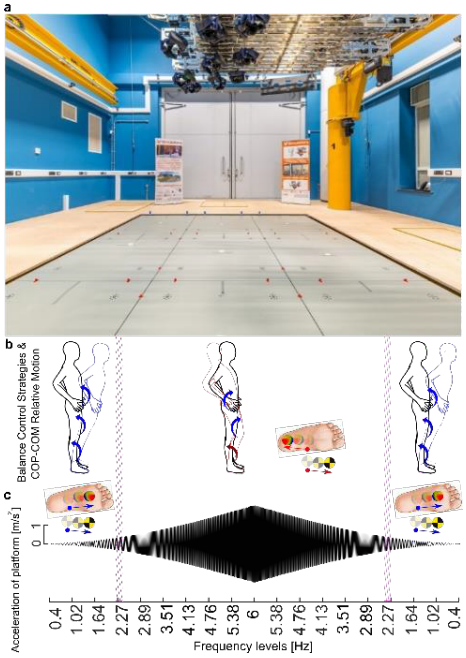

Figure 1 (a) VSimulators facility, (b) Balance strategy as defined by hip-knee and knee-ankle torque phase relation, (c) and COM-COP phase relation during changes in platform frequency.

CONCLUSIONS

The study identified the knee strategy as a new and relevant strategy used with small amplitude platform motion, that are more representative of real-world settings. We show evidence that the transition between ankle and knee strategies underpins the transition between COP-COM relative motion.
Work of our group in the VSimulators facility is focussing on health related (ageing, Parkinson's disease) and basic science research to understand mechanisms of human balance control.

INTRODUCTION

Many researchers have attempted to understand the fundamental properties of the human balance control system by quantifying recovery strategies in response to an external perturbation. For example, continuously scaling platform frequency has revealed a number of different transitions between adaptive balance strategies. Model predictive control (MPC) is an emerging advanced method applied to understand and predict human postural responses as it is able to represent characteristics of the human motor system such as prediction, adaptation, multi-joint control, and optimization. Building on previous MPC models that simulated postural response to sudden and short floor motions [2], here we aim to propose and test an MPC based scheme of human balance control in response to more demanding and continuous translational perturbations shown in (Figure 1g).

METHODS

The model was tested using data from our previous study [1] that analysed balance recovery in response to small amplitude underfloor movement where frequency was scaled from 0.4-6 Hz in the AP direction. The model consists of a four-segment biomechanical model with sensory feedback that maps joint recovery motion to the neural controller (MPC). Then, the MPC generates corrective torques through an optimization process, to maintain an upright standing position. Biomechanical constraints and optimization criteria in the MPC scheme were set to achieve human-like recovery behaviour and investigate effective regulation of postural strategies. Postural strategies are identified by the phase relationship between corrective output joint torques, as described in more detail in our previous work [1].

RESULTS AND DISCUSSION

Simulation results using the proposed MPC scheme, as shown in (Figure 1c-d, f) are well aligned with our experimental results [1]. Model results show a transition from in-phase to anti-phase (blue to red bars) for knee-ankle torque and COP-COM relative motion at a frequency of 3.5 Hz, while hip-knee torque remained in-phase at all frequencies. It seems that to deal with the loss of stability caused by scaling platform frequency, MPC controller can regulate adaptive postural responses and transit between them and change coordination between COP-COM motion accordingly.

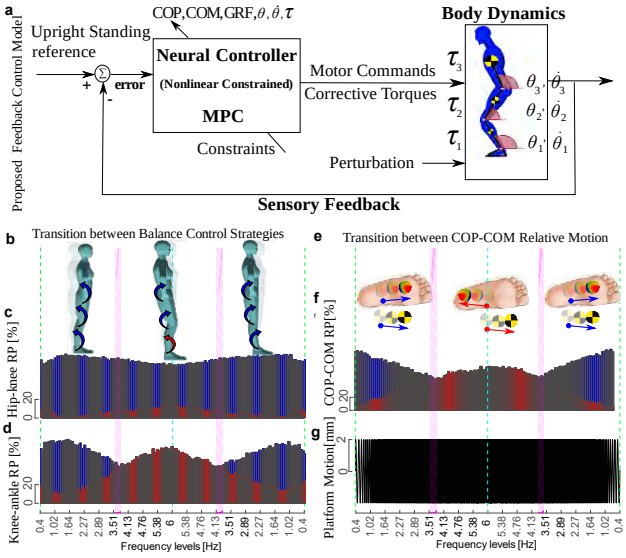

Figure 1 (a) Model schematic, (b) balance strategy as defined by (c) hip-knee and (d) knee-ankle torque phase relation, and (e, f) COM-COP phase relation during changes in platform frequency (g).

CONCLUSIONS

The facility of MPC to continually update predictions and control actions based on anticipated future events, while adhering to biomechanical constraints, makes it well-suited for handling complex and unpredictable dynamic behaviours, such as transition between postural strategies under effect of scaling platform frequency. Future work aims to apply this model to explore the landscape of postural strategies that emerge across a wide range of platform amplitudes and frequencies. By taking into account specific constraints or limitations associated with different population groups, such as the elderly or those with Parkinson's Disease, this model can also be refined to predict or simulate their behaviour.

INTRODUCTION

Wearable assistive devices have wide-ranging applications in human augmentation and rehabilitation. Spring-loaded exoskeletons provide mechanical assistance at the ankle joint by storing and returning energy, mimicking the behaviour of the Achilles tendon and plantarflexors. Previous studies have shown that passive devices reduce the energetic demands of locomotion [1]. However, wearing lower limb exoskeletons alters patterns of fascicle length changes and muscle activation [2]. This may complicate balance control which requires constant monitoring and adjustment of ankle muscle function. Balance is further challenged by manipulating the support base and sensory inputs. Increasing postural demand changes balance strategies and the neuromuscular behaviour of the plantarflexors [3,4]. As such, the influence of exoskeletons may extend beyond locomotor economy to affect postural control in a task-dependent manner. The aim of this study was to assess the influence of passive ankle exoskeletons on muscle fascicle behaviour during balance tasks of varied difficulty.

METHODS

Thirteen participants performed four balance tasks: (i) quiet standing with eyes open (EO), (ii) eyes closed (EC), (iii) active sway (AS), and (iv) reduced base of support (RBOS). Tasks were performed for 60s on a force plate (Bertec Corp., USA) at three exoskeleton spring stiffnesses: 0, 42, and 85 Nm rad^{-1}. Medial gastrocnemius (MG) fascicle lengths were measured using B-mode ultrasound (ArtUS, Telemed), and processed using a semi-automated algorithm (UltraTrack v4.2). Linear mixed-effects models determined the influence of exoskeleton assistance and balance condition on the mean and standard deviation (SD) of fascicle length during the task. Tukey's post hoc tests were performed to identify significant differences between conditions. Significance was set to $p<0.05$.

RESULTS AND DISCUSSION

There were significant main effects of exoskeleton stiffness ($p=0.002$) and balance condition ($p=0.012$) on mean MG fascicle length, but no stiffness*condition interaction (Fig.1A,C). Post hoc analyses revealed that during AS with low exoskeleton assistance (42 Nm rad^{-1}), MG fascicles operated at 4.3% longer lengths compared to no assistance ($p=0.032$), but there were no differences with the highest level of assistance (85 Nm rad^{-1}). During the EC balance condition with low assistance (42 Nm rad^{-1}), MG fascicle lengths increased by 4.9% and 5.2% compared to no assistance ($p=0.031$) and the stiffest assistance (85 Nm rad^{-1}) ($p=0.02$), respectively. Fascicle lengths did not differ between exoskeleton stiffnesses for EO or RBOS. There was a main effect of condition ($p<0.001$) and a stiffness*condition interaction ($p=0.003$) on the variability (SD) in MG fascicle operating lengths, but no effect of exoskeleton stiffness. This meant that fascicles operated at shorter lengths (Fig.1C) and tended to vary more (Fig.1D) during more challenging postural tasks (AS and RBOS) than quiet standing (EO and EC).

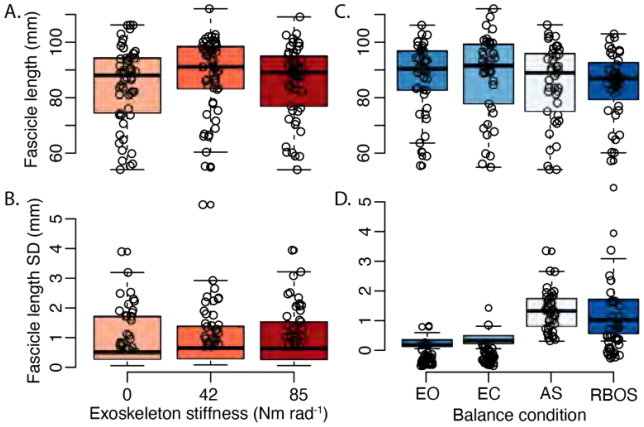

Figure 1 Mean MG fascicle length (A,C) and standard deviation (B,D) for three exoskeleton spring stiffnesses and four balance conditions (eyes open (EO), eyes closed (EC), active sway (AS), reduced base of support (RBOS)).

CONCLUSIONS

When balancing with passive ankle exoskeletons, changes in plantarflexor fascicle dynamics are dependent on the level of exoskeleton assistance and the difficulty of the balance task. Future investigations into the influence of these wearable devices on neuromuscular control in populations with balance deficits (e.g., ageing) will provide insights into the restorative potential of passive devices.

A SINGLE SESSION TREADMILL PERTURBATION-BASED BALANCE TRAINING FOR FALL PREVENTION: EFFICACY AND MECHANISMS

Deepak Ravi[1], Friederike Schulte[2], William Taylor[1], Navrag Singh[1], Chris Awai[3], and Raphael Schweri[1]

INTRODUCTION

Perturbation-based balance training (PBT) has been demonstrated to be an effective and feasible task-specific approach for reducing fall incidence in older adults. Previous studies have shown that a single session of PBT can impart fall-resistance skills, which can be retained for up to a year [1]. However, most of these single-session studies focus on overground slip perturbation training, even though treadmill setup seems to enable greater perturbation loads and clinical feasibility. The goal of our study was to establish the efficacy of such a treadmill protocol with respect to balance outcomes and mechanisms underlying the intervention's effect, in order to gain acceptance in clinical practice.

METHODS

In this pilot study, 20 older adults without neurological or orthopaedic conditions were recruited. The participants were randomly and equally divided into an intervention group (50% female, with a mean age of 67.1±2.7 years) and a control group (50% female, 72.8±4.9 years). The control group received treadmill walking training in a single session consisting of three blocks of 8 minutes each. For the participants in the intervention group, the training additionally included antero-posterior perturbations (32 in total) by sudden acceleration or deceleration of the treadmill belt (increments of 0.25 m/s^2, from 0.5 m/s^2 up to a maximum of 2.25 m/s^2). Training efficacy was evaluated by analysing 4-minute assessment blocks, which feature a single deceleration perturbation at 2.25 m/s^2, before (Pre) and after (Post) training. We measured the individual's resilience to perturbations through the maximum center of mass (COM) deviation from pre-perturbation, steady-state movement patterns, and the time taken to recover [2]. The mechanisms were evaluated by determining the degree of coordination between the COM and foot placement [3].

RESULTS AND DISCUSSION

The control group had a decrease in maximum deviation of COM of 12.3±17 millimetres, while the intervention group showed a decrease of 24.2±28 millimetres. Additionally, the control group saw an average increase in recovery time of 2.3±3.2 seconds, while the intervention group experienced a decrease of 2.5±6.9 seconds. The degree of coordination between COM and foot placement increased in both the control (3.7±11.3%) and the intervention (2.8±5.4%) groups. Both groups exhibited a relatively high foot placement control before training, which may have limited their ability to improve it further.

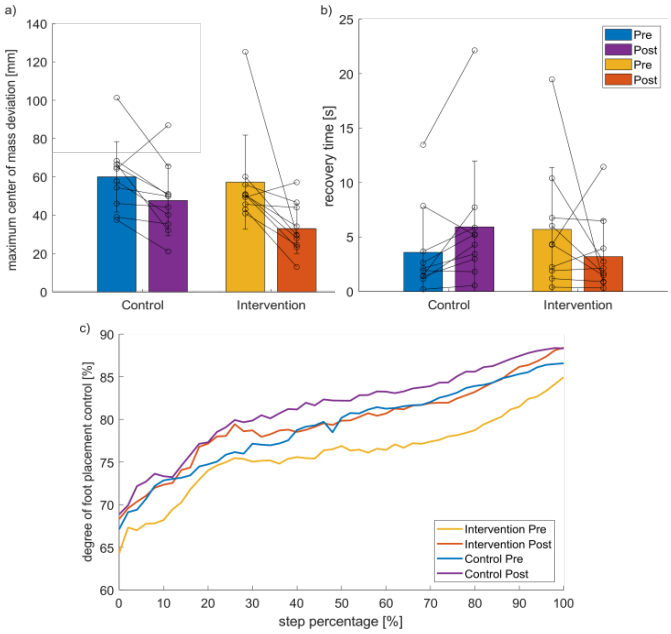

Figure 1 Effects of PBT on a) maximum center of mass deviation b) recovery time c) degree of foot placement control for the swing phase from toe off (0%) to heel strike (100%) - quantified as the relative explained variance of a regression model linking mediolateral foot placement to mediolateral position and velocity of CoM [3].

CONCLUSIONS

Our results indicate that a single session of treadmill PBT may yield greater within-session benefits in improving balance in comparison to conventional treadmill walking training. The significance of these findings remain to be investigated in a more in-depth analysis of mechanistic changes to e.g., base of support or step length and its relationship to maximum COM deviation and recovery time.

Emulating human postural control adjustment with perturbation using quadratic objective function

Seongwoong Hong, Sukyung Park
Department of Mechanical Engineering, KAIST, Daejeon, Republic of Korea.
Email: sw.hong@kaist.ac.kr

INTRODUCTION

Human postural control refers to the mechanisms that allow people to generate motions in response to external perturbations while maintaining an upright posture. Previous research that have attempted to explain these mechanisms based on control theories gave a suitable analysis using simple controllers. However, in a study explaining the postural control as a trade-off between stability and control effort [1], the controller has low reproducibility with respect to human data. In contrast, research that accurately duplicates human postural control using a feedback controller [2] has not identified objectives that could be useful for interpreting human movement. This study therefore quantified the contribution of postural stability and control effort that can reproduce human movement. Specifically, we determined the objective function of a linear feedback controller that reproduces postural response adjustments with external perturbation.

METHODS

To examine the relative contribution between stability and control effort in postural control, a quadratic cost function of the stable linear feedback controller was identified. The response of human postural control was collected in the same way with the previous study [2]. Angles, angular velocities, and torques were collected and calculated.

A linear feedback controller for the angles and angular velocities of two joints was introduced to reproduce the human data. The controller gain was determined to minimize the discrepancy between human data and simulation data for external perturbations, while stabilizing the closed-loop system.

A quadratic cost function for the angles, angular velocities and torques of two joints was formed to reflect the trade-off between postural stability and control effort. In order to quantify objectives, the parameter matrix was determined to obtain the optimal gain for the linear feedback controller that reproduces human data.

RESULTS AND DISCUSSION

The linear feedback controller reasonably well reproduced the human postural data in response various perturbation magnitudes. It replicates human trajectories well in time trajectories and ankle-hip trajectories graphs, as shown in Figure 1-A,B, and exhibited a gradual decrease in ankle torque as perturbation magnitude increased.

In addition, the penalization factor of ankle angle within the objective function was gradually scaled with perturbation. Among the eigenvectors of the cost function matrix that reproduces human data, the eigenvalue of the vector dominated by ankle angle declines gradually as the magnitude of perturbations increases, as shown in Figure 1-C. This indicates that the objective function changed in the direction of reducing the control effort to move ankle as the magnitude of perturbations increased.

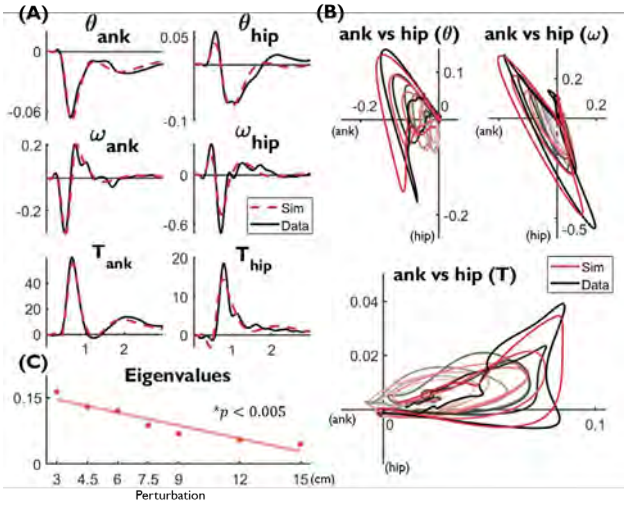

Figure 1 (A) Time trajectories and **(B)** the change in ankle versus hip trajectories in response to the change in perturbations of the linear feedback controller that imitate human data, and **(C)** increased perturbation decreases ankle angle dominated eigenvalue

CONCLUSIONS

This study identified the objective function of a controller that replicates human postural control, and showed that stabilization of ankle movement control decreases with perturbation. This result is consistent with previous studies that the human postural control strategy gradually reduces the contribution of ankle torque in response to increasing perturbations due to the influence of biomechanical constraints [2]. The outcomes demonstrated that the trade-offs between stability and the expense of human movement control could be quantified using the quadratic cost function.

Motor performance after treatment of pilocytic astrocytoma in childhood

Fredrik Öhberg[1], Gunilla Elmgren Frykberg[2], Artin Omar[1], Jens Lundin[1], and Ingela Kristiansen[3]

INTRODUCTION

Low grade astrocytoma is the most common central nervous tumour in childhood and pilocytic astrocytoma (PA) the most common tumour type in this group. These tumors can be located in different parts of the brain but are mostly found in the posterior fossa [1]. The cerebellum, located in the posterior fossa, plays an important role in the acquisition of new motor skills, coordination, and quality of movement as well as being involved in cognition [2]. Treatment of a tumor in the posterior fossa can lead to future neurocognitive complications for the patient [3].
Studies (e.g. [4]) have described motoric, and cognitive complications for treated patients with pilocytic astrocytoma, but there is still a lack of knowledge on the full extent of said complications.
The goal was therefore to analyse motor performance in children and young adults with treated PA when performing a dual task compared to a matched control group without disability.

METHODS

The study was conducted as a cross-sectional case control study at Uppsala University Hospital, Sweden and 8 children (ages 9-17) and 12 young adults (ages 21-33) participated. All the patients had been surgically treated for PA in the posterior fossa between 1995-2011. One young adult patient was excluded due to factors affecting motoric functions. A total of 19 patients were included in the final analysis. The controls were population-based and were matched for age, gender, height, and weight. Each patient was matched to two controls. In total, 16 children and 22 young adults gave their informed consent and data from these were included in the final analysis.
Data collection of the motor performance was performed during some of the tests included in the Mini-BESTest (e.g., the test Timed Up and Go (TUG)). Both the study and the control group performed a TUG test and repeated the same test as they solved a cognitive task.
The data come from 5 inertial measurement sensors placed on both thighs and shanks and one around the waist, where each sensor contained a three-dimensional gyroscope (16-bit, range ±2000°/s), accelerometer (16-bit, range ±16 g), and magnetometer (13-bit, range ±1200 µT). Each sensor sent data wireless to a laptop equipped with the software MoLab regarding their orientation in a global space during the performed tests.
Several outcome variables (both temporal and spatial) were calculated offline and split into separate datasets (i.e., children and young adults). A linear mixed model analysis was then performed on each outcome variable set as dependent with the independent factors set to patient/control and single/dual task. The estimation method used was restricted maximum likelihood and alpha value was set to 0.05 with confidence interval adjustment LSD(none) for all statistical tests.

RESULTS

The statistical analysis was conducted separately for the different datasets and the interaction between the addition of a cognitive task and the patient- and control group were examined. Statistically significant interactions were found for children dataset regarding absolute time, but not for younger adults (Figure 1).

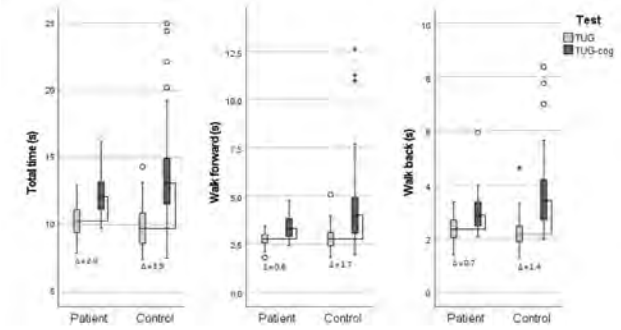

Figure 1 *Boxplots illustrating total time, and time to complete the walk forward and walk back subphase during a Timed Up and Go (TUG) and a Timed Up and Go-cognitive (TUG-cog) for the child patient- and control group. Mean difference between TUG and TUG-cog for patients and controls is shown. s: seconds; Δ: mean difference; o: outside value; ∗: far out value.*

CONCLUSIONS

Children in the control group performed worse than patients regarding total time and time to complete two subphases. No statistically significant differences were found for young adults. The patients were therefore not more impaired than controls with the addition of a cognitive task to a TUG-test.

ACCURACY OF A 2D CAMERA FOR OBTAINING 3D DATA IN RUNNING

Iain Hunter, John Hedengren, McGyver Clark, and Luke Vankeersbilck
Exercise Sciences, Brigham Young University Provo, United States of America.

INTRODUCTION

In the past, three-dimensional motion capture data required multiple cameras. Utilizing machine learning, a framework called MediaPipe (Google Corp) generates three-dimensional data of 33 body landmarks [1,2]. This is different than other machine learning frameworks such as OpenPose that only provide two-dimensional data. Running mechanics are of specific interest to us. Thus, we set out to determine which camera views would provide the greatest accuracy for sagittal plan hip, knee, and ankle angles.

METHODS

Eight subjects ran on a treadmill while being recorded with a traditional 12 camera motion capture system (Qualisys with Visual3D) and a single cell phone camera (iPhone SE 2020, Apple Corp) at 240 Hz. The iPhone was placed behind the runner, then rotated to a front view in 30 deg increments allowing for 30-s clips at -90, -60, -30, 0, 30, 60, and 90-deg camera positions. MediaPipe Pose produced 3D positions of hip, knee, ankle, and shoulder that were used to calculate sagittal plane angles for comparison with the output from Visual 3D.

Pearson-r correlations were computed for the hip, knee, and ankle calculations for each camera view between MediaPipe and motion capture data. ANOVA compared these correlations between camera views for each angle with Bonferroni post-hoc tests with alpha set at 0.05.

RESULTS AND DISCUSSION

Correlations between MediaPipe and motion capture were excellent statistically speaking for the knee (Figure 1 and Table 1). However, there were some notable differences between the two methods when looking at peak flexion and extension angles. Ankle and hip angles were not predicted well by MediaPipe. Camera views in the frontal plane produced very low accuracy from MediaPipe for all joint angles. This is likely due to the feet and sometimes knees becoming hidden from view. All other camera views were much more similar.

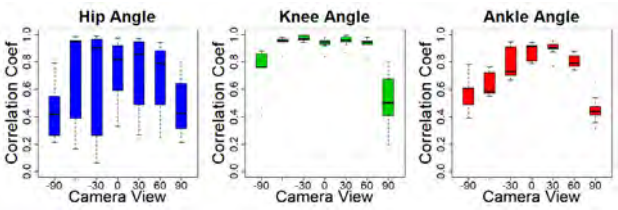

Figure 1 Boxplots of correlation coefficients. -90 represents a front view of the subject, 0 is a side view, and +90 is a rear view.

Motion capture data calculated hip angles from the thigh relative to vertical while for MediaPipe, hip angles were calculated with a vertex of hip and endpoints of the matched knee and the average of the two shoulders. This explains some of the low correlations observed for hip angles.

MediaPipe has a nice advantage of other methods such as OpenPose due to providing three-dimensional data allowing for sagittal, frontal, and transverse joint angles, but needs accuracy improvements especially for certain body parts.

We are interested in how other frameworks accuracy compares to motion capture when using just a side view as most other frameworks utilize.

CONCLUSIONS

MediaPipe provides three-dimensional data for 33 body landmarks. These landmarks can be used to produce joint angles, but have some limitations from certain camera views when body parts become obscured. The hip is especially inaccurate due to not knowing pelvis orientation for obtaining hip angles.

INTRODUCTION

Energy expenditure (EE) during running is a key metric for health management and runner motivation. Although several wearable devices, such as smart watches, provide EE information, it is known that estimation error is substantial (NRMSE 2793%). [1] Using biomechanical criteria such as mechanical work, recent research in the field of biomechanics has attempted to quantify EE at different running speeds with great precision. [2] However, since mechanical work can only be measured in a laboratory setting, if it is estimated via a basic wearable device and then employed, the estimation accuracy of the wearable device might be enhanced. Therefore, in this study, we estimate mechanical power(P_{mech}) when running from a single inertial measurement unit (IMU) by using running biomechanics and use it to increase the accuracy of EE estimates while maintaining convenience.

METHODS

For estimating EE using a single wearable sensor, we estimated P_{mech} from estimated ground reaction force (GRF) from a single IMU and use it to estimate EE. In detail, we GRF from sacrum-mounted IMU data based on our previous work [3] that estimated GRF during walking using an artificial neural network model (ANN) derived from a spring-loaded inverted pendulum model (Figure 1. (B)). P_{mech} was calculated from mechanical power done to centre of mass (P_{com})derived from estimated GRF and estimated centre of mass velocity (v_{com})(Figure 1. (B)) EE was estimated by an ANN using P_{mech} and running speed (V_{run}) as inputs. (Figure 1. (B)) Through the whole EE estimation process, leave-one-subject-out cross validation was used to verify the proposed method.

Ten young male subjects were participated in this study. They ran for 10 minutes on the treadmill at three kinds of speed; high (>75%$VO2_{max}$), moderate (50~75%$VO2_{max}$), and light intensity (<50%$VO2_{max}$). EE, GRF, and kinematic data from a sacrum-mounted IMU were measured.

Table 1: Validation of EE estimation result.

Intensities	RMSE (W/kg)	NRMSE (%)	R^2
Low	1.05	27.5	0.18
Moderate	1.05	28.4	0.01
High	1.58	24.4	0.03
Overall	1.38	18.6	0.48

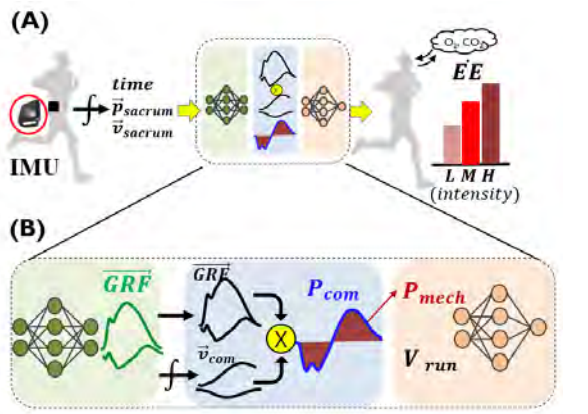

Figure 1. (A) Schema of whole EE estimation process (B) Details of inner process. 1) Estimating GRF using neural network. 2) Deriving v_{com} P_{com} and P_{mech} from estimated GRF 3) estimating EE using P_{mech} and V_{run}

RESULTS

Using a single IMU, we estimate EE during running through estimating GRF and P_{mech} from a single IMU. GRF, v_{com} and P_{mech} were estimated with normalized root means square error (NRMSE) 13.0%, 12.6% and 9.0%, respectively. The NRMSE of EE estimation in case of low, moderate and high intensity was 27.5% 28.4% and 24.4% respectively. (Table 1.) The overall EE was estimated with NRMSE about 18.6% and R^2= 0.48. The proposed method improves the accuracy of EE estimation with an error less than 20% that was reported error of smart watches.

CONCLUSIONS

In this study, we estimated mechanical power from a single IMU in order to enhance the accuracy of the EE estimation during running from the wearable device. Ultimately, we could estimate EE with NRMSE 18.6% and R^2=0.48, which is more accurate than smartwatch. It was demonstrated that the accuracy of the information provided could be enhanced while keeping the practicality of wearable devices by using biomechanical knowledge.

Groucho running reveals disparate results between ground reaction force and tibial bone strain: a finite element analysis

INTRODUCTION

Several studies have examined the relationship between ground reaction forces and stress fractures in running [1]; however, the majority of the load borne by bone stems from muscular contraction [2], and even then, the relationship between applied load and bone strain is often complex and nonintuitive. Groucho running [3], i.e., running with increased stanced-leg knee flexion, is characterized by reduced ground reaction force and increased muscular work. The purpose of this study was to determine if reductions in ground reaction force associated with Groucho running were associated with corresponding reductions in bone strain.

METHODS

Twelve physically active males ran on an instrumented treadmill (Bertec Corps., Columbus, OH) for 5 minutes in each of three conditions: Preferred, Groucho, and Exaggerated Groucho. The latter two conditions were accomplished by having participants reduce their peak vertical ground reaction force to 85% and 75% of the Preferred condition, respectively by exaggerating knee flexion in stance. Inverse-dynamic-based musculoskeletal modelling was used to calculate lower extremity muscle and joint contact forces. These forces served as inputs to a participant-specific finite element model of the tibia-fibula complex [4], which was created from computed tomography images of each participants lower-limb. The 90th percentile pressure-modified von Misses strain (peak strain) and volume of bone experiencing strains over 3000 με (strained volume) were calculated for the main outcomes.

RESULTS AND DISCUSSION

On average, there was 15.6% and 22.6% reduction in peak vertical ground reaction force during Grouch and Exaggerated Grouch running compared to Preferred condition. To date, finite element analysis has been completed for a single participant. Compared to Preferred running, peak vertical ground reaction force for this participant was reduced by 14.6% and 27.1% during Groucho and Exaggerated Groucho running, respectively. Proportional reductions in ground reaction forces were not observed in tibial bone strain metrics (Table 1). Although, peak strain and strained volume in Groucho decreased by 9.7% and 19.6%, respectively, corresponding changes in Exaggerated Groucho running were negligible (-1.5%) or considerably higher (+19.1%). In this scenario, the increased strained volume of 19.1% in the Exaggerated Groucho conditions would be expected to cause bone failure much sooner than the Preferred condition [5].

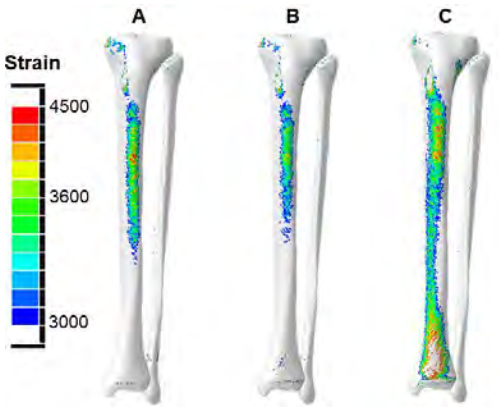

Figure 1 Tibial-fibular strain distribution for the three running techniques. A) Preferred, B) Grouch, and C) Exaggerated Groucho Only high strain parts (>3000 με) are shown in colormap.

CONCLUSIONS

This study used Groucho running as a model to reduce ground reaction forces and increase muscle work. These preliminary findings, to be confirmed with additional participants, suggest that running conditions that reduce ground reaction forces are not necessarily associated with corresponding reductions in bone strain. Interventions aimed at decreasing stress fracture risk through ground reaction force modification should be interpreted with caution.

INTRODUCTION

The popularity of running as a regular exercise may be explained because it allows for self-organized training in nearly any environment leading to variations in running speed and inclination (which have rarely been included in biomechanics analyses of runners). The sport has also been associated with a considerable amount of overuse injuries (OIs) resulting in around 2.5 to 33.0 OIs per 1000 h of practice [1]. Medial tibial stress syndrome (MTSS) is one of the most common OIs. The development of OIs is multifactorial while the types of injuries are likely related to exceeding a tissue-specific stress threshold. Direct measurements of tissue stress are difficult. Recently researchers have linked specific OIs to biomechanical risk factors (BRFs) [2]. As the effect of altered running speed and inclination on BRFs for MTSS has not yet been investigated, the purpose of this study was to assess the previously identified BRFs during varied running conditions.

METHODS

We collected 30s trials of full-body motion (17 cameras, 200 Hz, Qualisys) and ground reaction force (GRFs) data (2000 Hz, Gaitway 3D) from 21 recreational runners (8 female, 13 male, 176 ± 6.55 cm, 68.6 ± 9.20 kg, 25 ± 4 years). They ran in their own shoes on uphill (+5%, +10%, +15%), downhill (-5%, -10%, -15%), and level (0%) conditions, each at 2.5 m/s, 3 m/s, and 3.5 m/s in a semi-randomized order. We calculated BRFs for MTSS [2] (peak rearfoot eversion - PRE, rearfoot eversion duration - RED, peak contralateral pelvic drop - PCPD) using a custom-build Matlab script (R2022a) averaged over at least 20 steps. A 20 N threshold of raw vertical GRF defined the stance phase. Two-way repeated measures ANOVAs on BRFs (inclination x running speed) were used for testing significant (sig.) main and interaction effects (JASP 0.16). We further conducted Bonferroni-corrected post hoc tests and calculated effect sizes (partial eta squared - η_p^2, small: 0.01 - 0.059, medium: 0.06 - 0.139, large > 0.14 [3]). Data were checked for normality and sphericity.

RESULTS AND DISCUSSION

We found sig. main effects for running speed (PRE: p_{Speed} = .02, η_p^2 = .20; PCPD: p_{Speed} = .002, η_p^2 = 0.34), for inclination (PCPD: $p_{Incline}$ = .023, $\eta_p 2$ = 0.16), but no sig. interaction effects. Post hoc results are summarized in (Figure 1) with effect sizes being small (speed) and medium (inclination) at most. Although no differences were found compared to level running, a sig. trend towards reduced PCPD for downhill running was found. While PRE was affected by speed, RED was not, suggesting that the underlying structures had less time to get into greater eversion with increasing running speed. This may result in higher stress on the tissue and may progress MTSS development [4]. While sig. trends for the BRFs exist absolute changes in angles are small.

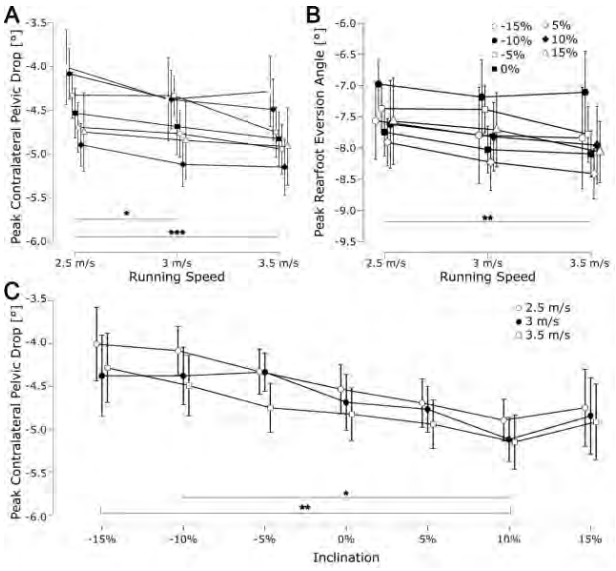

Figure 1 Descriptive plots for post hoc tests with significant differences indicated by asterisks (* p < .05, ** p < .01, *** p < .001). Bars display confidence intervals (95%).

CONCLUSIONS

Running at higher speed increases BRFs (PRE and PCPD) for MTSS. In combination with the inclination effect, this emphasizes that a combination of downhill running and reduced running speed is to be preferred when recovering from MTSS.

INFLUENCE OF WALKING AND RUNNING SPEEDS ON TIBIA IMPACT STRESS

INTRODUCTION

Tibia pain has been one of commonly documented injury among distance runners, which was primarily due to the accumulation of repetitive impact[1]. The realigned mechanical axis in the lower extremity may redistribute the impact loading[2], thus leading to micro-damage in the bone structure. Once the remodeling failed, the tibia pain was presented, or even stress fracture.

This study was aimed to evaluate the loading patterns in the tibia using a musculoskeletal-driven Finite Element simulation approach.

METHODS

This study included two sections. Participants joint a motion captue experiment in a lab in the first section. Runners performed walking (at 1.0m/s and 1.4m/s) and running (at 2.7m/s, 3.3m/s and 4.0m/s) tests on a forceplate instrumented treadmill with synchronously collection of marker trajectories. Marker positions and ground reaction forces were used to calculate joint angles, moments, muscle forces and joint reaction forces following an established musculoskeletal (MSK) modelling workflow[2].

During the second section, participants attended a MRI scanning to collect the medical imaging of the lower extremity, which were then segmented to obtain the 3D geometries in '*stl*' files. The geometries were meshed in HyperMesh, and then extracted as '*inp*' files for post-process the material properties assignment and assembly in ABAQUS. The joint angles, muscle forces and joint reaction forces were loaded as boundary conditions for Finite Element (FE) simulation using a standard explicit static solver.

RESULTS AND DISCUSSION

As in the **Table 1**, the ankle reaction forces in the axial directions were presented during landing impact for walking and running. The specific knee angles in the sagittal plane were showed as well, that knee flexion angles are 13.1° (1.0m/s), 14.9° (1.4m/s), 32.4° (2.7m/s), 34.5° (3.3m/s) and 38° (4.0m/s). The knee flexion angles were employed to position the tibia model, and axial ankle forces were loaded to run FE simulation in ABAQUS (**Figure 1**).

As observed from the MSK-driven FE simulation, the main stress was focalised at the distal one-third region in the anterior facet of tibia (cortial layer). The peak stresses across the incremental speeds were between the magnitude of 3.3-5.1GPa in the cortial bone, and 0.2-1.8GPa in the trabeculae bone.

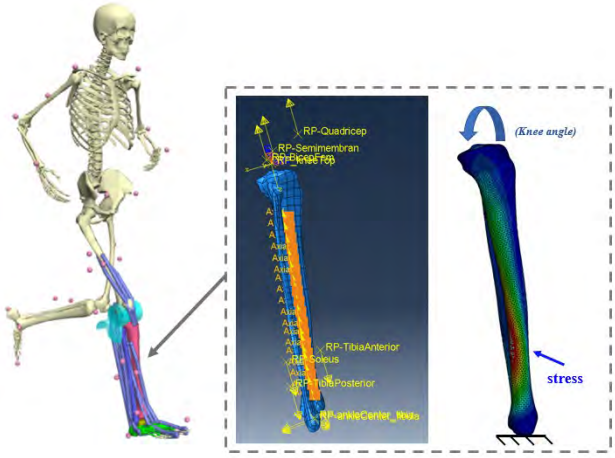

Figure 1. Outline of MSK-driven FE simulation approach.

CONCLUSIONS

The influence of walking and running speeds on the biomechanical loadings and tibia stress were reported. Findings may provide implications for the monitoring of tibia stress and loading accumulation, and prevention of tibia pain related running related injuries.

INTRODUCTION

The shoulder is one of the most complex structures in the human musculoskeletal system due to its many degrees of freedom, the numerous muscles spanning it, and its inherent instability. Shoulder movements are generated by a synergy of large superficial muscles and deeper stabilizing ones, where musculoskeletal simulations are necessary to gain an in-depth understanding of the actions of individual muscles. The effect of glenohumeral (GH) stability on the estimated actions of individual muscles, however, remains widely unknown. In this study we aim to quantify the effect of GH stability.

METHODS

To estimate individual muscle forces, we developed a Rapid Muscle Redundancy (RMR) solver, that leverages the OpenSim API to compute estimates of muscle activations and joint reaction forces (JRFs) from a musculoskeletal model through optimization, given recorded motions. The RMR solver introduces two innovations that enable it to solve for muscle activations efficiently. First, we enforce first-order dynamic feasibility of the activation values through linear constraints, and second, we formulate JRFs as linear functions of the predicted muscle activation. The latter consists in the following expression, evaluated at each time-step:

$$JRF = Ax + JRF_0$$

where x is a vector containing the activations of each muscle, JRF_0 is the force produced in the current state when all of the muscles are de-activated, and A represents the effect of maximum (1.0) activation of each muscle on the joint reaction force. This simple formulation allows for efficient inclusion of the GH stability constraint in the optimization, formulated as a directional constraint on the JRF at the glenoid (similarly to Chadwick et al. [1]). We compared the RMR solver's estimates against the computed muscle control (CMC) algorithm and EMG measurements. To analyse how the GH constraint affects muscle activations, we used RMR to estimate activations with and without inclusion of the GH constraint. The shoulder model, as well as the dataset (motions and filtered EMG signals) were obtained from a previous study [2].

RESULTS

The comparison between the RMR solver and CMC for shoulder movements resulted in virtually the same estimates of muscle activations, but in a fraction of the time: while CMC needed a computation-to-real-time ratio of over 200 to complete the analysis, the RMR solver required only 40. The effect of the GH stability constraint on muscle activations (Table 1) indicates that stability does not affect the activations of most superficial muscles, but significantly affects the activations of the rotator cuff muscles (first four rows of the table, where shaded cells represent high difference).

Muscle	Flexion+	Abduction+	Shrugging+
Teres minor	0.02	0.03	0.07
Infraspinatus	0.07	0.08	0.11
Subscapularis	0.05	0.13	0.11
Supraspinatus	0.04	0.03	0.00
Trapezius	0.01	0.00	0.01
Serratus Anterior	0.00	0.00	0.02
Deltoids	0.04	0.02	0.01
Lats dorsi	0.00	0.00	0.00
Teres major	0.03	0.05	0.12
Pectoralis major	0.03	0.00	0.02

Table 1: Maximum RMS difference between the activations of various muscles predicted by the RMR solver, with and without the inclusion of the GH constraint. Tasks considered are shoulder flexion, abduction and shrugging performed holding a 2-kg load.

DISCUSSION AND CONCLUSIONS

We introduced a RMR solver that estimated muscle forces of a shoulder model in agreement with CMC but more than 5 times faster. The RMR solver formulation shows promise for real-time or human-in-the-loop applications. Moreover, the novel way in which the JRFs are handled makes it easy and quick to consider additional constraints as we demonstrated with the GH stability constraint. Our findings show that stabilizing the GH joint can have substantial effects when estimating muscle activations of the rotator cuff muscles, while having little effect on other shoulder muscles. Our results indicate that comparing superficial muscle activations to EMG is a necessary but insufficient condition to validate estimates of shoulder muscle activation.

THE EFFECT OF TOUCHDOWN CONFIGURATION ON TOP SPRINTING SPEED: A SIMULATION STUDY

Nicos Haralabidis[1], Jennifer Hicks[1], Scott Delp[1,2]
[1] Department of Bioengineering, Stanford University, Stanford, USA.
[2] Department of Mechanical Engineering, Stanford University, Stanford, USA.
Email: nicos.haralabidis@stanford.edu

INTRODUCTION

Increasing sprint speed is a priority for coaches and athletes in many sports. Numerous biomechanical investigations have explored how the kinematics at touchdown affect top sprinting speed (e.g., [1,2]); however, the conclusions from these studies differ, potentially because observational experimental approaches make assessing cause-effect relationships difficult. We used a predictive simulation approach to determine how changes in touchdown kinematics affect top sprinting speed. We also explored how simuation results compare with previous studies and coaching principles.

METHODS

We scaled a three-dimensional musculoskeletal model [3] to an international caliber male sprinter, and used a direct collocation optimal control framework to generate two predictive simulations of maximal speed sprinting. In the first simulation ('nominal') we constrained the model's positional kinematics at touchdown to closely match (within ± 1.5°) previous experimental sprinting kinematics data. In the second predictive simulation ('widened') we widened the permissible bounds of the model's positional kinematics at touchdown (permitted to vary by ± 15°). The simulations were formulated in MATLAB (2022b; MathWorks Inc., Natick, MA, USA) using CasADi [4] and solved using IPOPT [5]. Horizontal touchdown distance (the horizontal distance between whole-body center of mass and foot at touchdown) and inter-knee touchdown distance (the horizontal distance between the knees at touchdown), important coaching parameters, were also extracted from both simulations.

RESULTS AND DISCUSSION

The simulation with widened bounds resulted in a 7.1% increase in speed compared to the nominal simulation (12.1 vs. 11.3 m/s). In addition, the widened simulation was characterized by a 6.5% increase in the horizontal distance between the whole-body center of mass and foot at touchdown (0.33 vs. 0.31 m) and a 95% increase in the inter-knee distance at touchdown (0.13 vs. 0.06 m). Interestingly, the changes we observed in the altered touchdown simulation, despite the improvement in speed, did not align with current coaching theory or prior literature. Previous studies have suggested that reducing the horizontal touchdown distance enhances speed, by reducing the horizontal braking force. Instead, increasing the horizontal touchdown distance may allow the ankle plantarflexor muscles to generate greater force through operating eccentrically and thus contribute to the sharp rising-edge of the vertical ground force, which is critical to attaining greater top speeds. This is supported by the greater peak force we observed in the gastrocnemii in the widened simulation. A reduced inter-knee touchdown distance is also advocated in sprinting, as the non-stance limb is thought to be more favourably positioned to contribute to the generation of vertical momentum and force. However, the increased inter-knee touchdown distance we observed, through the non-stance limb being positioned further behind, may have resulted in the non-stance limb being positioned in a more advantageous configuration at touchdown from which to be accelerated and contribute to vertical force production.

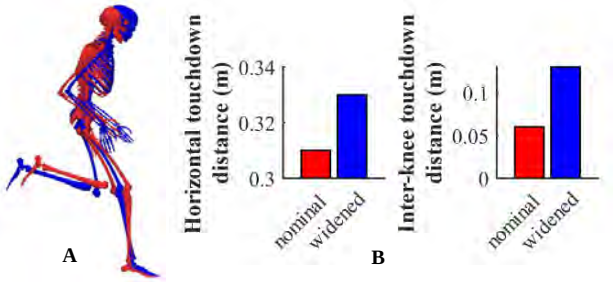

Figure 1 Touchdown configuration of the nominal (red) and widened (blue) simulations (A) and changes in coaching parameters (B).

CONCLUSIONS

Enabling changes in kinematics at touchdown led to an increase in top speed, although the changes in technique variables differed from current coaching ideologies. Future work will further explore the mechanisms responsible for the technique variable changes we observed.

INTRODUCTION

Bone can heal small defects by itself but fails to do so in case of severe bone damage. A common treatment for severe damage is grafting bone. Approximately 1.6 million bone grafts are performed in the United States per year [1]. Unfortunately, this treatment has several serious drawbacks, such as a high risk of infections or even donor site morbidities. Tissue Engineering and regenerative medicine is a promising biomedical alternative to cure severe bone damage. Scaffolds can be used to re-build the bone structure since they can support seeded cells and provide an optimal environment for cell growth [2]. The scaffold's geometry design influences flow characteristics, mass transfer rates, and wall shear stress (WSS). The WSS is an important parameter to investigate because it affects the differentiation and bioactivity of cells inside the scaffold. In this work, we investigate the influence of the scaffold geometry on the flow field, WSS and mass transport using computational fluid dynamics (CFD). The reliability of the numerical results is evaluated using the µ-particle image velocimetry (PIV) method.

METHODS

Scaffold geometries, which have a sinusoidal channel featuring different amplitudes and frequencies, are designed and meshed using SALOME®. The CFD simulations are performed using the open-source software OpenFOAM®. The evaluation of the nutrient distribution is investigated using the *scalarTransportFoam* solver. This solver is a steady-state laminar flow solver with a superimposed diffusive-advective mass transport equation. The fluid flow is described by the three-dimensional Navier-Stokes equation. For the µ-PIV validation experiments, scaffolds are printed inside a micro-channel using the Two-Photon polymerization method. A cross-linking photosensitive polymer called ethoxylated trimethylolpropane triacrylate, trimethylolpropane triacrylate (ETA:TTA) is used and polymerized using a femtosecond pulsed laser. Polystyrene fluorescent tracer particles with a diameter of 2 µm are excited at two points in time induced by a synchronized laser in the µ-PIV system to visualize the flow fields.

RESULTS

The numerical results indicate that increasing the frequency or amplitude affects the flow velocity in the sine cavity. Secondary vortexes are formed exceeding the threshold frequency of 3.5 mm^{-1} for an amplitude of 0.1 mm. The CFD simulations indicate that WSS depends on the flow rate and scaffold design and decreases by increasing frequencies. For an inlet flow rate of 5 mm/s, the WSS inside the sine cavities is below 0.1 Pa, whereas the highest WSS is at the negative peaks of the sine wave. The CFD results for the mass transport of the nutrient are unsymmetrically distributed inside the sinusoidal cavities. The concentration decreases over the length of the scaffold. The µ-PIV experiments validate the flow behaviour of the CFD results, and they reveal the formation of vortexes at the same frequencies.

CONCLUSIONS

The results confirm the potential of CFD to easily pre—evaluate and optimize geometric variations before printing the scaffolds for experimental evaluation. The numerical results show that the WSS and the mass transfer depend on the geometry and the flow rate. The sinusoidal texture decreases the WSS and is at least 75 % lower compared to the channel wall. The µ-PIV results confirmed the numerical results, but the experimental evaluation is still a challenging technique and depends on several factors as the seeding concentration of the tracer particles.

INTRODUCTION

Finite element (FE) analysis has been proven to be effective for gaining a better understanding of bone mechanics and improving implant design [1]. However, FE models are mostly developed based on a generic template which is not representative of the diverse population. To address this issue, statistical shape models have been recently used to capture anatomical variations in bones and incorporated these variations into FE analysis. The statistical shape and density modeling requires point-to-point and element correspondences between each model through manual or semi-automatic placement of landmarks on the surface and volumetric mesh morphing [2]. A previous study have looked at the variation in shape of lower limb bones in children [3]. Now, we would like to create volumetric meshes that are consistent with the shape variation of that population. Therefore, the aim of our study was to develop an algorithm capable to automatically morph a volumetric mesh from a femur template to 663 femurs from a paediatric population aged 4 to 18 years.

METHODS

A previous study [3] developed a template mesh for the femur and fitted it to 663 femurs from 333 children aged 4 to 18 years old, with heights from 96 to 192 cm [3]. We decided to convert this femur template mesh into a 4-noded tetrahedral volumetric mesh using TetGen (WIAS, Berlin, Germany). Due to the large variation in height from our dataset (148 cm ±24 [min: 96, max: 192]), each femur surface mesh was first scaled isometrically to the template surface mesh before morphing to lower down the potential deformations during the morphing step. Second, the volumetric template mesh was fitted into each scaled model using "host-mesh" fitting described in a previous study [4]. Then the morphed models in scaled sizes were linearly scaled back to their original size. Finally, the scaled-back models were fitted again into their corresponding original surface mesh to minimize the error between the shape of the morphed mesh and their original shape. Volumetric mesh quality was computed for each femur using the radius ratio [5]. The radius ratio is determined as the normalized ratio of the radius of the inscribed sphere to the radius of the circumsphere.

RESULTS AND DISCUSSION

The morphed meshes were found to be within an acceptable range of 1-3, with values closer to 1 considered as being an equilateral tetrahedron (figure 1). However, the standard deviation was a bit high for some femurs which was not related to size (figure 2). The mesh quality was maintained throughout the automatic morphing process. This study agreed to the conclusion in a previous study of automatic mesh generation in adult femurs [2].

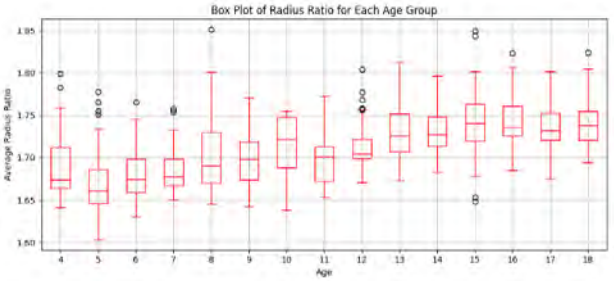

Figure 1: Average of radius ratio of morphed meshes.

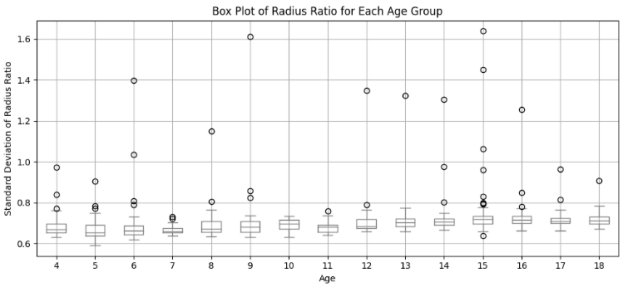

Figure 2: Standard Deviations of radius ratio of morphed meshes.

CONCLUSIONS

Based on the quality values, we can conclude that our morphed meshes are suitable for the next step of our modeling framework which is building a statistical density model and personalized FE. In the future, we will expand our work to include the tibia, fibula and pelvis of our dataset. This workflow will be used to create personalised (bone geometry and material properties) FE models for a population of children and adolescent aged from 4 to 18 years. This model will provide a better understanding of bone biomechanics for a paediatric population.

PHYSICS-BASED FEATURES IMPROVE THE GENERALIZABILITY OF A NEURAL NETWORK PREDICTING GROUND REACTION FORCES

Janelle M. Kaneda[1], Scott D. Uhlrich[1], and Scott L. Delp[1,2,3]

INTRODUCTION

While wearable and video-based technologies have enabled out-of-lab estimation of kinematics [1], additionally estimating ground reaction forces (GRFs) for kinetics would enable estimation of loading measures related to musculoskeletal injury and disease [2]. Deep learning models have predicted GRFs for specific tasks such as running and walking [3,4]. However, a task-independent model to predict GRFs would be more generally useful. Physics-based measures, like center-of-mass (COM) accelerations, are directly related to GRFs [5,6]. Using these terms as inputs to a machine learning model may improve accuracy for tasks within [6] and outside of the training set, improving generalizability. We hypothesized that including physics-based features in a deep learning model trained on walking and jumping will improve GRF predictions for a cutting task not included in the training set (i.e., unseen task).

METHODS

We used marker-based inverse kinematics and GRFs from 68 individuals (40 women, 46–80 years) with medial knee osteoarthritis walking at different foot progression angles (100 trials/subject) [7], and from 76 female soccer athletes (10–18 years) performing cutting and double- and single-legged jumping (15 trials/subject) [8]. We trained a bidirectional long short-term memory (LSTM) model [3] to predict bodyweight-normalized GRFs from 42 time series features derived from OpenSim models [9–11]: joint angles, COM position and acceleration × subject mass, and foot velocity. We split our data by subject 80:10:10 across the training, development, and test sets, resulting in 5,949 training and 805 test examples. The development set was used for hyperparameter tuning, and the test set was held out for model evaluation. The training set had walking and jumping, and development and test sets had all tasks. We calculated root mean square error (RMSE) and Pearson's *r* for test set predictions from stance limbs.

RESULTS AND DISCUSSION

For the unseen cutting task, adding physics-based features reduced RMSE for vertical GRF from 1.38 to 0.69 body weights (BW, Figure 1B). The inclusion of physics-based features did not substantially change performance for antero-posterior or medio-lateral GRFs during cutting (Figure 1B), nor for vertical GRFs for tasks in the training set (Figure 1A).

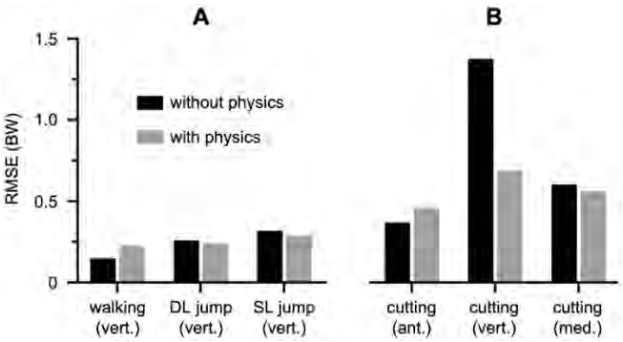

Figure 1 GRF RMSE in body weights (BW) for tasks within (A) and outside of (B) the training set, with (grey) and without (black) physics-based features. Vertical GRF is shown for training set tasks (A), and antero-posterior and medio-lateral components are also shown for cutting (B). DL: double-legged; SL: single-legged.

Adding physics-based features resulted in the largest accuracy improvement for vertical GRF in the unseen cutting task, while accuracy did not substantially change for the other GRF directions. This could be improved by adding tasks with more medio-lateral acceleration to the training set. Additionally, a generalized model trained on multiple tasks may reduce accuracy for a single task. An LSTM model trained solely on walking achieved *r* values of 0.98, 0.93, and 0.88 for antero-posterior, vertical, and medio-lateral GRF [4], while our comparable values are 0.91, 0.86, and 0.94.

CONCLUSIONS

Including whole-body COM features as inputs to a neural network predicting GRFs reduced vertical GRF error for the unseen cutting task. Physics-based features may make GRF prediction models more generalizable, but a more diverse training set is needed to train a useful generalized model.

INTRODUCTION

A study conducted on 101 patients with Parkinson's found that 48% of patients had experienced a fall, and 24% of them had fallen more than once [1]. The number of Parkinson's disease patients continues to grow and is predicted to reach 6.17 million in 2030 [2]. Therefore, early and automatic detection of the symptoms of this disease is important to avoid the risk of falling and death. One way of early detection is to use the IMU sensor which is often found on smartphones. With the current developments in computer and machine learning science, gait abnormalities can be classified automatically. Thus, the purpose of this research is to develop a method which can detect gait abnormalities in general.

METHODS

In this study, there were 35 subjects who participated in which there were 25 healthy subjects and 10 subjects with movement disorders. Healthy subjects are subjects who have never fractured a bone and have no nervous disorders. Subjects with impaired gait were patients at the Department of Physical Medicine and Rehabilitation Hasan Sadikin Hospital, Bandung. The subject's walking motion data was taken using the IMU MPU9250 which has six degrees of freedom. This IMU is placed on the thigh, lower leg and sole of the foot as shown in Figure 1.

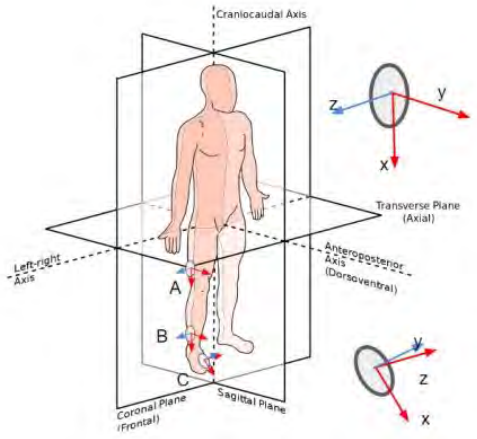

Figure 1 Location of placement of IMU sensors

The sensor output data is then filtered with a low-pass filter with a cut-off frequency of 5 Hz. Alignment of data is done to classify one cycle of walking motion. Each data cycle is calculated the value of the lower control limit (LCL), the average and the upper control limit (UCL). Anomaly calculations are performed using two methods: (1) the frequency of the signal crossing the UCL/LCL boundary, and (2) the sum of each signal difference that crosses the UCL/LCL boundary against that boundary. The determination of LCL and UCL is carried out by decision trees and random forests. Accuracy, precision, and recall values are calculated for each method.

RESULTS AND DISCUSSION

The performance of the anomaly detection test using a decision tree (DT) and random forest (RF) is shown in Table 1.

Table 1: Performance of decision tree and random forest in detecting gait abnormality.

Sensor	Accuracy (%)		Precision (%)		Recall (%)	
	DT	RF	DT	RF	DT	RF
1st Method						
A	79.21	84.03	79.27	84.86	84.06	86.26
B	81.92	94.03	81.70	85.63	86.26	85.16
C	90.66	93.97	94.15	96.02	88.46	92.85
ABC	93.07	96.38	91.62	98.29	96.15	95.05
2nd Method						
A	83.43	85.24	84.32	85.12	85.71	88.46
B	83.43	86.74	87.13	90.11	81.86	85.16
C	90.96	92.77	90.42	94.88	93.40	91.75
ABC	91.56	95.48	90.95	97.71	93.95	93.95

CONCLUSIONS

The best method for detecting walking motion anomalies is the random forest method. In addition, the sensor placement position that produces optimal detection is in the foot (metatarsal).

USING IMU TO PREDICT THE EFFECT OF PROSTHETIC ALLIGMENT ON KNEE MOMENTS

INTRODUCTION

The gait of transtibial amputees is dependent on prosthetic alignment. Inappropriate position of the prosthetic foot relative to the socket could lead to osteoarthritis or low back pain [1]. However, the interpretation of optimal prosthetic alignment is subjective [2]. The use of inertial measurement unit (IMU) in conjunction with machine learning (ML) allows the measurement outside the gait laboratory and could assist the prosthetist in finding the optimal prosthetic alignment. The aim of this study is to use IMU measurements and ML to predict changes in knee moment caused by altered prosthetic alignment.

METHODS

Motion capture and IMU data of 13 unilateral transtibial amputees and 13 controls were collected. The amputees walked with optimized prosthetic alignment defined by a prosthetist and with a standardized exceeding plantarflexion (PF) of prosthetic foot. 3D knee moments were calculated using inverse dynamics. A Long Short-Term Memory neural network (NN) was trained using the control (NN1) and amputee (NN2) data. The knee moments of both sides for a control (only NN1) and of the prosthetic side for the optimized and PF conditions of a patient (NN1 and NN2) were predicted using unseen IMU data as input. Normalized Root Mean Square Error (nRMSE) by range of the knee moment was calculated between inverse dynamics and prediction.

RESULTS AND DISCUSSION

We were able to predict knee abduction moment (KAM) for the control. NN1 could predict the reduced KAM of the patient in comparison to the control (Figure 1). Furthermore, the prediction of all knee moment components for the patient was improved using NN2 in comparison to NN1, especially for the knee rotation moment, where the nRMSE was reduced from 44.76% to 17.57% (Table 1). PF condition increased the first peak of KAM, which was predicted in both NNs (Figure 1).

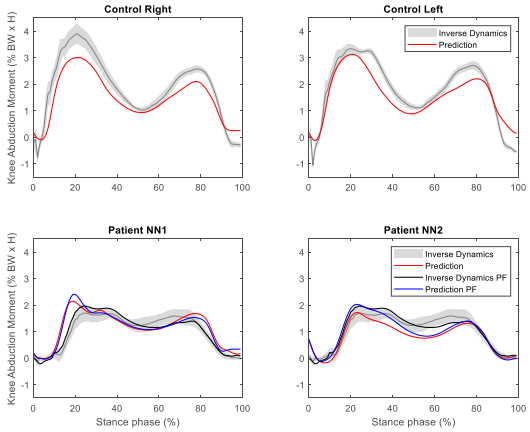

Figure 1 Knee abduction moment for the control and patient.

CONCLUSIONS

Even using control data as training, the differences between control and amputee patient and prosthetic alignments were predicted. Using patient data as training improved the predictions. However, the inter-individual variability of patients and a relatively small number of individuals may affect the NN training. The results indicate that the IMU can be used to predict altered knee moments in transtibial amputees as a function of improper prosthetic alignments. Future work will focus on introducing a classification model to identify prosthetic gait with different perturbations regarding the alignment.

ACKNOWLEDGEMENTS

The work was funded by the Bundesministerium für Wirtschaft und Energie (Germany) (“VarioFit” no. 16KN089720).

The approach chosen for data dimensionality reduction affects the results of running technique clustering

Introduction

Clustering to find patterns in high dimensional human biomechanics datasets, such as those collected by modern motion capture systems, is gaining popularity. For example, it has been shown that runners clustered based on their technique react differently to different footwear [1] and rehabilitation interventions [2]. Dimensionality reduction (DR) is a critical step prior to clustering to prevent data from becoming sparse as the number of dimensions increases [4]. It is common practice in general machine learning research to test several DR techniques to choose the most optimal solution for a specific problem [4]. Researchers in human biomechanics on the other hand seem to have defaulted to using Principal Component Analysis (PCA) to perform DR [2, 3], which may not always be the optimal choice, especially if nonlinear relationships are present in the data. Furthermore, it is unclear how the DR approach affects the clustering output and, therefore, whether studies are comparable.

We used three different DR techniques combined with hierarchical clustering to group runners based on their technique and compared the resulting cluster partitions.

Methods

Ninety-eight long-distance runners (48 females, 50 males; age: 34±10 years; height: 1.73±0.09 m; body mass: 65.74±9.9 kg) completed a four-minute run at 12 km/h on a treadmill at 1% gradient. Full body kinematics were collected using motion capture (Oqus, Qualysis, Gothenberg, Sweden). Mean trunk-to-pelvis, hip, knee and ankle sagittal plane angles, centre of mass vertical displacement normalised by leg length (time-continuous variables, 1D), stride frequency and duty factor (discrete variables, 0D) were calculated to characterise running technique. The three DR techniques tested were:

Fourier + PCA. 1D variables were modelled as Fourier series with the minimum number of harmonics required to reconstruct angular and translational signals with an error <2° and <5 mm, respectively. The Fourier coefficients and 0D variables were then concatenated and PCA was applied.

Direct PCA. 1D and 0D variables were concatenated and PCA was applied.

Autoencoder. 1D and 0D variables were concatenated and a fully connected neural network autoencoder was trained and tested using all the individual curves from every participant (70/30, train/test). Hyperparameter optimisation (number of hidden layers and units per layer) was performed using a grid search and a 5-fold cross validation scheme on the training data. The encoder part of the network was then used for DR.

For PCA methods, the number of components explaining 95% of the variance in the data were kept. For the autoencoder, the number of latent dimensions (encoder output) was selected experimentally based on reconstruction error.

Hierarchical agglomerative clustering (similarity metric: Euclidean distance, linkage criteria: Ward) was then implemented. Our objective was to find clusters as separable as possible, so we calculated Silhouette scores for different numbers of clusters and chose the largest Silhouette score. The optimal number of clusters was two regardless of the DR technique used. The Adjusted Mutual Information (AMI [0-1] random-perfect agreement) score was calculated between the clustering partitions resulting from each DR technique.

Results

The Silhouette scores (Table 1) were low regardless of the DR technique, indicating low separability of our dataset. The autoencoder resulted in marginally more separable clusters. There were differences in cluster assignments when comparing direct PCA to the autoencoder and especially when comparing Fourier + PCA to the autoencoder.

Table 1: Silhouette and AMI scores compared to autoencoder.

DR	Silhouette score	AMI score
Autoencoder	0.19	
Direct PCA	0.16	0.42
Fourier + PCA	0.15	0.03

Discussion

Our analysis indicates that clustering results obtained with different DR techniques may not be comparable as DR methods can capture different aspects of the data. The autoencoder seemed to result in slightly better separability of the data in our dataset. However, it requires more development and computing resources compared with direct PCA for marginal improvements in our case. Researchers using clustering algorithms are advised to select their DR techniques carefully according to their objective when conducting a clustering analysis.

INTRODUCTION

Data collection and sharing in biomechanics is often limited by lack of access to participants, time, ethical and financial constraints. In a previous study, we developed a workflow to augment existing datasets by synthetic trials using generative adversarial networks (GANs) [1] and an app [2] to generate synthetic data was shared with the community. A limitation of that study was the impossibility of controlling the generation of synthetic data, for example based on subject anthrophometrics. Thus, this study aims to extend our initial approach and generate mocap data, marker trajectories and ground reaction forces (GRFs) of synthetic walking trials based on subject leg length and mass.

METHODS

A small gait dataset (real dataset) collected from 8 healthy subjects (mass: 68.4±11.5 kg, leg length: 91.5±7.5 cm, height: 1.74±0.13 m) was divided into two classes based on subject mass and leg length, with conditions set at 60 kg and 91 cm (corresponding to a height of around 1.71 m), respectively. The classes were labeled as "low mass" and "high mass" for subject mass, and "short" and "tall" for subject leg length. The same optimized GAN architecture as in [1] was used to train the data, with separate networks trained for subject mass (M-GAN) and subject leg length (LL-GAN). During training, a single number (0 or 1) was used to inform the network of the subject's condition (mass or leg length). For example, a "short" subject's data was labelled with 0, while a "tall" subject's data was labelled with 1. After proper training, synthetic gait data was generated using the conditions specified by M-GAN and LL-GAN.

RESULTS AND DISCUSSION

The two models were able to generate mocap data based on their corresponding conditions (50 trials for each condition). Our M-GAN generated two subject mass ranges, with "low mass" subjects weighing 55.4±3 kg and "high mass" subjects weighing 69.9±3 kg (Figure 1.a). Additionaly, LL-GAN generated "short" subjects having 84.6±4.6 cm leg lengths, and "tall" subjects having 96.5±3.3 leg lengths (Figure 1.b).

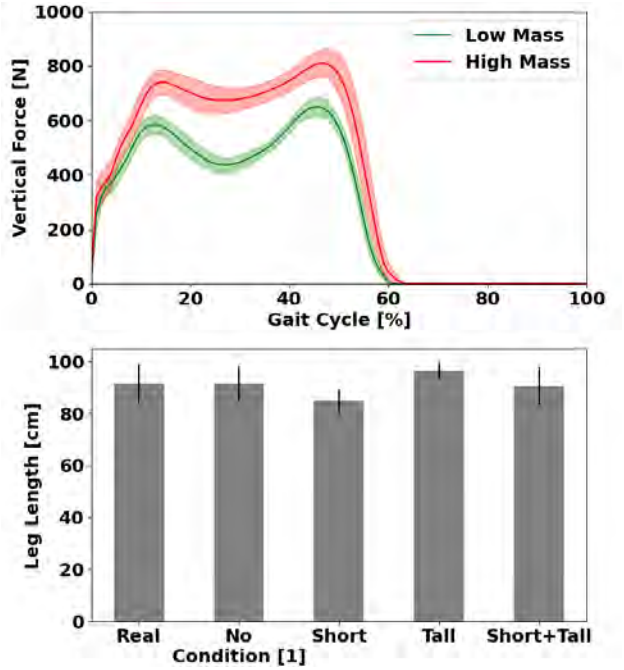

Figure 1. a) Distribution of generated vertical forces with mass conditions (M-GAN), b) Comparison of generated subject leg lengths (LL-GAN) to the real subject leg lengths.

CONCLUSIONS

With the intention of extending our previous generative approach [1], we developed two separate models to generate synthetic mocap data based on two classes of subject mass and height. M-GAN model could generate data based on subject mass, while LL-GAN achieved data generation by conditioning on leg lengths. Both models will be deployed into our web app [2] for conditional mocap data generation. A limitation of this approach is that the data generation conditioning had to be done separately for only two conditions. The main reason behind our adopted strategy was that the real dataset does not contain a wide range of subject anthrophometrics. Thus, future work will adress this limitation by incorporating publicly available datasets into our framework to generate synthetic mocap data for a wide range of subject anthropohometrics using walking speed as an additional condition.

INTRODUCTION

Person re-identification (re-ID) involves matching biometrics (i.e., biological cues to identity) over time to re-establish identity. There is great interest in using walking gait for person re-ID in security applications (e.g., threat detection) as it can be measured discreetly in dynamic environments. Using machine learning (ML), studies have shown that features encoded in one set of ground reaction force (GRF) data are effective for distinguishing between another set of previously unseen GRF data for re-ID, provided that the latter is acquired from the same group of individuals under the same experimental conditions [1]. This study aimed to determine the extent to which features encoded in GRF data from one set of IDs can be used to distinguish between GRF data from another set of IDs with different demographics under different experimental conditions.

METHODS

The aim was achieved by training and testing a ML model on separate force platform datasets. Four public datasets containing GRFs and centres of pressure from healthy individuals were utilised: ForceID A (number of IDs (N)=193), a subset of GaitRec (GaitRec (shod) (N=208)), Gutenberg (N=350), and AIST (N=300) [2-5]. Each dataset was constrained to contain 185 IDs × 10 samples to control for the effects of dataset size and distribution on model performance. Scenario I involved training (N=148) and validating (N=37) a fully-connected neural network model on one dataset and then testing it on another (N=185). Scenario II was the same as Scenario I except a second dataset was included for training (N=296) and validation (N=74) to see if this changed test performance. Five-fold cross validation (5-CV) was conducted on training and validation sets, with the test set constant on each fold. All possible training and validation vs. test combinations of the four datasets were implemented. Predictions were generated based on a challenging evaluation setting where there was only one random prior sample per ID to match with a given query sample. Mean rank-1 re-ID accuracy over 5-CV was reported.

RESULTS AND DISCUSSION

In scenario I, accuracy was above 90% when a barefoot (B), preferred speed (PS) dataset (AIST or Gutenberg) was used for testing, regardless of the dataset used for training and validation (Figure 1). Accuracy was 79-88% when a shod (S), multi-speed (MS) dataset (ForceID A or Gaitrec (shod)) was used for testing and the remaining S, MS dataset was used for training and validation. Finally, accuracy was 54-57% when a S, MS dataset was used for testing and a B, PS dataset was used for training and validation. In scenario II, accuracy increased by 26-31% when the test set was a S, MS dataset and a S, MS was included with a B, PF dataset for training and validation (Figure 1 – right). Findings suggest that S, MS data are more challenging and more generally applicable for person re-ID than B, PS data. Perhaps models trained on S, MS data must learn features that are robust to increased gait variability due to complex interactions between walking speed and footwear. This could explain why models trained on B, PS data were relatively ineffective at distinguishing between S, MS data for re-ID.

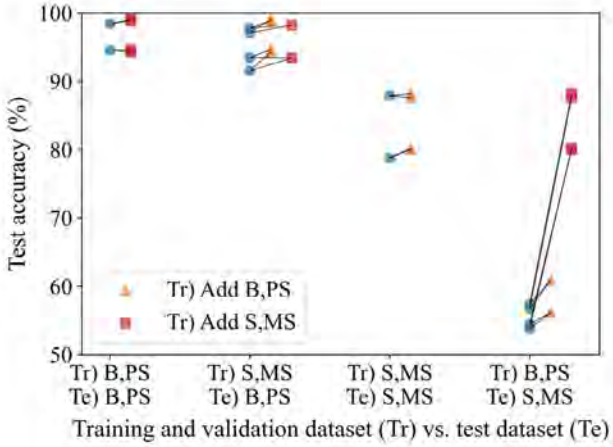

Figure 1 Test accuracy according to dataset configuration in terms of footwear and walking speed characteristics. B=barefoot, S=shod, PS=preferred speed, MS=multi-speed.

CONCLUSIONS

A simple ML model can encode features of GRF data from one set of IDs and then use these to distinguish between GRF data from another set of IDs with different demographics under different experimental conditions with 80+% accuracy.

INTRODUCTION

Vertical ground reaction force (vGRF) is important information in gait analysis and is typically measured with a force plate. Thus, the gait analysis is usually conducted in specific indoor environments such as in a laboratory. To overcome this limitation, previous studies have estimated vGRFs using one inertial measurement unit (IMU) of the left shank [1] and three IMU of the left thigh, shank, and foot [2]. In this study, we construct a deep learning model and estimate vGRFs during walking from three IMUs, one each on the left wrist and both heels to realize daily gait analysis with a smartwatch and smart shoes and compare the accuracy of estimation with other sensor positions employed in the previous studies [1, 2].

MATERIALS AND METHODS

A motion analysis software [3] was used to generate IMU data from the AIST Gait Database 2019 [4], which contains motion and vGRF data. The vGRF data were normalized by the body weight of each subject and used to extract the stance phase to construct a dataset of IMU data and normalized vGRF data while the foot was in contact with the floor. The dataset was then divided into those for the left or right foot to ensure better estimation accuracy.

After removing the abnormal data by visual inspection, the dataset of the left stance phase was 2999 trials of 350 subjects, while the dataset of the right stance phase was 3003 trials in total. Five subjects for the left (493 trials) and for the right stance phase (495 trials) randomly sampled from each age group, 20s to 70s in 10 years increment, were used to test the estimation accuracy.

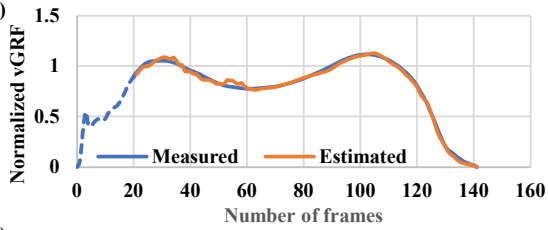
Our model comprises two long short-term memory layers with 256 units and one dense layer with one unit. It considers three-axis acceleration and angular velocity inputs from the previous 19 frames and the current frame (i.e., a total of 0.1 s) and estimates the current vGRF. To evaluate the influence of the IMU position on the estimation accuracy, we trained the models for the left and right vGRFs separately with three different IMU position sets as follows.

- IMUs on the left wrist and both heels (our proposal)
- An IMU on the left shank (same as [1])
- IMUs on the left thigh, shank, and foot (same as [2])

RESULTS AND DISCUSSION

Figure 1 (a) shows the measured and estimated vGRFs of one trial when the IMUs were attached to the left wrist and both heels. It is clear from this subfigure that our proposed model can estimate the overall waveform of the vGRFs except for the first 19 frames shown in the dotted line. Figure 1 (b) summarizes the accuracy of estimation for different IMU position sets. We compared the accuracy using normalized root mean squared errors (NRMSEs) for three cases: (1) the overall waveform, (2) the amplitude of the first peak, and (3) the time of the first peak. As can be seen from this subfigure that our proposed model was comparable to the most accurate estimation result of the overall waveform achieved by three IMUs on the left thigh, shank, and foot. In terms of the peak amplitude and peak time, our proposed model was the most accurate. It is necessary to estimate the stance phase only from the IMU data when this system is in actual use. Our proposed model is advantageous in this respect since having IMUs of both heels makes phase estimation easy.

(a)



(b)

IMU position	Waveform	Peak amplitude	Peak time
Left wrist and both heels	6.70 %	7.12 %	4.38 %
Left shank	8.02 %	8.68 %	4.81 %
Left thigh, shank and foot	6.26 %	7.32 %	4.41 %

Figure 1 (a) Measured and estimated vGRFs of one trial. (b) NMRSEs for different IMU position sets

CONCLUSIONS

We estimated vGRF during walking with only three IMUs. While the model should be verified with real data, it could be used in daily life.

INVESTIGATING THE EFFECTS OF TRANSFEMORAL AMPUTEE ANATOMY ON STRESS AND STRAIN DISTRIBUTION IN OSSEOINTEGRATED IMPLANTS USING A 3D FE MODEL

Tiereny McGuire[1] and Anthony M J Bull[1]
[1] Bioengineering, Imperial College London, London, UK.
Email: t.mcguire19@imperial.ac.uk

INTRODUCTION

Osseointegrated prostheses (OIP) for transfemoral amputees represent a solution to the array of complications caused by sockets. Bypassing the soft-tissues, loads are transferred directly through the musculoskeletal (MSK) system. Mechanical complications such as bone fracture, loosening, and implant failure represent a barrier to OIP success [1]; it is important to identify how the human anatomy affects the biomechanical profile of these OIPs so that clinicians can feel confident in their recommendations. The aim of the study is to assess the effects of gender and amputation length on stress/strain distribution across the bone-implant interface through utilisation of a 3D finite element (FE) model. The overarching goal is to improve patient outcomes by producing hypotheses on biomechanical failure to inform surgical intervention and implant design.

METHODS

Four healthy adult CT scans (2 female) were used to generate 12 femur models of different lengths. Each bone was amputated at 30, 40 and 50% of the original lengths and the surgical procedure of implantation simulated to create bone-implant assemblies. The assemblies were meshed (minimum element size of 3mm) and material properties applied (using grey scale values for bone) forming 3D FE models. The femurs were subdivided into seven Gruen Zones (GZ) and fixed proximally. Representative loads [2] were applied to the distal face of the device in a static structural analysis with assumed full osseointegration contact. Data were cleaned and statistical analyses ($p < 0.05$) performed using non-parametric tests to understand the effects of anatomy on stress and strain distribution across the system.

RESULTS AND DISCUSSION

Median stresses and strains in the system were found to be similar amongst the different bone lengths (Table 1). More detailed bone analysis, however, showed there were significantly different strains experienced in GZ3&5 ($p = 0.022$ and $p = 0.029$) and stresses in GZ4 ($p = 0.018$) (Figure 1). As femur length decreases, the implant is located higher up the medullary canal, closer to the increased proportion of trabecular bone that is less dense and more fragile than cortical bone. The results also showed a statistical difference ($p = 0.004$) between genders, with female bones experiencing higher strains (F:0.0068 and M:0.0002).

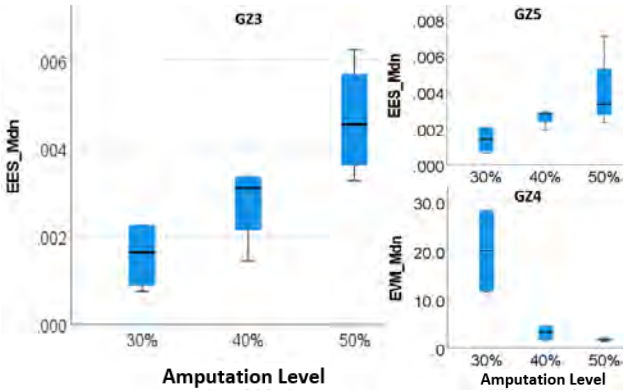

Figure 1 Volume of stress and strain due to level of amputation.

CONCLUSIONS

This model facilitates quantification of stress and strain distribution, allowing predictions of mechanical complications associated with anatomical differences. Results indicate the importance of prescribed implant geometric specification in directing load transmission through the MSK system to optimise this stress/strain distribution and improve the probability of implant success.

INTRODUCTION

Time since amputation (TSAmp) is one of the factors that affect the walking ability and social reintegration among lower limb amputees. For example, it was found that gait outcome and mobility score were improved with longer TSAmp [1,2]. However, little is known about how the TSAmp affects gait mechanics in lower limb amputees. Therefore, the aim of this study was to investigate the relationship between TSAmp and the asymmetry of spatiotemporal parameters in unilateral transfemoral amputees over a wide range of walking speeds.

METHODS

We recruited 26 individuals with transfemoral amputation (7 females and 19 males, K-3 or K-4 levels, average TSAmp 12 ± 8.7 years). All participants were asked to walk on an instrumented treadmill (FTMH-1244WA, Tec Gihan, Kyoto, Japan) at 8 speeds from 2.0 to 5.5 km/h in 0.5 km/h increments. We determined spatiotemporal gait parameters, such as stance phase, swing phase, double support time, cadence, step time, and step length were calculated for their intact and prosthetic limb, respectively. The asymmetry ratio was calculated by prosthetic value/intact value [3]. If the asymmetry ratio equals 1, it indicates perfect symmetry. If the asymmetry ratio is greater than 1, it means a smaller value on the intact limb compared to the prosthetic limb and if it is less than 1, it means a greater value on the intact limb compared to the prosthetic limb. After that, Pearson correlation or Spearman's rank correlation was conducted at each speed to determine if there were any linear correlations of the spatiotemporal asymmetry ratio in response to TSAmp. Statical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

As shown in Figure 1, there were no significant correlations between the TSAmp and asymmetry of spatiotemporal gait parameters (except for double support time at 5.0 km/h). Current results agree with a previous study, which demonstrated that TSAmp had little impact on mobility score [2]. These results suggest that the association between TSAmp and asymmetry of spatiotemporal gait parameters would be weak. In other words, while gait outcome and self-reported mobility score showed improvement with longer TSAmp [1,2], TSAmp may not be necessarily correlated with the asymmetry of gait parameters in unilateral transfemoral amputees.

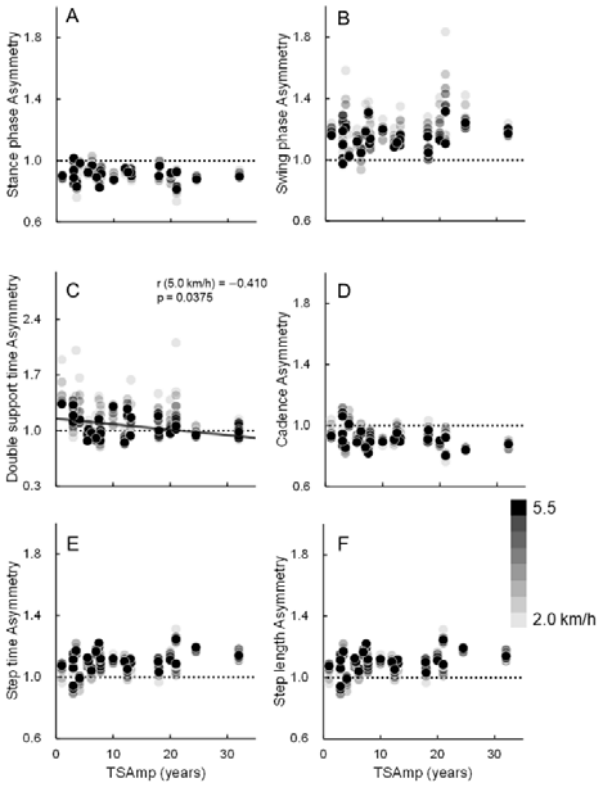

Figure 1 Scatter plots of time since amputation (TSAmp), and asymmetry of spatiotemporal gait parameters at eight speeds (A: stance phase, B: swing phase, C: double support time, D: cadence, E: step time, F: step length).

CONCLUSIONS

The results of the present study suggest that the association between TSAmp and the asymmetry of spatiotemporal gait parameters may be weak.

METABOLIC COST AND MUSCULOSKELETAL METABOLIC QUANTIFICATION OF WALKING WITH AN ABOVE KNEE PROSTHESIS SIMULATOR

INTRODUCTION

Above-knee amputees show an increase in metabolic consumption of nearly 50% compared to asymptomatic subjects [1]. Walking with a prosthesis alters joint moments and powers and there is an increase in work at the residual hip and at the contralateral limb. COM work has also been quantified using the Individual Limb Method, again showing a severe decrease in propulsion of the prosthetic limb and significant compensation on the contralateral limb [2]. However, this increase in mechanical work remains far more lower than the increase in metabolic cost. In order to take into account the action of the bi-articular muscles, the cost associated with isometric muscle work and the elastic part of the muscle work [3], the objective of this study is to quantify the energy cost of walking using a simple 2D musculoskeletal model including the 8 main muscles of the lower limb and to compare these results with the metabolic consumption estimated from gas exchanges.

METHODS

Six asymptomatic subjects (AS) walked first without a prosthesis and then equipped with a knee prosthesis associated with an energy restitution foot (Above Knee prosthesis Simulator: AKS). Kinematics, kinetics, and gas exchanges were collected. A musculoskeletal model composed of 8 muscles per leg was used to quantify the metabolic cost of each muscle with the muscle metabolic model of Minetti et al [4].

RESULTS AND DISCUSSION

The measured metabolic cost is doubled between walking without versus with a simulator (3.6 (0.4) J.kg^{-1}.m^{-1} vs. 7.6 (1.1) J.kg^{-1}.m^{-1}). The model, consistent with the results of Koelewijn et al [3], shows an asymmetry of hip muscle recruitment between the two legs, with an overall increase in muscle effort during simulated amputation (Table 1).

Despite greater efforts at the ankle than at the hip, the metabolic cost is about 40% of the total cost for these two joints in healthy subjects. When subjects are fitted with the prosthesis simulator, native ankle and knee are replaced by prosthetic joints and therefore do not induce any metabolic cost anymore. The increased metabolic costs of the hip muscles on the prosthetic side and of the muscles of the contralateral limb do not compensate for this reduction. (Table 1).

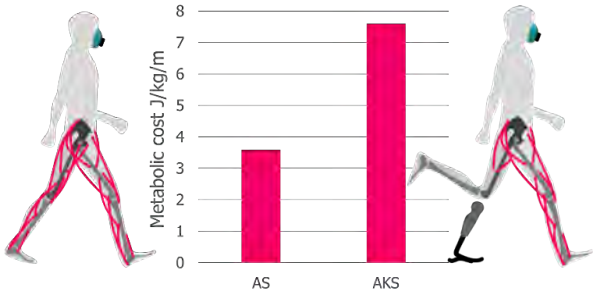

Figure 1 Metabolic cost measured for asymptomatic (AS) walking and with the above knee prosthesis simulator (AKS).

CONCLUSIONS

The current model does show an increase in muscle work related to the use of the femoral prosthesis, but this very simple model (2D, 8 muscles) does not explain the additional metabolic cost observed in amputees. Two ways of improving the model could be to integrate the muscles of the abdominal and lumbar spine and to take into account the frontal plane.

INTRODUCTION

52% of above knee amputees are affected at least once by low back pain, but the influent parameters are far to be fully understood. In the same time, above knee amputation can result in hip flexion contracture (HFC) characterized by a persistant hip flexion. HFC therefore limits the extension capacity and decreases the hip range of motion (ROM). The recommandation of prosthesis fitting is to align the socket with 5° of flexion in the absence of HFC and to the value of the measured HFC otherwise [1]. Previous studies have found pelvic compensations during gait as consequence of HFC in different populations such as patients with neurological disease or osteoarthritis [2]. The main objective of the study is to quantify sagittal pelvic and spinal ROM of above knee amputees with and without HFC during gait. Secondary objectives concern frontal and transverse plane and general gait parameters.

METHODS

An observational study was conducted, including above knee amputees, with healthy contralateral limb, walking with a prosthesis since at least 1 month without walking aids. Hip ROM, socket flexion and HFC were measured with a goniometer. Gait analysis was performed using Vicon® with 27 reflective markers. Data were analysed with Excel® and Matlab® softwares.

RESULTS AND DISCUSSION

12 patients were included and classified in two groups: with HFC (7 persons), and without HFC (5 persons). Differences were observed between groups with and without HFC (Figure 1). A t-test highlighted significant differences in the sagittal plane at pelvis and thoracic level during gait (Table 1). Regarding secondary judgement criteria, patients with HFC had a significantly lower stance phase time (p = 0.036), and a higher swing phase time than patients without HFC (p = 0.036), a decrease in the sagittal hip ROM on the amputated side (p = 0.001) as well as a significant increase in pelvic ROM in the transverse plane (p = 0.011). A decrease of the amputated limb hip ROM seems to be correlated with an increase of sagittal pelvis and thoracic ROM (respectively r = -0.525, p = 0.04; r = -0.578, p = 0.024). These results suggest that further studies should be focused on parameters that can be modified to increase the hip ROM and decrease spinopelvic ROM during gait. Other studies are needed to understand the link between spinopelvic conditions of above-knees amputees during gait and complications such as low back pain.

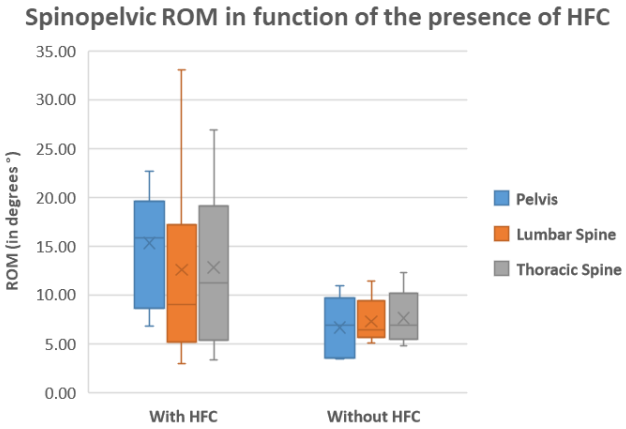

Figure 1: ROM of spinopelvic level in transfemoral amputees with and without HFC.

CONCLUSIONS

Spinopelvic ROM seem to be more important at the pelvic and thoracic spine level for above knee amputees with HFC and correlated with the hip ROM on the amputated side during gait. A larger number of patients is needed to confirm our initial finding.

Bilateral asymmetry of ground reaction forces during running in unilateral transfemoral amputees

Mai Watanabe[1], Hiroaki Hobara[2]
[1]Graduate School of Advanced Engineering, Tokyo University of Science
[2]Faculty of Advanced Engineering, Tokyo University of Science
E-mail: 8219124@ed.tus.ac.jp

INTRODUCTION

The development of running-specific prostheses (RSP) contributed to the sports and exercise opportunity for unilateral transfemoral amputees (UTFAs). However, due to the morphological and functional asymmetric feature of the running biomechanics in UTFAs, running-related injuries frequently occur in the intact limb of UTFAs [1]. Previous studies investigated the kinetic features, such as peak value and the initial slope of the ground reaction forces (GRFs), and compared the feature between intact and prosthetic limbs [1,2]. However, little is known about how the bilateral differences in the GRFs exist during the entire stance phase. Therefore, the purpose of this study was to clarify the differences in GRFs between intact and prosthetic limbs in UTFAs at various running speeds during the entire stance phase.

METHODS

Ten runners with unilateral transfemoral amputation (7 males and 3 females) participated in this study. Each participant performed running trials on an instrumented split-belt treadmill at incremental speeds of 30, 40, 50, 60, 70, and 80% of their maximum running speeds. GRFs were measured from both prosthetic and intact limbs over 16 consecutive steps at each running speed. Then, Statistical Parametric Mapping (SPM) was applied to the acquired time series of GRFs to quantitatively evaluate the differences in ground reaction forces between both limbs.

RESULTS AND DISCUSSION

The anteroposterior and vertical GRF of the intact limb was significantly greater than those of the prosthetic limb in the early stance phase in a range of running speeds (Fig. 1). These results were consistent with a previous study which showed that the intact limb had a significantly greater anteroposterior and vertical first peak during sprinting in UTFAs [2]. A potential explanation of the between limb differences in the early and midstance GRF may be the foot strike pattern, which would be caused by the different foot shapes and leg lengths between limbs [3]. On the other hand, in the late stance phase, the prosthetic limb showed significantly larger vertical GRF than the intact limb. One reason may be suggested that the prosthetic limb does not have active plantar flexion of the ankle joint.

CONCLUSIONS

This study revealed that differences in GRF between the prosthetic and intact limbs in UTFA were distributed throughout the stance phase. These differences may be related to leg length, foot shape, mechanical properties, and functional anatomy of ankle joint motion.

ACKNOWLEDGEMENTS

We thank all the athletes who participated in this study.

THE EFFECT OF A 6-WEEK INTRINSIC FOOT MUSCLE TRAINING INTERVENTION ON STATIC AND DYNAMIC BALANCE IN TEAM SPORTS PLAYERS

INTRODUCTION

The intrinsic foot muscles (IFM) support the foot arches and are proposed to enhance plantar proprioception and thus aid dynamic balance [1]. Strengthening the IFM using the short foot exercise (SFE) technique has been shown to be more effective in enhancing dynamic balance than foot/ lower leg exercises that also activate the extrinsic foot muscles [2]. Despite this, team sports players currently lack training aimed at strengthening the IFM. Moreover, previous foot strengthening research has mostly assessed barefoot balance, but sports players often wear athletic footwear during training practice which diminishes stimulation of the plantar mechanoreceptors. The effect of IFM training to improve shod balance is currently unknown. Therefore, the aim of this study was to compare the effect of footwear in a 6-week IFM training programme on static and dynamic balance ability in team sports players.

METHODS

Twenty-six team sports players were randomly assigned to an intervention group (n=13) or a control group (n=13). All participants completed a familiarisation, a pre and post-test sessions. Participants in the intervention group completed a 6-week IFM training intervention between the pre and post-testing sessions, which involved 100 repetitions of the SFE on each foot, every day [2]. During pre and post-tests, static balance was determined using a standard 30 second single-leg stance test [3] while ground reaction forces (AMTI, BP400600) were recorded. The standard deviation of the medial lateral (ML) centre of pressure velocity was calculated. Dynamic balance was assessed using an 8-direction star excursion balance test (SEBT) and a single leg, 10-second wobble board task. Reach distances from the SEBT were averaged across directions and normalised to the participants' leg lengths. ML stability index was computed from the wobble board data [4]. The mean of three trials per test were calculated on the dominant leg in both barefoot and a standardised athletic shoe for control and intervention groups respectively. Pre-test results were subtracted from post-test results and compared statistically using a 2-way mixed ANOVA ($p<0.05$).

RESULTS AND DISCUSSION

The 2-way mixed ANOVA revealed no significant main effects of group or shod condition in the static and dynamic balance tasks (Table 1). Individual differences from the single-leg wobble board task in the intervention group revealed the 6 participants with the highest ML stability index score (>4.0) at pre-test whilst barefoot had improved balance at post-test (≥1.0). No trends were observed in the shod condition in the intervention group or either footwear condition in the control group. This implies that the wobble board task could detect barefoot balance improvement after SFE training in team sports players with worse balance. In the single-leg static balance task, no such individual improvements were observed. This balance test may have not been challenging enough to reveal balance ability differences in this sports population. The SEBT revealed similar results, with no observable improvements in both groups, regardless of shod condition. SEBT performance varies due to sport, playing ability experience and so this could have had a factor in this current multi-sport study [5].

Table 1. The difference in the pre and post-test results for the balance test across groups and shod condition. Data is presented as mean (S.D.); a positive value represents an improvement in the SD ML velocity of and SEBT reach distance. A negative value represents an improvement in the stability index

	Barefoot		Shod	
	Control	Intervention	Control	Intervention
ML Velocity SD	1.37 (2.40)	1.42 (12.9)	0.39 (4.64)	4.94 (19.6)
Normalised Reach Distance - (%)	3.05 (8.72)	3.56 (8.04)	1.76 (5.77)	2.96 (6.79)
ML Stability Index – (au)	-0.16 (1.05)	-0.99 (1.15)	-0.34 (1.38)	-0.07 (1.74)

CONCLUSIONS

Short foot IFM training did not elicit improvements in barefoot or shod balance performance in healthy, team sports players after a 6-week intervention. Future research should consider the use of more sensitive metrics, a progressive overload approach to the training and focus on individuals with poor balance.

INTRODUCTION

Due to the critical role of lumbar and pelvis movement on the axial rotation of the trunk rotation and hitting speed, pelvis movement plays a crucial role in powerful hitting sports, such as table tennis, tennis, and baseball [1]. Players need to increase the acceleration of their playing hand by optimizing their stroke skill and the efficiency of the power chain transmission, which brings gains to the spin effect and flight speed of the ball during the topspin forehand [2]. The cross-court (CC) and long-line (LL) topspin forehand, as the basic strokes in racket sports, have been widely studied not only in table tennis but also in tennis. The purpose of this study was simulation the musculoskeletal model in the OpenSim software to investigate the difference in lumbar and pelvis movements between CC and LL topspin forehand strokes in table tennis.

METHODS

Sixteen male table tennis athletes (Height: 1.73±0.03 m; Age: 22.89±2.03 y; BMI: 23.45±0.69 kg/m^2; Experience: 8.33±0.71 y) performed CC and LL topspin forehand to return the ball from the coach. The kinematics and kinetics of the trunk and lower limb were recorded by the Vicon motion capture and Kistler force platform. Input the data to OpenSim and establish the Giat2392 musculoskeletal model for simulation. The one-dimensional statistical parametric mapping (SPM1d) and independent samples t-test was performed in MATLAB and SPSS to analyze the kinematics and kinetics. LAR indicates lumbar axial rotation, LLB indicates lumbar left lateral bending, LF indicates lumbar flexion, and PAR indicates pelvis axial rotation.

RESULTS AND DISCUSSION

As shown in Figure 1 and Figure 2, the key finding of this study was (1) the main difference between CC and LL topspin forehand in the lumbar movement was found in the LLB and LF, the Rom, peak moment, and maximum angle of the LLB and LF in CC were significantly higher than LL; (2) the Rom, peak moment, and maximum angle of PAR in CC were significantly higher than LL; (3) the moment of LL in the LF and LLB was significantly higher than CC in the early stroke phase.

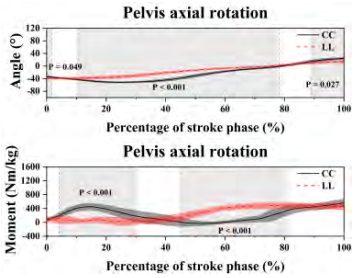

Figure 1 Illustration of the angle and moment of the PAR between the CC and LL topspin forehand. Grey-shaded areas indicate significant differences ($p < 0.05$).

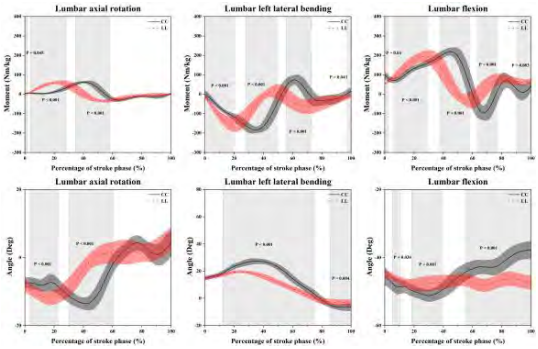

Figure 2 Illustration of the angle and moment in the lumbar and pelvis between the CC and LL. Grey-shaded areas indicate significant differences ($p < 0.05$).

CONCLUSIONS

Players could enhance the motor control of lumbar and pelvis movements, either by enhancing core strength to improve the explosive power of lumbar and pelvis movements or by flexibility training to enhance lumbar and pelvis synergy, as these modalities are able to enhance the level of energy transfer in the power chain and improve performance. Beginners could quickly understand the role and contribution of the lumbar and pelvis in topspin forehand skills based on the results of this study, thus making it easier to master CC and LL topspin forehand skills.
