In recent National Basketball Association (NBA) games, the number of mid-range two-point shots and three-point shots have reversed; the percentage of mid-range shots decreased from 31% in the 2010-11 season to 13% in the 2020-21 season while those of three-point shots increased from 22% to 39% [1]. Furthermore, although the three-point shot distance for NBA is set at 7.24 m, many shots are currently attempted far behind the three-point line. However, release conditions such as the release speed and release angle that are required for making those shots from long distances have not been reported elsewhere. Additionally, the influence of release height on release conditions for different shot distances is of our interest because each player's body size and physical fitness varies. Although it has been reported that a higher release height is advantageous in terms of shot probability in free-throw shots [2,3], the influence of release height in long shots has not been investigated. Therefore, the purpose of this study is to investigate optimal release conditions by assuming shooting distances in line with recent basketball trends and release heights that consider various physical characteristics of players. Specifically, the influences of the release height and shot distance on the optimal release angle and release speed were quantified.

METHODS

The ball trajectories after release from different heights and distances were simulated using the fourth order Runge-Kutta algorithm. The equation of motion of the ball in air was formulated by considering the air drag and lift force. The spin rate, coefficient of air drag, and coefficient of lift force were fixed at 117 rpm, 0.20, and 0.16, respectively, based on the experimental data obtained by motion analysis of three-point shots by ten male collegiate basketball players. Release height, position, speed, and angles varied from 1.5 m to 3.5 m, from 2.0 m to 12.0 m, from 3.0 m/s to 15.0 m/s, and from 30.0 deg to 65.0 deg, respectively. The shot success was judged based on the ball arrival position at the height of the goal ring, or 3.05 m from the floor; if the position was where it could go through the ring without touching the rim, it was regarded as a success. The minimum-speed angle [2] and the average release speed at the minimum-speed angle were calculated for each condition of release height and distance, and regarded as the optimal release condition.

RESULTS AND DISCUSSION

The influence of the release height and shot distance on the minimum-speed angle and the release speed at the minimum-speed angle were observed. In the three-point shot (7.24 m distance) condition, for example, as the release height increased from 1.5 m to 3.5 m, both minimum-speed angle and the release speed at the minimum-speed angle decreased (Figure 1). In addition, the area of successful shot combination of the release speed and release angle was larger at higher release heights, especially at a lower release angle and release speed.

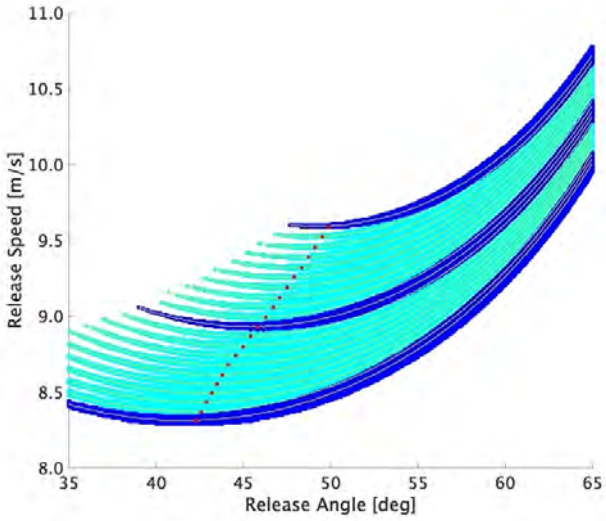

Figure 1 The combination of release angle and speed which results in successful shots from various release height from 1.5 m to 3.5 m in shots from 7.24 m distance are shown in blue (dark blue at the top is the one from the lowest release height 1.5 m, in the middle is from 2.5 m, at the bottom is from 3.5 m, and the ones between those release height are shown in light blue). The red dots show the minimum-speed release angle for each condition.

CONCLUSIONS

The optimal release speed and angle differ depending on the release height and shot distance, which should be considered for efficient coaching and practice.

THE INFLUENCE OF POCKET CHARACTERISTICS ON LACROSSE SHOT PERFORMANCE

Scott Dominey, Dean C. Hay
School of Physical and Health Education, Nipissing University, North Bay, Canada.
Email: deanh@nipissingu.ca

INTRODUCTION

The effect of pocket design on ball accuracy and velocity in lacrosse is not well researched. Ball velocity is greater than estimated using a rigid body stick model [1], suggesting the shape of the pocket can affect performance. Whip, defined as the pocket shape responsible for changing the resistance of the ball as it releases, can be altered by adjusting the pocket strings. Anecdotally, higher whip holds the ball in the pocket longer, resulting in greater throwing velocity. Conversely, lower whip is thought to release the ball earlier in the throwing motion [2]. In this study, the effect of whip on ball accuracy and velocity was tested using two overhand throwing techniques.

METHODS

Fourteen varsity male lacrosse players (21.6 yr ± 3.0; 180 cm ± 8.7; 84.1 kg ± 14.0; mean ± SD) gave their informed consent to participate in this study (NUREB102710). Ball, stick, and participant kinematics were recorded at 300 Hz with a 15 camera passive-marker system (Qualisys, Sweden).

Evo Warp Pro 2 sticks (Warrior, USA) with Whip 1, Whip 2, and Whip 3 heads, along with each participant's personal stick were used in counterbalanced order for the static (throwing motion with limited lower body movement) and dynamic (throwing motion with a stepping sequence) throws. Three trials were completed for each condition, resulting in 24 total trials per participant. Participants were instructed to throw the ball as hard and as accurately as possible at a target located ≈ 2.5 m in front of the participant at a height of 1.02 m.

Repeated-measures ANOVAs (type of throw x whip) were used to test for significant (α = .05) differences in ball velocity and accuracy. The mean values of the three throws for each condition were used in the analyses.

RESULTS AND DISCUSSION

For throwing velocity, significant main effects for type of throw (p < .001, $\eta 2$ = .479) and whip (p < .001, $\eta 2$ = .849) were found. Significant (p < .05) differences were found between Whip 1 and Whip 3; Whip 2 and Whip 3; and Whip 1 and Personal Stick (Table 1). For throwing accuracy, a significant main effect of whip on mean resultant error (p < .001, $\eta 2$ = .557) was found. Significant differences were identified between Whip 1 and Whip 2; Whip 1 and Whip 3; and Whip 1 and Personal Stick (Figure 1).

Higher whip resulted in increased throwing velocity and accuracy. These trends were consistent between the dynamic and static throwing techniques and suggest that pocket design can significantly impact throwing performance [1].

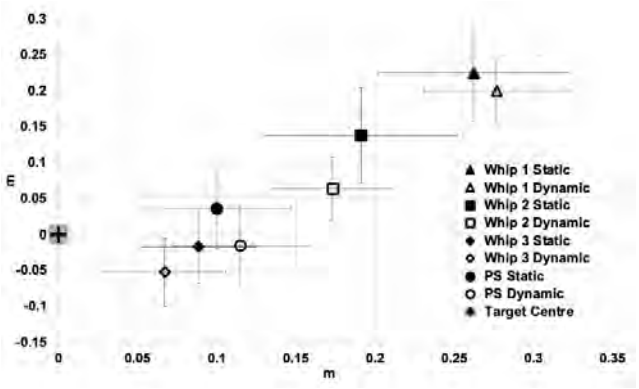

Figure 1 Throwing accuracy of different whips for static and dynamic lacrosse shots (means ± 95% CI).

CONCLUSIONS

Lacrosse sticks with a higher whip pocket produced greater ball velocity and greater accuracy. As experienced players tend to use a relatively high whip level in their personal stick, it was likely that they were able to match their release point for accurate throws with the Whip 3 stick. Conversely, with a low whip stick, the players had difficulty adjusting their release point, resulting in shots landing high and right of the target. An analysis of stick angle at release found significant differences between conditions that support our conclusions. These trends were consistent between throwing techniques.

INTRODUCTION

In professional sports, when deceleration tasks are inappropriately performed, the resulting mechanical loads at the knee joint can increase risk of injury. Greater insight into soft tissue loading mechanisms is therefore essential for investigating the causes of injuries in elite sports. To this end, the goal of this work is the study of knee mechanics whilst performing maximal forward braking and backward acceleration in elite athletes.

METHODS

Fourteen injury-free elite male team-sports athletes participated in this study (age:22 ± 4 years, height:185 ± 4 cm, mass:77 ± 11 kg). Biomechanical data were collected using 8 infrared cameras (Qualisys) at a frequency of 300Hz and 2 force plates (Kistler). Musculoskeletal modelling was performed using a scaled version of the model from Lenhart [1]. The motion analysis measurements were input to the COMAK algorithm to predict muscle forces, secondary knee kinematics, ligament forces and cartilage contact pressures [2].

RESULTS AND DISCUSSION

The *vasti* produced the largest forces, with an early peak while absorbing impact during braking and a late peak while propelling the body to through the backward acceleration phase of the movement (Figure 1-(A)). Patellar Tendon (PT) loading demonstrates a similar double peak, whereas, the ACL is loaded during the backward acceleration phase of the movement, peaking slightly below 2160N, the ultimate failure load of an intact ACL (Figure 1-(B)) [3]. These findings can be explained by the presence of a posteriorly directed ground reaction force during this task, which fixes the foot and tibia to the floor and thus the inertia of the body causes the femur to translate anteriorly and protect the ACL by counteracting the strain produced by the eccentric contraction of the *vasti* [4]. Also, when the knee is flexed beyond 60º, the PT is oriented posteriorly relative to tibia, so the PT force would off-load ACL. During the second phase, the loading of the ACL may occur due to trunk and knee extension. Contact forces of the tibiofemoral (TF) and patellofemoral (PF) joints (Figure 1- (C);(D)) reflect the GRF and *vasti* force profiles. Two peaks in the TF joint were measured during the braking phase, with the majority of the first peak occurring on the lateral compartment, and the second on the medial compartment.

CONCLUSIONS

This work leveraged musculoskeletal simulation to gain a comprehensive understanding of knee mechanics during maximal forward braking and backward acceleration. The lack of ACL loading during braking is an interesting finding and can inform rehabilitation programs.

NEUROMUSCULAR EFFECT OF WARM-UP ON REGULATION OF MOTOR UNIT PROPERTIES DURING ISOMETRIC TORQUE PRODUCTION TASKS

INTRODUCTION

The warm-up exercise is assumed to be a well-discovered and applied methodology for enhancing muscle force generation. Remarkably, little is known about the neuromuscular mechanism of the warm-up exercise at the level of the motor unit within a muscle. The activation components of motor units are assumed to be regulated by the central nervous system (CNS), including the firing rate and recruitment threshold (i.e., order of the recruitment) [1]. The current experiment attempted to observe the changes in the two components of motor units after the established protocol of the warm-up exercise in an isometric condition of muscle force generation.

METHODS

Fifteen healthy subjects were recruited, and they performed isometric maximal voluntary torque (MVT) production by the elbow joint. The experimental conditions included elbow flexion and extension with two joint angles, 10° and 90°. The trajectories followed a ramp contraction. They increased at a rate of 10% MVT/s and were sustained at 100% MVT for 4 s. The same experiments were done before and after the warm-up exercise. The warm-up protocol for the muscle of the elbow flexor and extensor complied with the ACSM guideline. In particular, the index of the warm-up effect was the gross body temperature (i.e., the increment by about 6%). The decomposition EMG system was employed to identify multiple motor units using a specialized surface EMG electrode and placed on the biceps brachill (BB) and triceps brachii (TB) muscles. Further, the isometric machine was used to record biomechanical signals (i.e., torque and joint angle).

RESULTS AND DISCUSSION

Isometric elbow flexion and extension torques were increased significantly after the warm-up exercise for both 10° and 90° of elbow angle ($p < 0.001$), which were associated with the recruitments of higher threshold motor units after the warm-up exercise (Figure 1). Also, the firing rates of motor units observed in the same threshold were larger with the warm-up exercise (i.e., scaled-up and elongated regression line after the warm-up exercise in Figure 1) [2].

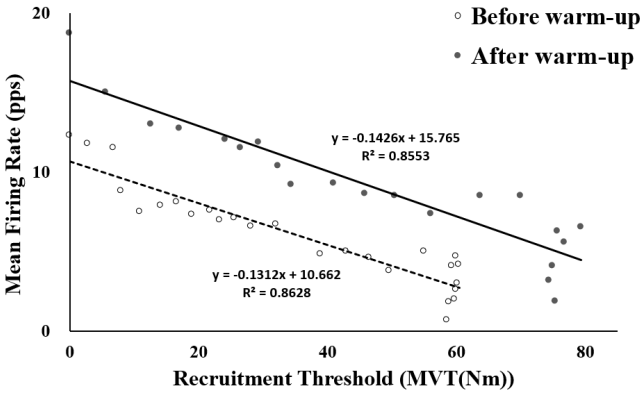

Figure 1. Linear regression line showing the relationship between the mean firing rate and the recruitment threshold for a representative subject.

These results were further associated with significant increments of power spectral densities of the gamma band (35-60 Hz), especially in the relatively large motor units ($p < 0.0001$).

CONCLUSIONS

The current results confirmed the fact that the warm-up exercise causes changes in the neuromuscular components of the motor units within muscles in such a way that the firing rate of the recruited motor unit was increased. In addition, the warm-up exercise seemed to be associated with the recruitment of large motor units (e.g., Type II, fast-twitch motor units) with larger spectra power at the frequency band of the voluntary contraction (35~60Hz).

Effects of Speeds on Ground Reaction Forces during Skipping Gait

Genki Tokuda[1], Toshiki Uchiyama[1] and Hiroaki Hobara[2]
[1] Graduate School of Advanced Engineering, Tokyo University of Science, Tokyo, Japan.
[2] Faculty of Advanced Engineering, Tokyo University of Science, Tokyo, Japan.

INTRODUCTION

Skipping has a double support phase as displayed during walking but it also incorporates a flight phase as observed in running. Although a simulation study demonstrated that skipping gait was stable over a wide speed range [1], very few studies have experimentally verified the effects of speed on skipping gait mechanics. Especially, the ground reaction forces (GRFs), which are defined as the force exerted by the ground on a body in contact with it, are known as fundamental gait parameters used in biomechanics. Thus, the aim of the present study was to investigate the effects of speeds on the GRF parameters during skipping gait.

METHODS

Ten healthy male subjects without musculoskeletal impairments performed bilateral skipping gait on an instrumented treadmill (FTMH-1244WA, Tec Gihan, Kyoto, Japan) at 10 speeds (2.0–11.0 km/h with increments of 1.0 km/h). We collected ground reaction forces (GRFs) from the instrumented treadmill at 1000 Hz. We determined four peak values of anteroposterior GRF, and two peak values of vertical GRF (Fig. 1-A). Negative peak values of anteroposterior GRFs (F_{Y1}, F_{Y3}) were defined as the minimum GRF in the range of 0% to 30% and 30% to 70% stance, respectively. Positive peak values of anteroposterior GRF (F_{Y2}, F_{Y4}) were defined as the maximum GRF in the range of 30% to 70% and 70% to 100% stance, respectively. The peak values of vertical GRF (F_{Z1}, F_{Z2}) were defined as the maximum ground reaction force in the range of 0% to 50% and 50% to 100% stance, respectively. The Shapiro–Wilk test was used to confirm data normality. Then, we used one-way repeated measures ANOVA (10 levels) and a post-hoc comparison when the data were normally distributed. If the data were not normally distributed, the Friedman test (10 levels) and a Wilcoxon signed rank test were used. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Initial peak braking GRF (F_{Y1}) increased with increasing belt speed (Fig. 1-B), but midstance braking GRF (F_{Y3}) decreased from 2.0 km/h to 6.0 km/h and kept constant afterward (Fig. 1-B). Initial propulsive GRF (F_{Y2}) increased from 2.0 km/h to 7.0 km/h but it kept similar values until the top speeds (Fig. 1-C). Propulsive GRF at the terminal stance (F_{Y4}) was nearly zero until 6.0 km/h, but it significantly increased from 7.0 km/h to 11.0 km/h (Fig. 1-C). The peak vertical GRF (F_{Z1} and F_{Z2}) increased with increasing belt speeds, respectively (Fig. 1-D). A previous study approximated the skipping gait using a simple bipedal spring-loaded inverted pendulum model [1]. The GRF patterns in their study were similar to the current results. Further, the previous study suggests that anteroposterior GRFs at the earlier (F_{Y1} and F_{Y2}) and later half (F_{Y3} and F_{Y4}) of the stance were related to the trailing limb, and the leading limb, respectively. Thus, the main propulsive force of the skip is provided by the trailing limb, and the leading limb also exerts a propulsive force from 7.0 km/h to adapt to speed increments. The increase in peak vertical GRF (F_{Z1} and F_{Z2}) can be attributed to the decrease in stance time and the increase in flight time.

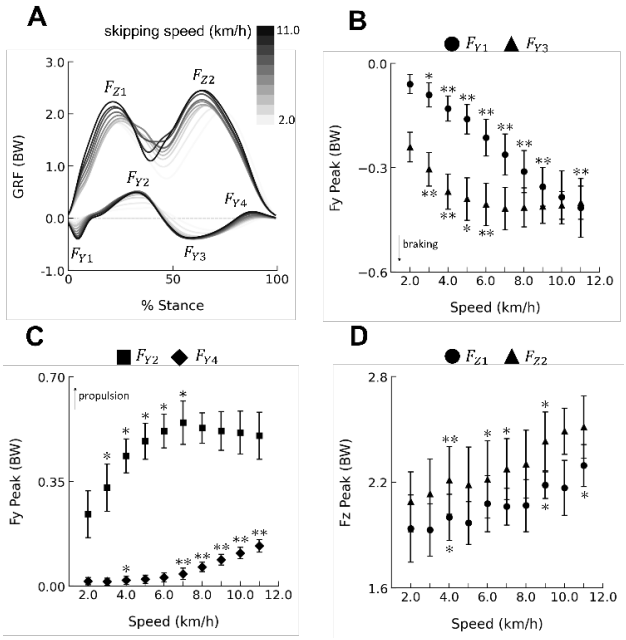

Figure 1. A) Averaged trace of vertical and anteroposterior GRFs of all speeds. B) Peaks of anteroposterior GRF (braking function, F_{Y1} and F_{Y3}). C) Peaks of anteroposterior GRF (propulsive function, F_{Y2} and F_{Y4}). D) Peaks of GRF (F_{Z1} and F_{Z2}). Asterisks (*, **) indicate significant differences from previous speeds at $p < 0.05$, and 0.01, respectively.

CONCLUSIONS

The results of the present study suggest that the skipping GRFs vary according to changes in speeds.

ACKNOWLEDGEMENTS

We appreciate all subjects who participated in the study.

NEUROMUSCULAR RESPONSES TO UNEXPECTED SLIPS DURING HUMAN WALKING

India Lindemann[1], Taylor Dick[1]
[1] School of Biomedical Sciences, Faculty of Medicine, University of Queensland, Australia
Email: uqilinde@uq.edu.au

INTRODUCTION

Falls result in over 680,000 deaths worldwide each year [1]. Understanding how humans maintain balance to stay upright during movement in the face of unpredictable environments is thus of critical importance to public health. Perturbation experiments largely extrapolate muscle dynamics from joint kinematics, rather than through *in vivo* measurements. Previous results from perturbed hopping showed that co-activation of the ankle plantarflexors and dorsiflexors enables favourable plantarflexor muscle dynamics for perturbation recovery [2]. However, measures of how both agonist and antagonist muscles behave *in vivo* during unexpected perturbations remains unknown. The aim of this study is to determine how neuromuscular control and muscle–tendon dynamics are modulated in the ankle plantarflexors and dorsiflexors to maintain stability during unexpected slip-induced perturbations to human walking.

METHODS

Fifteen young adults (23.3±3.5 yrs; 8 males, 7 females) participated in the study. Slip perturbations were delivered by rapidly accelerating and decelerating the right belt of a split-belt instrumented treadmill over 50% of the stance phase duration to 0.7 m s^{-1} above their preferred walking speed (Fig 1B). During the perturbations, lower limb kinematics and kinetics were obtained using 3D motion capture (Qualisys) and force plates (Bertec); muscle activity in the triceps surae and tibialis anterior (TA) using surface electromyography (Trigno Delsys); and fascicle lengths in the medial gastrocnemius (MG) and TA using dual probe B-mode ultrasound (ArtUS, Telemed). Comparisons in muscle activation and fascicle dynamics were made between normal walking, the perturbation, and the recovery step (one step after perturbation). Preliminary analysis (n=3) is presented here.

RESULTS AND DISCUSSION

The perturbation led to a reduction in stance time of the perturbed limb and an increase in peak ground reaction force (GRF) in the second half of stance after belt velocity had peaked. Stance time also decreased in the non-perturbed limb in the recovery step following the perturbation. Plantarflexor (MG, LG, SOL) and dorsiflexor (TA) muscle activity increased during the perturbation compared to normal walking (Fig. 1A). During the perturbation, TA fascicles underwent a brief period of lengthening, followed by active shortening whilst the MG fascicles shortened for the duration of the perturbation (Fig. 1B). This coactivation of the ankle plantarflexors and dorsiflexors enabled fascicle length changes to behave 'in phase' (i.e. both shortening) as opposed to out of phase behaviour present during normal walking. Stretch reflexes in the TA may be responsible for altered muscle behaviour during the initial phase of the slip to enable successful balance recovery.

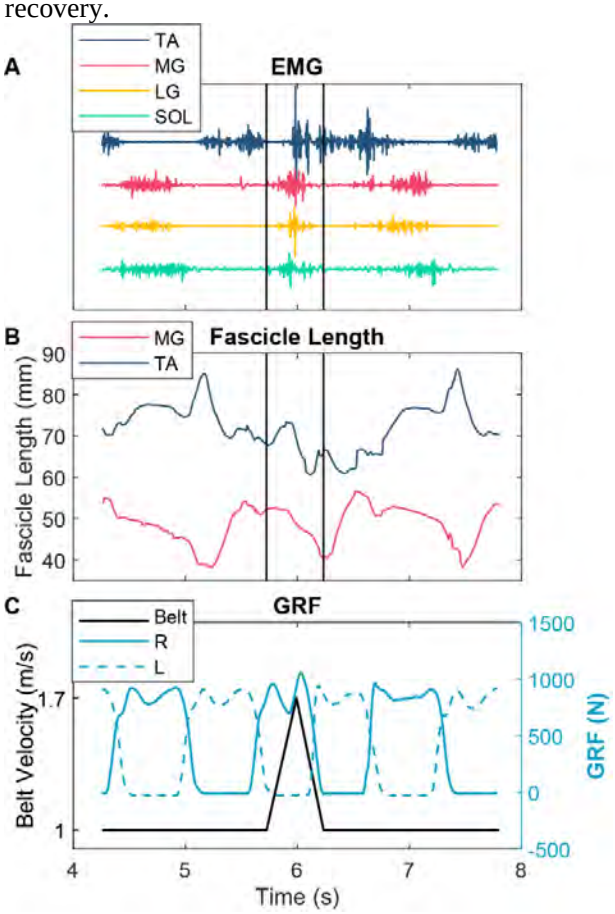

Figure 1 Measures for the perturbed step and one step either side are presented from one slip trial. EMG traces are shown for the tibialis anterior (TA), medial (MG) and lateral gastrocnemius (LG), and soleus (SOL) (A), as are fascicle lengths of the MG and TA (B). GRFs are shown with the belt velocity, illustrating the timing and strength of the slip perturbation (C)

CONCLUSIONS

Our preliminary results suggest that a muscle-based latch mechanism may mediate the perturbation response via sensory feedback. Further analysis will determine the generality of these results in the larger sample of participants for which we have collected data (n=15).

The differences in the characteristics of the body part angular momentum in the frontal plane during walking between young and older adults

INTRODUCTION

Whole-body angular momentum (WBAM) about the whole-body center of mass has often been used to investigate dynamic balance during walking [1]. WBAM on the frontal plane changes periodically during walking, and its amplitude is larger in older adults than younger adults [2]. The larger amplitude suggests that older adults walk with a larger postural sway in the mediolateral direction. However, it remains unclear which body parts mostly affect the age-related difference in WBAM during walking. Such knowledge can provide a better understanding of the underlying mechanisms of dynamic balance regulation in older adults during walking. Therefore, the purpose of this study was to investigate the age-related differences in the body part angular momentum (BPAM) during walking between young and older adults.

METHODS

Kinematic data in AIST Gait Database 2019 provided by National Institute of Advanced Industrial Science and Technology in Japan were used for data analysis in this study [3]. 50 young (Age: 26.8±5.4) and 78 older adults (Age: 67.7±3.3) were randomly chosen from the database, and five separate walking data from each of them were utilized for the analysis.

The whole body of the participant was modelled with 15 linked rigid-body segments based on the coordinate data of 42 markers. BPAM and WBAM on the frontal plane during walking were calculated. The postural sway during walking was evaluated by the maximum WBAM about the whole-body center of mass during a stride cycle. The angular momentum of each segment was categorized into five BPAMs: the right and left legs (foot, shank, and thigh), right and left arms (hand, forearm, and upper arm), and torso (head, thorax, and pelvis). The frame in which the WBAM was maximum during the stride cycle was used to calculate the five BPAMs. WBAM and BPAMs were normalized by a square of body height and the whole-body mass.

WBAM and BPAMs over five strides of each participant were used to calculate the average of WBAM and BPAMs of each participant. An independent sample t-test was used to compare the average values of WBAM and BPAMs between young and older adults. The significance level was set at 0.05.

RESULTS AND DISCUSSION

The maximum WBAM in older adults was significantly larger than that in young adults ($p<0.001$, Figure1). This result indicates that older adults walked with a larger postural sway in the mediolateral direction, and this result was consistent with the previous study [2]. BPAM of the left leg, left arm, and torso in older adults were significantly larger than those in young adults ($p=0.014$, $p=0.004$, $p<0.001$, Figure 1). These results indicate that the age-related difference in WBAM during walking is caused by the larger angular momentum of the left leg, left arm, and torso in older adults. A previous study reported that the hip abductor muscle was important for the regulation of WBAM, and this muscle torque was a deficit in older adults [4] [5]. The age-related difference in BPAMs during walking could be caused by age-related deficits in joint torque especially of the hip.

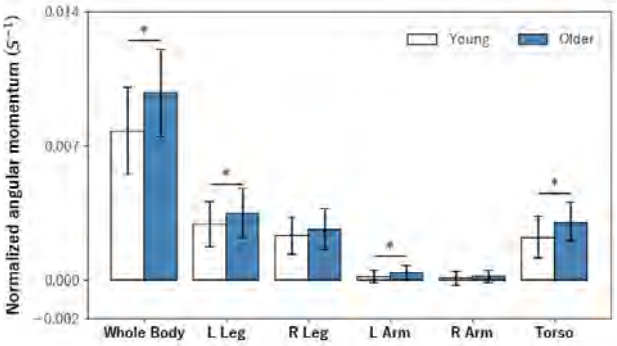

Figure 1 The maximum WBAM and five BPAMs (*: $p<0.05$)

CONCLUSIONS

The age-related difference in WBAM during walking was caused by the large angular momentum of the left leg, left arm, and torso in order adults. The findings in this research would be useful to program an effective intervention for improving the dynamic balance during walking in older adults.

Pendular energy exchange at very slow walking speeds reveal positive work shift from double support to single stance

Timothy K. Byles-Ho[1] and Amy R. Wu [1]

[1] Department of Mechanical and Materials Engineering, Queen's University, Kingston, Canada.
Email: 16tkbh@queensu.ca, amy.wu@queensu.ca

INTRODUCTION

Humans need to expend energy to walk. Previous research has found that taking advantage of the energy transfer between kinetic and gravitational potential energy could reduce the amount of mechanical energy expended during gait. By calculating the phase shifts between kinetic and potential energy curves, Cavagna et al. (2020) demonstrated that the optimal speed is 1.6 m/s, which was the speed that required the least mechanical energy to maintain steady-state gait [1].

Aging, neurological deficits, or lower limb injuries can lead to walking at slower speeds [2]. Investigations of energy exchange could help improve our understanding of the mechanics of walking, such as whether dynamic walking breaks down at very slow speeds. Prior research has captured energy phase shifts at normal speeds, however it is unclear how the phase shift behaves at slower speeds. We aimed to measure the phase shift between kinetic and gravitational potential energy at very slow speeds (<0.5 m/s). We hypothesized that as speed decreased, the kinetic and gravitational potential energy would move further out of phase.

METHODS

We used slow walking data from a public dataset [2]. Eight subjects walked on an instrumented treadmill at prescribed speeds of 0.4, 1.2, 1.8, 2.2 km/h (denoted here as 0.11, 0.33, 0.50, and 0.61 m/s) and at a self-selected speed. The position and velocity of the body centre of mass (BCOM) was determined using a double integration of force platform data [3]. From the BCOM position and velocity data, kinetic energy and gravitational potential energy were calculated per stride.

We determined the phase shifts for each speed using the method proposed by Cavagna et al. (2020) [1]. Ground reaction forces were used to separate each stride into single stance and double support phases. The α phase shift was measured during double support (Equation 1):

$$\alpha = 360 * \frac{t_{pk+}}{\tau} \qquad (1)$$

where τ is step time and t_{pk+} is the time between maximum kinetic energy and minimum gravitational potential energy. The β phase shift was measured during single stance (Equation 2):

$$\beta = 360 * \frac{t_{pk-}}{\tau} \qquad (2)$$

where t_{pk-} is the time between maximum potential energy and minimum kinetic energy during single stance [1]. We performed a t-test on the mean values of α and β across all subjects to determine if the mean values were significantly different from zero.

RESULTS AND DISCUSSION

As speed decreased, α remained positive until the slowest speed of 0.11 m/s (Figure 1). The β values followed a similar trend, changing from positive to negative at the slowest speed. All shifts were significantly different from zero ($p<0.05$). The α and β values at the fastest two speeds (0.61 m/s and self-selected) were comparable to Cavagna et al. (2020) [1].

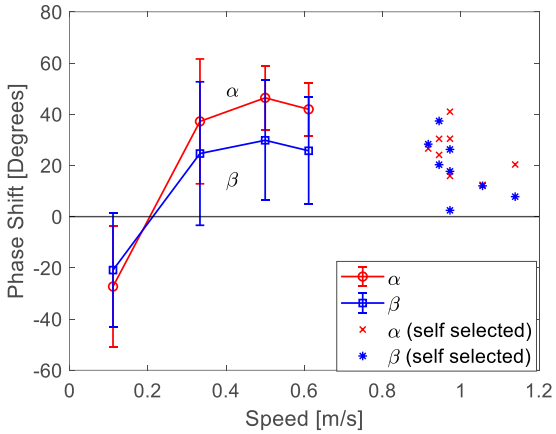

Figure 1 Phase shifts α and β as a function of speed. Average α (circles), β (squares), and s.d. bars shown for each speed except for self-selected, where individual subject means are shown.

A positive α indicates that positive work was done during double support to accelerate the body while a positive β indicates that negative work was being performed during single stance [1]. At very low speeds (~0.2 m/s), both phase shifts become negative. Our finding suggests that at extremely slow speeds, positive work is required during single stance, possibly due to a reduction in pendular dynamics. In contrast, less positive work is required during single stance at faster speeds due to the pendular exchange of energy [1]. One limitation that necessitates further research is the increased variability observed in both phase shift values as speed decreased, likely derived from varying methods of walking very slowly among subjects.

CONCLUSIONS

At very slow speeds, humans seem less able to take advantage of pendular dynamics and need to rely more on mechanical energy added during single stance to maintain steady-state gait.

INTRODUCTION

Whole-body energy expenditure and muscle fatigue minimization are important criteria dictating human locomotor performance [1,2]. In running, these criteria are closely related—more motor units are recruited when a fatigued muscle must maintain its pre-fatigued force contribution [3], and the volume of active muscle affects the total metabolic expenditure observed during running [4]. The current study aims to explore this relationship further by considering the effect of localized knee extensor (KE) muscle fatigue. It is hypothesized that running in presence of KE fatigue will increase the metabolic cost of locomotion when compared to an unfatigued run.

METHODS

Two male recreational runners participated. They first completed a warm up, which was followed by a baseline run (BR) on a standard treadmill at 10 km h^{-1}. Participants then performed a maximum voluntary contraction (MVC) on a dynamometer (Humac, USA) and completed a fatigue protocol on a leg extension machine (three sets of repetitions to failure). Their MVC was assessed to ensure fatigue had reached the study's target value of 75-85% [5] ('pre' MVC). When this occurred, participants completed a fatigued run (FR) on the treadmill at 10 km h^{-1}, before their MVC was captured for a final time ('post' MVC).

Net metabolic cost of transport was computed from gaseous exchange data (Cosmed, Italy). Integrated electromyography (iEMG; Delsys, USA) was computed from the linear envelope of the raw vastus lateralis (VL) and biceps femoris (BF) signals, normalized to the mean peak value in the BR, parsed into strides and integrated. Preliminary results are presented for both participants; however it is expected that a full dataset will be prepared ahead of the conference.

RESULTS AND DISCUSSION

KE peak torque reduced to 75.4% and 83.7% of pre-baseline run MVC values after the fatiguing protocol for Participants 1 and 2, respectively. Post-FR values were 67.3% and 81.7% of the pre-baseline run MVC for Participant 1 and Participant 2, respectively. Thus, fatigue recovery did not occur during the run. Net metabolic cost responses to localised KE fatigue were variable. Participant 1's metabolic cost of transport was reduced between the BR and FR (5.02 vs. 4.67 J kg^{-1} m^{-1}, respectively), however, Participant 2 did not demonstrate a noteworthy change (4.85 vs. 4.95 J kg^{-1} m^{-1}, respectively). The complete dataset is required to understand whether an overall trend can be established for this population, or whether large variability in responses will exist. Interestingly, iEMG data indicate that while VL (agonist) muscle activity increases, BF (antagonist) muscle activity decreases when fatigued (Fig. 1). This observation conflicts with previous data showing a rise in antagonist muscle contributions with increased agonist fatigue [6]. However, this is the first study to consider localized fatigue in relation to a highly metabolically demanding task: running.

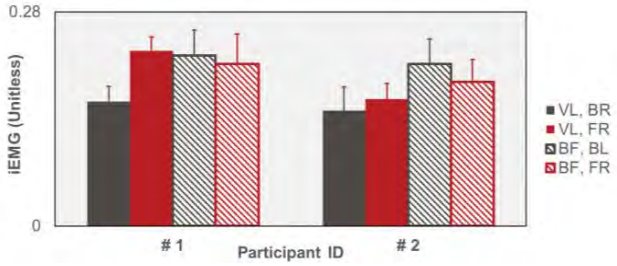

Figure 1 iEMG for the vastus lateralis (VL) and biceps femoris (BF) during the baseline (BR) and fatigued (FR) runs.

CONCLUSIONS

Our results may indicate that recreational runners can avoid substantial metabolic cost penalties—that may otherwise be invoked by fatiguing the knee extensors—through a reduction in knee flexor muscle activity. Data collection and analysis is ongoing.

THE ACHILLES SUBTENDONS EXHIBIT DISTINCT LOADING PATTERNS DURING WALKING

Lauren Welte[1], Darryl G Thelen[1,2]

INTRODUCTION

Propulsive energy generated at the ankle during locomotion is primarily contributed by the Achilles tendon (AT) [1]. The morphologically complex AT is composed of three subtendons, one from each of the three triceps surae muscles. Relative motion between the subtendons has been well-documented at various slow walking speeds [2], [3], and reduction in relative motion is linked to propulsive deficits in older adults [4]. However, understanding how subtendon loading changes during gait has been limited by challenges in measuring depth-dependent differences in *in vivo* load. Here, we use novel depth-dependent tensiometry to investigate subtendon loading at faster walking speeds.

METHODS

One participant (F, 25, 173 cm, 60 kg) gave informed consent to participate in this study (University of Wisconsin IRB: 2018-0487-CP019). They walked on a treadmill at three speeds (1.25, 1.50 and 1.75 m/s). A shear wave tensiometer, composed of an electrodynamic tapper and a high-speed linear ultrasound transducer (Phillips CL 15-7, 22mm, centre frequency 8.92 MHz, used with 64LE Vantage, Verasonics), were attached to the participant's ankle, at the level of the free tendon (Figure 1). The induced taps' (50 Hz) shear wave propagation speed along the tendon, as a surrogate for tendon loading [5], was measured by a custom algorithm and averaged over 0.5mm depths of the AT. Time synchronized electromyography data of the soleus (SOL), medial gastrocnemius (MG) and lateral gastrocnemius measured muscle activations.

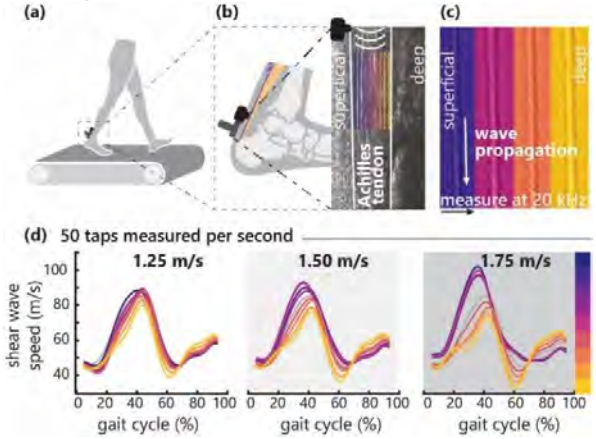

Figure 1: (a) Participants walked on a treadmill at 1.25, 1.50 and 1.75 m/s while (b) ultrasound images were captured at 20,000Hz for each tap at 9 tendon depths. (c) The wave speed is measured at each tap. (d) Shear wave speed, as a surrogate for tendon loading, and derived from the first two principal components, is shown over stance for each depth and walking speed.

Principal component (PC) analysis was conducted on the wave speed during each stride (~2 per trial) at each depth (9). PCs 1-3 were tested for linear correlation with depth and walking speed. PCs 1 and 2 explained 54% of the variance in the shear wave speed waveforms and were linearly related to both tendon depth and walking speed ($p < 0.01$, $R^2 = [0.07, 0.53]$). Based on the results of the regression, discriminant analysis classified the first two PC scores as a function of depth and walking speed. Waveforms were reconstructed from the mean PC scores for each classified walking speed and depth.

RESULTS AND DISCUSSION

Tendon depth was one of the primary sources of variability in the wave speed time series (Figure 1d). The reconstructed waveforms for each depth clustered in two distinct groups, strongly suggesting that we imaged two independent sub-tendons (likely MG and SOL). The shear wave speed was generally faster in the superficial tendon than in the deep tendon and increased with walking speed. Simultaneous increase in MG muscle activation with walking speed suggests that the gastrocnemius supports increased demand for forward propulsion, and therefore likely makes up the superficial tendon [6].

The deep tendon showed a plateau effect in wave speed in mid-stance, whose effect increased with walking speed. A quicker increase in tension between 10-20% of the gait cycle drove this plateau effect, suggesting the deeper tendon requires tension earlier in stance when walking faster. During swing phase, consistent with passive loading from ankle dorsiflexion in late swing, the AT had increased tension, with higher wave speeds occurring in the SOL subtendon. AT tension resulting from passive stretch may be more easily redistributed across the bi-articular MG than the uni-articular SOL.

CONCLUSION

Load-sharing strategies in the AT subtendons are task-dependent. Measurement of these loading patterns are critical to understanding propulsive deficits in older adults and improving treatment for AT injury.

PATELLOFEMORAL KINETICS WALKING IN MAXIMAL, MINIMAL AND TRADITIONAL SHOES

INTRODUCTION

Maximal and minimal shoes, characterized by the amount of midsole cushioning, have both become popular in older populations for activities of daily living, such as walking. However, previous gait research has suggested that the external knee adduction moment (KAM) may increase in maximal shoes, while the knee flexion angle at initial contact as well as the peak knee flexion angle may increase in minimal shoes compared to traditional footwear [1]. Together, this may indicate an increased risk of developing knee osteoarthritis (OA) over time in these shoes [2-3]. However, it is currently unknown how minimal and maximal shoes affect patellofemoral kinetics, and thus patellofemoral OA risk [4], during gait. Therefore, the purpose of this study was to compare patellofemoral joint kinetics between maximal, minimal, and traditional shoes during gait.

METHODS

After signing an informed consent document, twenty-one reflective markers and six marker clusters were placed 16 healthy females (age: 59.0 ± 3.6 years). All participants performed 5 successful walking trials in three shoe conditions: maximal (Hoka Bondi), traditional (New Balance 880) and minimal (Merrell Trail Glove) shoes. Lower extremity biomechanics were measured with a 3D motion capture system (Vicon Motion Systems) collecting at 250 Hz, and two force plates (AMTI) collecting at 1000 Hz.

Angular kinematics and kinetics were calculated using Visual3D software (C-Motion). Quadriceps force, patellofemoral joint reaction force, patellofemoral contact area, and patellofemoral joint stress were estimated using the formulas described in Brechter & Powers [5]. Patellofemoral joint kinetics were then compared using a repeated measures ANOVA ($\alpha = .05$).

RESULTS AND DISCUSSION

The peak knee flexion angle was significantly larger in the minimal shoe compared to the maximal and traditional shoes ($p < .001$). No significant differences were noted for the peak knee extension moment, peak quadriceps force, peak patellofemoral joint reaction force, and peak patellofemoral joint stress, $p > .05$ (Table 1).

CONCLUSIONS

Despite differences in sagittal plane knee kinematics, no significant differences between shoes were noted for any measure of patellofemoral joint kinetics, most notably patellofemoral joint stress. Previous research suggested that maximal shoes may increase the external knee adduction moment [1], which has been correlated with increased medial compartment contact forces and knee OA disease progression [2-3]. However, the results of this study suggest that altering shoe cushioning may not affect patellofemoral joint kinetics. Thus, based on these findings, walking in maximal or minimal shoes may not alter patellofemoral knee OA risk [4]. More research is needed on the effect of footwear in individuals currently suffering from knee osteoarthritis.

HOW WELL DO MACHINE LEARNING MODELS TRAINED ON TREADMILL WALKING DATA PERFORM ON OVERGROUND DATA?

INTRODUCTION

In gait analysis, accurate estimation of ground contact timings (time between initial contact and toe-off of the same foot) is essential for determining spatio-temporal parameters. While using treadmills for gait analysis increases the number of strides that can be analysed per measurement, some gait characteristics differ between treadmill and overground walking, which hinders the translation of treadmill walking to overground conditions [1].

Machine learning (ML) based assessments have high accuracy in determining spatio-temporal parameters for healthy adults in overground and treadmill walking using kinematic data [2]. However, they are tuned to specific features of their training datasets and hence may not make accurate predictions on unseen datasets.

In this study, we examine how 4 common ML models trained to identify ground contact timings for treadmill walking perform on overground walking data from different individuals. By doing so, we aim to comment on the generalization of these ML models to different gait conditions.

METHODS

3-D kinematic and kinetic data were collected from 27 healthy adults (26 ± 2.6 years). 3-D raw IMU signals (input) from sensors placed at the waist, left foot and right foot were sampled at 120 Hz. Ground contact sampled at 100 Hz (ground truth) was determined using pressure insoles in the shoes of the participants. Approximately 400 steps (overground walking; self-selected speeds) and 600 steps (treadmill walking; 3.5 to 6 km/h at increments of 0.5 km/h) were collected from each participant.

4 supervised ML models- K-nearest neighbour (KNN), Random Forest (RF), Support Vector Machine (SVM) and a multilayer feed-forward Neural Network (NN)- were implemented using treadmill walking data from 21 participants (Figure 1). A 5-fold cross validation was performed to check for overfitting. Algorithm performance was tested on treadmill and overground walking from the remaining 6 participants. The results were also compared to a kinematic method of gait event detection [3]. RMSE was calculated on the difference between the true ground contact timings (from insoles) and the timings predicted by the algorithm in milliseconds (ms).

RESULTS AND DISCUSSION

On treadmill data, RMSE (±SD) values of 8.1 ± 3.3 ms (KNN), 9.2 ± 3.8 ms (RF), 8.4 ± 4.3 ms (SVM) and 6.9 ± 3.8 ms (NN) were observed. As expected, the performance on overground walking was considerably worse, with the respective values being 14.3 ± 5.7 ms (KNN), 18.2 ± 7.2 ms (RF), 15.3 ± 4.6 ms (SVM) and 16.7 ± 6.3 ms (NN). All ML approaches surpassed the performance of the kinematic algorithm which reported values of 23.3 ± 10.8 ms (overground) and 28.4 ± 12.6 ms (treadmill). This was expected as kinematic algorithms generally rely on certain heuristics which may be difficult to generalize across different individuals and gait conditions.

The KNN and SVM methods outperformed the NN approach when testing on overground data. Overall, the KNN approach performed best on unseen data.

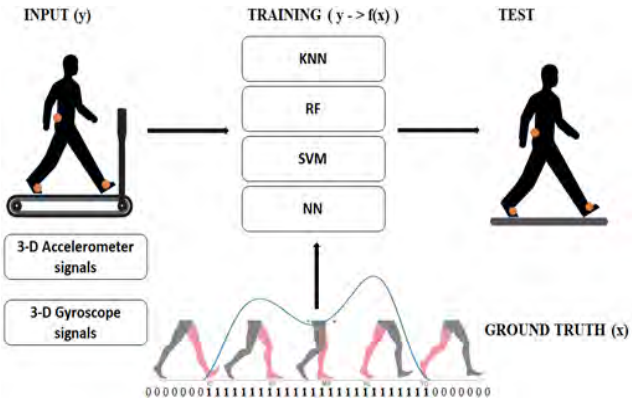

Figure 1 Schematic diagram of the methodology. 4 ML approaches were used to approximate target function f that mapped 3-D accelerometer and gyroscope signals from the waist and foot IMUs (y) to ground contact timings obtained from vertical ground reaction force data (x). KNN- K-nearest neighbour; RF- Random Forest; SVM- Support Vector Machine; NN- Neural Network.

CONCLUSIONS

The results indicate that while all ML approaches outperformed the kinematic approach in both treadmill and overground walking, there is not a “one-model-fits-all” approach due to the inability of ML approaches to generalize to unseen gait conditions. Evidence suggests that simpler ML algorithms may have an advantage over NN approaches in this regard. However, this experiment should be replicated in other gait conditions (e.g. jogging and stair-climbing) and compared to deep learning approaches before drawing this conclusion.

INTRODUCTION

Due to different phases, the timed-up-and-go (TUG) test requires a complex coordination of the lower and upper limbs. Wearable sensor technology can provide detailed evaluation of the biomechanics of the movements during this test. Previous studies have shown high reliability and sensitivity of the instrumented TUG (iTUG) test in several patient populations, but little validation has been performed, especially in people with multiple sclerosis (pwMS) and only on the total duration of the test [1]. Therefore, in this study we validated an algorithm that extracted different subphases of the TUG test based on wearable sensors.

METHODS

Forty-one pwMS and 15 age-matched controls were recruited for the study (AutoActive project, number 270791, a research project in the IKTPLUSS program financed by the Norwegian Research Council). Participants were equipped with three Physilog® 5 (MindMaze SA, CH) sensors on sacrum and feet. Accelerometer and gyroscope data was used with 128 Hz sampling frequency. Moreover, two GoPro 7 (GoPro Inc, US) cameras were recording videos with 50 fps. Participants performed the TUG test in two sessions. Based on signal processing methods, the total duration of the test, sit-to-walk, turning, and turn-to-sit durations were extracted from the wearable sensors (IMUs). One observer annotated the videos for each subphase of the TUG test. The difference between the IMU-based results and the observer's annotation as the reference was calculated. Pearson's correlation coefficient was also obtained to determine the degree of agreement between the two systems. Finally, pwMS were grouped into moderately and severely disabled groups based on their disability score. Wilcoxon rank-sum test was used to determine if the error of the IMU-based results were significantly different between control, moderate, and severe groups. Finally, to assess the inter-rater variability, a group of pwMS were randomly chosen for which a second observer annotated the videos.

RESULTS AND DISCUSSION

The difference as well as the correlation coefficient between the reference and IMU-based results were shown on Table 1. High agreements exist between the IMU-based measures and the reference values except for the sit-to-walk duration. The reason can be due to the difficulty of marking the end of this transition. The limits of agreement (mean ± 1.96SD) for the total duration of the test was (-1.3 , 1.1) seconds which is less than the minimal detectable change reported for pwMS [2]. Therefore, the IMU-based algorithm can reliably estimate the duration of different subphases of the TUG test and discriminate different stages of the MS. The Wilcoxon rank-sum test showed no significant difference in the errors between the control, moderate, and severe groups except for the turn-to-sit duration. This can be due to the difficulty of this complex transition for the severe group of the patients. The inter-rater variability and the absolute error of the IMU-based results have been shown in Figure 1. The latter was either in the same range or significantly lower than the difference between two observers which implies that IMUs can provide an objective measure of the TUG test.

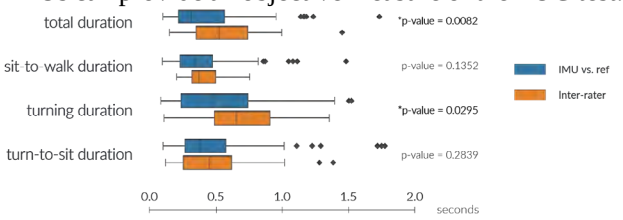

Figure 1 IMU error vs. inter-rater variability

CONCLUSIONS

The findings indicate that the IMUs along with the dedicated algorithm could estimate the duration of the subphases of the test in a reliable and objective manner.

Detecting the Progression of Gait Impairments in Parkinson's Disease using Wi-Fi

Tzu-Yang Weng, Chi-Lun Lin
Mechanical Engineering, National Cheng Kung University, Tainan, Taiwan.
Email: n16101905@gs.ncku.edu.tw
10408019@gs.ncku.edu.tw

INTRODUCTION

The Parkinson's disease (PD) can causes difficulties during gait, such as imbalance, decreased speed and stride length, and shuffling steps [1]. These issues may increase the risk of falls and further limit mobility in individuals with PD. The diagnosis of PD can be challenging because it has a gradual onset, making it important to continuously monitor the progression of the patient's condition.

Channel state information (CSI) represents the combined effect during the propagation of Wi-Fi signals from the transmitter to the receiver. Wi-Fi-based sensing has the advantages of being passive, contactless, and privacy-preserving. For gait detection, studies have used CSI to collect gait information to achieve human regonition. [2]. Therefore, this paper proposes a method to detect abnormality during gait and extract quantitative information for assessing the severity of PD.

METHODS

CSI data was collected when a healthy person walked in different levels of abnormality, including normal gait, short-stepped gait, one leg dragging [3] and shuffling gait.

Our computer algorithm processed a CSI sequence of magnitude and quantitatively extracted walking speed, cadence, and step length. The data processing included Butterworth band-pass filtering, principal component analysis and short-time Fourier transform. We superposed the output spectrograms of the first ten principal components to enhance the features of motion, and the maximum energy zone (torso contour [2]) in the resulted plot was used to extract walking speed. Next, the weighted average of the spectrogram was used to smooth out the torso contour curve for more accurate estimation of walking steps. Finally, the step length can be calculated from the walking speed and number of steps.

RESULTS AND DISCUSSION

The results indicated that the proposed method could distinguish different levels of abnormality (Figure 1). The variation in frequency during gait, which represented walking speed, was used to quantitatively differentiate between these cases. The torso contour (red zone) in a spectrogram contained oscillations, which illustrated acceleration and deceleration phases of steps caused by initial swing and terminal swing (Figures 1a – 1d). The normal gait and the other three abnormal ones performed by the same person were clearly distinguishable by showing different patterns and magnitudes of oscillation. The walking speeds were extracted from the data in time-frequency domain, and the number of steps could be identified by finding the peaks in the torso contour plot (Figure 1e). Therefore, the cadence and step length of these cases could be estimated. Special features could also be depicted by these plots. For example, the torso was nearly static during the period of dragging one leg during, leading to a flat area with relatively lower frequencies in the spectrogram (Figure 1c).

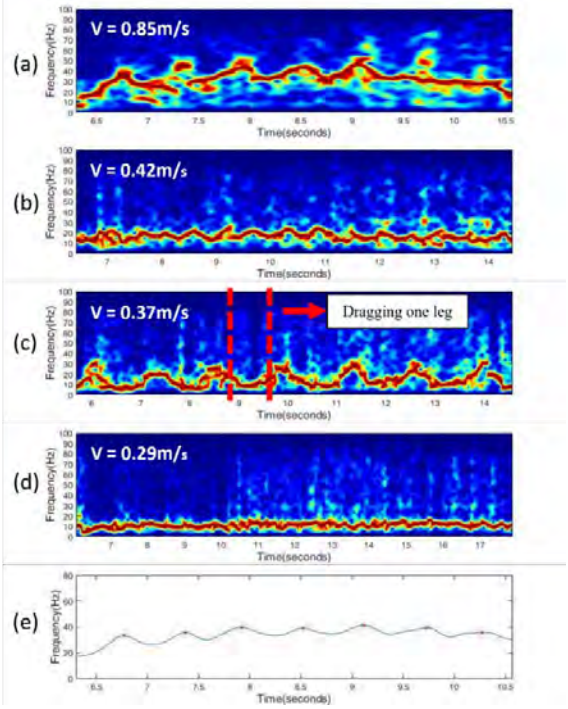

Figure 1 Spectrograms of (a) normal gait, (b) short-stepped gait, (c) one leg dragging, and (d) shuffling gait. (e) The profile curve of torso contour converted from (a) for counting steps.

CONCLUSIONS

The proposed method successfully detected gait impairments that would present in different stages of PD. Important gait parameters, such as walking speed, cadence, and step length, were quantified. With continuous detection, the patient's daily condition can be tracked to understand the disease progression and drug efficacy, which help the doctor prescribe more accurately.

CAPACITIVE SENSING FOR NATURAL ENVIRONMENT REHABILITATION MONITORING

Owen Pearl[1], Nataliya Rokhmanova[1], Louis Dankovich[2], Sarah Bergbreiter[1], & Eni Halilaj[1]

INTRODUCTION

Capacitive sensing (CS) is a mature technology that enables versatile, cost-effective, power efficient, flexible, robust to noise, and lightweight portable technologies like touch screens and promixity sensors [1]. However, previous use of CS on humans has only emphasized gesture recognition or activity classification [2]. Here we characterize capacitive touch sensing as a gait rehabilitation monitoring technology and show that it captures clinically relevant gait modifications in natural environments with the fidelity of laboratory tools. We hypothesized that CS would perform better than electromyography (EMG) and muscle-driven simulations (SIM) [3] at detecting adherence to therapeutic gait retraining prescriptions.

METHODS

We developed an affordable CS-based circumferential sleeve and benchmarked it against EMG and SIM muscle forces using marker-based motion capture (Figure 1). Our $35 (USD) custom-built CS sleeve measures circumferential capacitive profiles of the shank, which are primarily governed by bulging of the gastrocnemius, soleus, and tibialis anterior. Expansion in cross-sectional area decreases the distance between four copper tape electrodes in the CS sleeve and the subject's skin, which results in an increase in their capacitive coupling. We benchmarked the CS sleeve on 20 adults (12 males, 8 females; 25.2 mean ± 2.2 std years of age), both indoor and outdoor. A Freidman test was used to compare the ability of CS, EMG, and SIM to detect changes between baseline walking gait at a subject's preferred speed and a modified 5° toe-in gait, which has been shown to help slow knee osteoarthritus progression [4].

RESULTS AND DISCUSSION

Our results indicate that the CS sleeve can distinguish between baseline and toe-in gait as well as, or better than, existing laboratory benchmarks of muscle activity. The CS sleeve detected a higher root-mean-square difference (RMSD) between the baseline and toe-in gaits than EMG, both inside ($p < 0.0001$) and outside ($p = 0.0156$) of the lab. CS also detected a similar RMSD to simulations performed inside the lab ($p = 0.4076$). These findings indicate that CS matches or surpasses the ability of current state-of-the-art laboratory tools at detecting adherence to gait retraining prescriptions. Because CS uses circumferential electrodes, it likely captured additional information about the gait modification reflected in parts of the musculotendon complex that EMG and SIM were unable to capture (e.g., tendons and ligaments near the ankle). By synthesizing information from multiple muscles and tendons automatically, CS alleviates the need to select specific muscles for monitoring a priori.

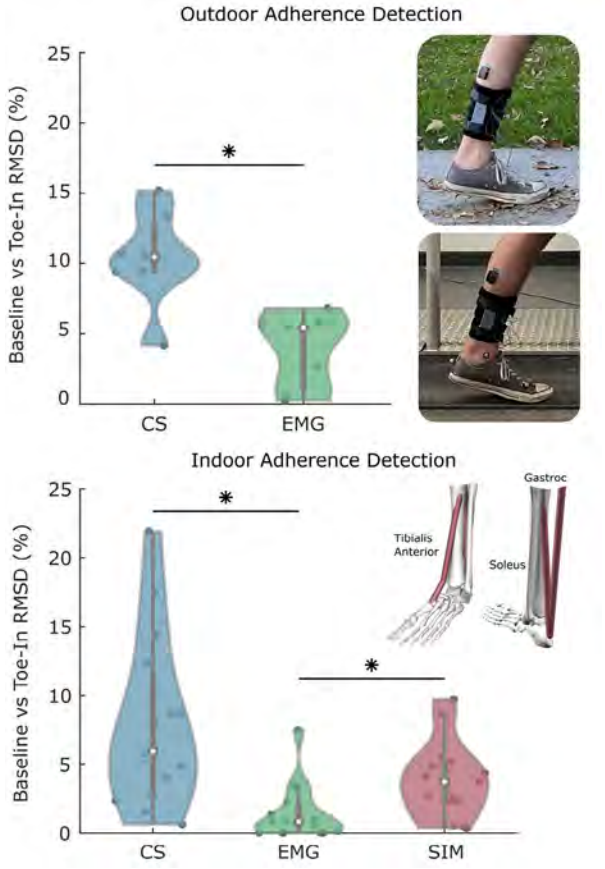

Figure 1. Capacitive sensing wearable detects larger physiological changes in muscle activity resulting from a therapeutic gait modification than EMG and musculoskeletal simulations.

CONCLUSIONS

CS has rich potential for democratizing rehabilitation monitoring with wearable sensors and smart garments of different form factors, given its flexibility, low cost, and sensitivity to even small changes in gait (i.e., 5°).

ESTIMATING ENERGY EXPENDITURE USING WEARABLE SENSORS DURING INDOOR AND OUTDOOR LOCOMOTION

Mohammad Mohammad[1], Abed Abu Hijleh[1], Gillian Phillips[1], Megan McAllister[1] and Jessica Selinger[1]
[1] School of Kinesiology and Health Studies, Queen's University, Kingston, Canada.

INTRODUCTION

Measures of metabolic energy expenditure can provide valuable insight into healthy and impaired gait, the design and control of assistive devices, and rehabilitation progress [1,2]. Currently, the gold standard for estimating energy expenditure is indirect calorimetry, where oxygen use is captured via a gas mask [3]. Although accurate, indirect calorimetry systems are expensive, cumbersome, and often limited to lab settings. Therefore, our aim is to develop a cheap, lightweight method for accurately and continuously estimating energy expenditure during outdoor locomotion using wearable sensors.

METHODS

Participants. We recruited healthy adults who are recreational runners with no known musculoskeletal or cardiopulmonary impairments (n = 22, 11 F). *Equipment*. Each participant was instrumented with a portable indirect calorimetry system to measure energy expenditure, as well as the following wearable sensors to estimate energy expenditure: accelerometers at the pelvis and foot, a heart rate monitor, and a respiratory belt. *Protocol*. During indoor testing participants walked and ran on a treadmill (~4.6 km) at varying speeds (1.25-2.5 m/s), inclines (0% and 5%) and added weight conditions (0 and 3% body weight at the ankle). During outdoor testing participants walked and ran, with and without the added weight, on a predefined outdoor route (~4.8 km) that included sections with distinct average inclines (~0% and 5%). *Analysis*. We used multiple regression (MLR) analysis, as well as long short-term memory (LSTM) recursive neural network (NN), with a leave-one-out cross-validation design to predict energy expenditure using custom metrics derived from wearable sensors and participant anthropometric data. Participant sensor data was binned using an estimation time interval of 10s. Due to equipment malfunction, only data from 18 participants (n = 18, 9 F) was included in the final analysis.

RESULTS AND DISCUSSION

We found that we could estimate energy expenditure in real-world settings with relatively high levels of accuracy across changing terrain and variable conditions. We found that our NN method has an average absolute error of 14%, which is among the most accurate wearable sensor methods reported to date [2,3]. We were also able to maintain relatively low error rates using a model that only used data available from a typical consumer smartwatch (SW model). The correlation (R^2) between measured and predicted energy expenditure was above 0.9 for all participants in all models (Figure 1a). Average absolute errors in estimated energy expenditure, across all conditions, were typically ~0.9 W/kg. This resulted in lower percent errors for higher work rate tasks, such as running, and higher percent errors for lower work rate tasks, such as standing (Figure 1b).

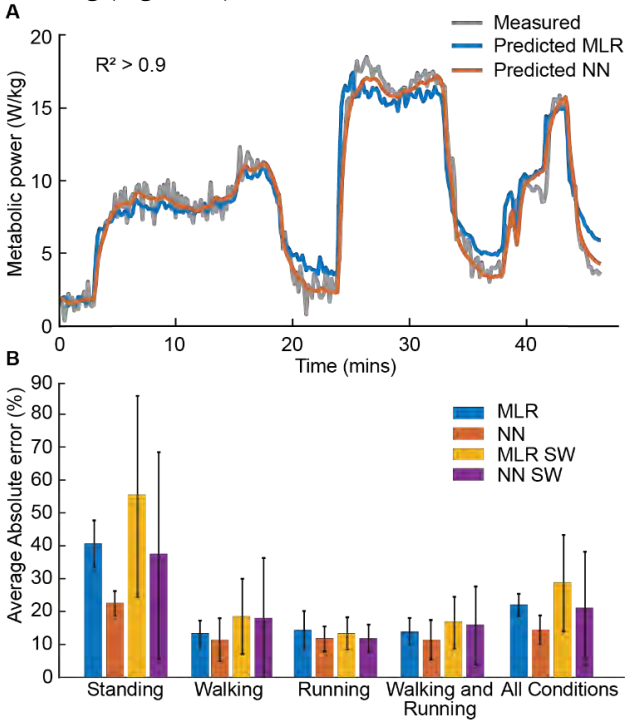

Figure 1. *A*: Measured and predicted metabolic power timeseries for a representative outdoor participant using full MLR and NN models. *B*: Across participant average absolute percent error between measured and predicted metabolic power for various outdoor conditions using full MLR and NN models, as well as smartwatch (SW) models.

CONCLUSIONS

Development of a cheap, lightweight method for accurately estimating energy expenditure could allow researchers and clinicians to predict energy expenditure outside lab settings, for extended periods, and in diverse populations [4]. This could have applications in the design and control of assistive aids, gait rehabilitation, weight-loss programs, and sport and recreation.

Validation of the Lower Limb Joint Kinematics in the Sagittal and Frontal Planes Calculated by a Self-Developed Dual Kinect Azure Sensors System

Kun-Chun Lin[1], Hsuan-Lun Lu [1]

[1] Department of Biomedical Engineering, Da-Yeh University, Changhua, Taiwan (R.O.C.)
Email: hllu@mail.dyu.edu.tw

INTRODUCTION

Human movement analysis is widely used in the fields of clinical diagnosis, treatment evaluation, sport science, cinema/game industry. Infrared stereophotography motion analysis system is most used to be implemented owing to its high accuracy and reliability. However, it requires experienced operators, sufficient space for system setup, expensive cost of the system, complicated experimental setup. These not only decrease the will of the target subjects but also limit the widespread implementation in the current clinical practices. Machine learning based depth-RGB camera system, i.e., Kinect azure, gave an opportunity to estimate the three-dimension positions of the body joints. Studies on evaluation capability, measurement accuracy and usages in clinical practices using Kinect Azure based measured system have increasing trend recently. However, the accuracy of the joint kinematics was not investigated in the previous studies. Therefore, the current study aimed to evaluate the accuracy of the joint kinematics in the lower limbs during gait determined using dual Kinect azure sensors by conducting with VICON system.

METHODS

Twelve young subjects were participated in the current study. Each subject wore Plug-In-Gait marker set and was asked to walk at his/her preferred walking speed, under surveillance of six-camera stereophotography system (VICON, Vero 2.2). At the same time, two Kinect azure sensors were positioned alongside to the walking direction, the camera focal axis was set to around 30 degrees faced to the subject. Two Kinect Azure were both calibrated following the procedure instructed by OpenCV [1]. The relative coordinate systems of the two Kinect sensors were then determined. Each joint position was calculated as the mean position when transformed the coordinates from slave Kinect sensor to master Kinect sensor. The definition of the sagittal and frontal planes was then determined by adjusting the walking direction of the whole gait cycle and vertical direction. The joint angles were obtained by connecting the target joint position to adjacent joints and then projected to sagittal and frontal planes, to derive flexion/extension and abduction/adduction angles of each lower-limb joint. Each joint angle in the complete gait cycle was then extracted from both systems. Following with a linear interpolation procedure, 101-point data will be determined for each joint angle in a gait cycle. Root-mean-square errors (RMSE) were then calculated by dividing two set of 101-point data. The larger the RMSE value, the less accurate the joint kinematics determined by Kinect system.

RESULTS AND DISCUSSION

The joint kinematics of the ankle had higher accuracy when compared to the knee joint (Fig. 1). The higher RMSE values of the knee joint could be caused by the noisy estimation of the hip joint. The machine-learning based joint position tracking kernel has been reported that lower measuring accuracy for the estimation of the hip joint. Therefore, the linkage represented of thigh that defined by knee and hip joint positions could thus be affected [2].

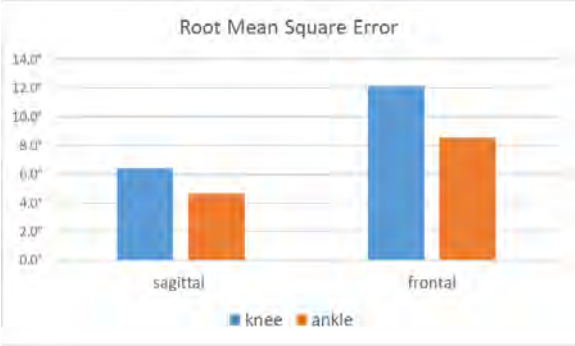

Figure 1 The root-mean-square error (RMSE) determined by dual Kinect Azure Sensor, which were compared to VICON system. The RMSE values of the knee (6.4° and 12.2°) and ankle (4.7° and 8.5°) in the sagittal and frontal planes, respectively.

CONCLUSIONS

The current study has successfully investigated the accuracy of the calculation of the joint kinematics determined by a dual Kinect Azure sensors system, when compared to the Vicon system. The current study could provide useful information for the implementations using Kinect Azure and the descriptions of error distribution for the further studies.

CHANGES IN FOOT PRESSURE DURING DOWNHILL WALKING AFTER USING A BIOFEEDBACK WHICH REDUCES ACCELERATION

Alexandra Giraldo-Pedroza, Winson Chiu-Chun Lee
School of Mechanical, Materials, Mechatronic and Biomedical Engineering, University of Wollongong, Wollongong, Australia
Email: ccwlee@uow.edu.au

INTRODUCTION

Maintaining stability during gait is a challenge for the postural control system, which increases with ageing and inclined surfaces. Older adults have greater landing vertical accelerations than younger adults [1]. Walking downhill can further increase acceleration and produce faster forward body movement [2], which affects postural stability. This increases the risk of falls outdoors [3]. Whilst wearable devices that provide customized biofeedback have been used to improve gait performance in older adults, there is a limited attempt in using biofeedback to improve stability during a downhill walk. Landing acceleration during walking reflects how well the centre of mass (COM) moves to disperse the force of the body as it lands. In this pilot study, we investigate the changes in stability after using biofeedback which aims to reduce landing acceleration. Stability was studied through the analysis of the plantar pressure distribution (PP) and the displacement of the COP.

METHODS

To measure landing acceleration (LA), a 2.4cmx2.4cm 9DoF IMU Breakout (SparkFun 9DoF IMU Breakout – ICM20948) was firmly taped to the anteromedial distal aspect of the tibia. The IMU was aligned with the tibia's longitudinal axis and LA was measured. The IMU communicated with a wireless biofeedback unit. It included a board ATmega32U4 (SparkFun Qwiic Pro Micro) and two vibrating motors (1027 Flat Coreless Vibrating Motor, Baolong Electronic Group) placed in the back of the pelvis. A customized Arduino (1.8.19) and MATLAB (20018b) program were built to analyse based on stride segmentation the peak acceleration during heel strike and provide a 3.5v signal noise indicating the exceed of the target acceleration.
The experiment involved a healthy 67-year-old female volunteer. Her initial LA was measured as she walked downhill on a 10° slope and 18.2 meters ramp. She then underwent a gait retraining walking for 15 minutes at the same downhill condition. The training involved the use of biofeedback, which vibrated unless 20% reduction in LA was achieved. The participant was instructed to move the pelvis' weight backwards as a strategy to reduce the acceleration.

The participant walked over the standardised pressure floor mat GaitRite to collect measurements of the COP and COM measurements. A total of 94 steps were analysed. To analyse the PP, the foot was divided into six areas: rearfoot (A1, A2), midfoot (A3, A4), and forefoot (A5, A6). LA was recorded by the IMU device and filtered using a weighted average low-pass filter at 8.3 Hz.

RESULTS AND DISCUSSION

Analysis showed that biofeedback has reduced the LA by approximated 20.4%. The total anteroposterior displacement of the COM increased by 2.7%. While its velocity increased by 3% at heel strike, it decreased by 27% at the end of the midstance phase.
The impulse was reduced at the heel and midfoot by more than 10% (A1, A2, A3) while it increased by 15% at the distal midfoot. The peak pressure decreased at the heel between 5-10% (A1, A2) while increased in the distal midfoot and toes (A4, A5, A6 >10%). The area of contact increased by more than 10% at the distal midfoot (A4).
Based on these results, a slower velocity in the COM at the mid stance suggests locomotion adjustments that may influence reductions in forward momentum during the propulsion phase and in agreement with the literature, it could promote stability [4]. It may be possible that due to the reduction of load at the heel and midfoot, there is a greater shock absorption, which is required for stabilising the walk. This pilot study found increments in the impulse at midfoot and toes. The push-off requires impulse to increase the swing capacity and further stabilise the heel during heel strike.

CONCLUSIONS

In this pilot study, it was observed that after using biofeedback which reduces landing acceleration, there was a reduction in the velocity of the COP, a reduction in the load and a greater impulse in the forefoot. This may imply evidence of strategies to promote stability, however further studies need to be completed with greater samples size.

SUMMARY

Gait events such as heel strike (HS) and toe-off (TO) are detected using inertial measurement unit (IMU) data, i.e., from a 3D accelerometer or 3D gyroscope, or both. IMU algorithms require sensor orientation and threshold tuning, which are operator-dependent and necessitate substantial expert user intervention. Deep learning (DL) offers a data-driven alternative for detecting gait events in an automated manner. However, little is known about how sensor placement affects DL's ability to detect gait events. Therefore, this study examined the usability of DL to classify sensor placement and then detect gait events by using a variety of IMU placement combinations as input. **Our approach was able to classify the placement of sensors with an F1 score of 98.9% using an accelerometer. Over 99% of the test set, all sensors detected HS within 15ms. TO detection decreased from Ankle (97.3%), Wrist (89.1%), Head (87.3%) to Trunk (65.2%).** As seen, the detection of TO compared to HS detection remained challenging, especially in Trunk. Thus, depending on the task, different sensor sets should be considered to detect gait events in a repeatable and fully automated manner.

INTRODUCTION

Neuromotor impairments in diseases like Parkinson's Disease are identified through clinical gait analysis. Accurate gait event detection is necessary for this study, especially for IC and TO. Experts must currently manually identify these occurrences in clinical practice using kinetic (which requires force plates) or kinematic data, which is time consuming, expensive, and operator dependent. Applications of Dl and IMUs have shown their ease of us and potential for detecting gait events[1], allowing extensive use cases in remote conditions, i.e., home monitoring. Little is known about how sensor placement affects DL's ability to detect gait events. Additionally, it is yet unclear how different combinations would affect the detection outputs of algorithms. This has substantial practical relevance because the number of sensors and their positions can vary greatly. Such evaluations would make it possible to choose the best placement of IMUs for screening and monitoring operations.

Therefore, this study aims to investigate a) how well DL can classify the sensor placement from IMU data and b) what sensor placement provides the most optimal performance for gait event detection.

METHODS

3-D kinematic and IMU data were collected from **22 participants** (Age: 26 ± 2.6 years) who performed barefoot walking on a treadmill for 6 minutes. The true events were found using a 3-D kinematic marker-based foot velocity algorithm. We assigned 80% of the data to the training set, 10% to the validation set, and 10% to the test set to avoid overfitting. The total dataset includes 25200 events (12600 IC and TO events each). The network utilized a Convolutional Neural Network (CNN) consisting of a **6-layer of conv1D (**specialized for capturing data that have long-range dependencies) **followed by BatchNorm1d and SiLU,** a fully connected output layer, and a sigmoid activation function. Tri-axial acceleration and angular velocity time series were cut to a length of 256 frames around the true event with a random offset and used as inputs to train the model with an Adam optimizer (learning rate=0.001) and a weighted binary cross-entropy loss to balance the occurrence of gait events within the data input (1HS and 255 no event).

RESULTS AND DISCUSSION

Table 1: An overview of performance for HS and TO evaluated recall, precision, and F1 score. TP: Detection rate of annotated events, FP: Detection of events that are not annotated, FN: No detection

Sensor Placement	Ankle						Wrist					
Matrix	TP	FN	FP	Recall	Precision	F1	TP	FN	FP	Recall	Precision	F1
HS	3596	0	0	100	100	100	3586	0	11	100	99.7	99.85
TO	3409	0	186	100	94.8	97.33	2733	165	505	94.3	84.4	89.076
Sensor Placement	Head						Trunk					
Matrix	TP	FN	FP	Recall	Precision	F1	TP	FN	FP	Recall	Precision	F1
LHS	1785	0	17	99.1	99.1	99.1	1798	0	2	100	99.9	99.95
RTO	1361	111	226	92.5	85.8	89.02	612	448	117	57.7	84	68.409
RHS	1791	1	8	99.9	99.6	99.75	1804	0	0	100	100	100
LTO	1328	24	427	98.2	75.7	85.49	725	164	726	81.6	50	62.006

The model successfully detects the placement of the sensor with an accuracy of 99.2%, using 3D acceleration. Overall, HS detection scored an average of 99.75%, and TO providing 81.8% using both the 3D acceleration and gyroscope. Despite the general acceptance of TO detection being more challenging, it is interesting to observe a substantial deterioration of performance at the trunk level. Our results were based on a primitive DL model; thus, more advanced models, such as Temporal Convolutional Network and Attention Transformer, could improve the overall performance. The robustness of the DL model can be improved by training on a different population group, such as the elderly, thus ultimately providing optimal gait event detection in a repeatable and fully automated manner to ease clinical gait analysis.

Evaluation of hip joint kinetics in rehabilitation exercises for children with cerebral palsy

Jasper Kwasny[1], Uwe Kersting[1], Ibrahim Duran[2], Eckhard Schönau[2] and Cynthia Fantini Pagani[1]
[1] Institute for Biomechanics and Orthopaedics, German Sport University Cologne, Cologne, Germany

INTRODUCTION

Children with cerebral palsy (CP) are often prescribed strength training exercises to improve independent gait and avoid or delay the necesity of orthopaedic intervention. However, strategies for preventing hip dysplasia in children with cerebral palsy lacks clinical consensus. Exercises which maximize hip extensors have been suggested as a possible target group [1]. Attempts to identify these exercises have been done from an EMG perspective, however, exercises which generate maximal hip extension moments in children with CP remains unknown.

METHODS

Four typically developing children (13.75±0.4 years, 60.3 ±15.1kg) and four (12.8±2.6 years, 44.5±11.9kg) children with CP participated in one kinematic and kinetic data collection session in a motion capture lab with 18 infrared cameras at 200 Hz (Qualysis) and in-ground and stairway instrumented force plates at 1000 Hz (Kistler). Subjects completed five repetitions of three typical rehabilitation exercises prescribed to children with CP: Bilateral squats, lunges, hip extension step up-and-down, as well as gait. The children with CP were permitted to use a rail for balance during squat and lunge. A generic musculoskeletal model [2] was scaled to static trials, and kinematics and kinetics were calculated for the exercises using OpenSim 4.4. Inverse kinematics and inverse dynamics were used to compute hip extension moments. Trials were time normalized to 100 percent and to subject body mass and mean moment curves were generated over all trials and subjects. Descriptive statistics and qualitative assessments were used to analyse the peak hip extension moments and mean hip extension moment curves due to the small sample size at this stage.

RESULTS AND DISCUSSION

Preliminary results indicate that the hip extension step up-and-down exercise generated the maximal hip extension moment in the children with CP (1.075 Nm/kg ±0.401), whereas in the control group, maximal extension moment occurred in the lunge exercise (1.408 Nm/kg ± 0.227) (Figure 1). Peak normalized hip extension moments decreased in the lunge and squat exercise relative to gait in the children with CP as they unloaded their hips while using the support rail.

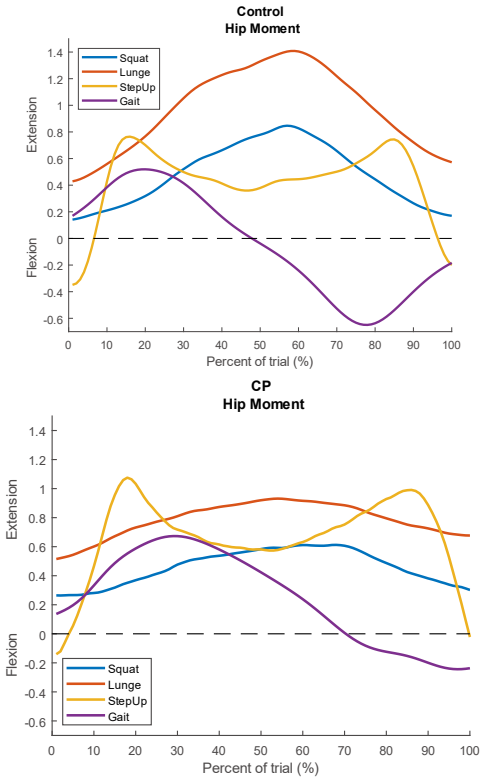

Figure 1 Normalized hip flexion and extension moments (nm/kg) of various exercises in children with CP and healthy controls.

CONCLUSIONS

Early results suggest hip extension step up-and-down exercise maximizes hip extension moments in children with CP. Future aims to evaluate the exercise protocols include increasing the sample size, and calculating the magnitude and orientation of the hip joint contact force, using subject specific musculoskeletal modelling.

INTRODUCTION

Cam deformity of the proximal femur leads to a loss in the naturally concave head-neck junction. It has been linked to the development of intra-articular damage, femoroacetabular Impingement and ultimately to the early onset of hip osteoarthritis. Compelling evidence has identified adolescent males with high levels of physical activity to be at greater risk of developing CAM.

Recent longitudinal studies have shown that adolescents who develop CAM have distinct morphological features of the femur on radiological scans.[1] However, findings were primarily extracted from static imaging thus neglecting the highly dynamic nature of the etiology. Therefore a multidimensional kinematic exploration of movement execution and its association with the longitiudnal changes of radiological spine-pelvic-femoral parameters is highly warranted in this population.

METHODS

26 elite football players were included for baseline measurements and 2-year-follow-up measures are currently ongoing (6/26 completed). Players were initially included if they trained for a minimum of 12 hrs/week and underwent physical screening to rule out current pain or injury. Both at baseline and follow-up, participants underwent a hip radiographic examination consisting of a modified Dunn view scan and a full body bi-planar radiography scan (EOS imaging, Paris, FR): Table 1. Based hereon (alpha angle > 60°), participants were divided in a CAM and no-CAM group at follow-up. In addition, 3D kinematics (Vicon, UK) were collected during a range of motor tasks, including unconstrained deep squats. Resulting data was exported to Visual3D software (C-motion, USA) to analyse peak joint angles of pelvis and hip in the dominant leg.

	Age (years)	Weight (kg)	Height (cm)	Alpha angle (°)	Neck Shaft Angle (°)	Pelvic Incidence (°)
CAM (n=3)						
Baseline	14.3±1	54±9.5	162.2±6.7	52.0±4.4	133.1±2.9	49.4±7.0
Follow-up	16.6±1.5	65.6±6.5	173.2±5.2	63.2±2.8	134.3±1.7	49±3.0
No CAM (n=3)						
Baseline	13.4±0.2	52.0±11.4	168.0±10.6	51±2.7	129.0±5.1	45.9±3.0
Follow-up	15.5±0.2	65.3±7.6	179.9±3.2	53.2±2.2	130.6±3.7	46.3±5.8

Table 1: Descriptive statistics and femoro-spinoplevic angles for the two measurement points.

RESULTS AND DISCUSSION

Statistical significance was set to p <0.05 and a non-parametric approach was used. Kinematics at baseline vs. Follow-up showed significant differences in pelvis anteversion and hip abduction within the CAM group. Pelvic anteversion also significantly differed between the CAM and no CAM groups at follow-up. A Spearman correlation revealed a significant positive correlation between alpha angle and pelvic anteversion (r=0.92) as well as pelvic incidence (PI) (r=0.84) at follow-up.

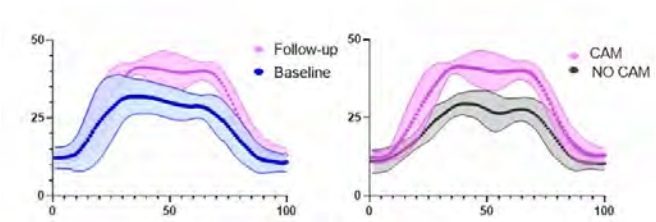

Figure 1: Y-axis represents Sagittal Pelvis range of motion in degrees (anteversion +) and X-axis represents 1 deep squat cycle.

CONCLUSIONS

Our preliminary results show that adolescents who develop CAM exhibit peak pelvic anteversion values that are higher than their baseline values as well as higher than peers with no CAM at follow-up. Such movement pattern has been linked to excessive anterior femoral head coverage which can lead to impingement.[2] This seems to be associated with an increase in PI values. A higher PI has been identified in adults with CAM as a predictor of symptom development in femoroacetabular Impingement.[3] Hence longitudinal analysis of dynamic spinopelvic characteristics has potential to identify adolescents that are at high risk of developing CAM as well as recognize charaterstics linked to symptom development in adulthood.These findings can be relevant in establishing clinical screening protcols.

INTRODUCTION

Postural abnormalities are widespread in developed countries that can contribute to musculoskeletal disorders, pains, and diseases [2]. Although some advanced postural screening technologies exist, they are typically only available at specialized clinics [1]. Bodiometer is an innovative and accessible solution for mobile devices, offering a non-invasive, user-friendly, and cost-effective postural screening technology. This study aimed to evaluate the validity and reliability of the Bodiometer mobile app for 2D postural analysis in the sagittal plane.

METHODS

Step 1 – Validity: Bodiometer scans (using an iPad 8th) were compared to the data generated from a Vicon Motion System (6 Cameras, Vero, 100Hz), the reference gold standard. To conduct the tests, we used a mannequin. This approach helped eliminate the variability in individual participants. It enabled a clear understanding of the instrument's functionality and the potential for operator measurement errors without the interference of posture variability. To ensure consistency with Bodiometer's automatic virtual marker set, we placed reflexive markers on specific landmarks, including the right ear, shoulder and hip joint, lateral knee, and ankle. Then, we measured the angles of body parts – head, shoulder, hip, and knee – relative to the vertical line using the reflexive markers placed on specific landmarks, following the Bodiometer's approach (Figure 1). A total of 15 trials were collected using a tripod. The data was analyzed using one-sample t-test (Vicon's mean angle vs. Bodiometer), Intraclass Correlation Coefficient (ICC), and Root Mean Square Error (RMSE). Step 2 – Reliability: To assess the inter-rater reliability, five raters used iPads to screen posture, replicating the process used in clinical settings. To determine the intra-rater reliability, each rater repeated the tests three times within a single session, with a 3-minute. The app automatically calculated the angles of the body parts. To evaluate both the inter-rater and intra-rater reliability, we used the Intraclass Correlation Coefficient (ICC).

RESULTS AND DISCUSSION

Table 1 shows significant differences between Bodiometer and Vicon. The ICC was 0.95 for the validity data. For the reliability we observed excellent inter-rater reliability with an ICC of 0.99. Additionally, all evaluators exhibited excellent intra-rater reliability, with ICC values raging from 0.97 to 0.99.

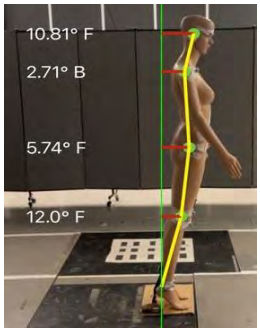

Figure 1 Virtual markers and body part angles generated using Bodiometer's mobile app for postural analysis.

CONCLUSIONS

Our study demonstrates that Bodiometer's mobile app is a valid and reliable tool for 2D postural analysis in the sagittal plane.

ACKNOWLEDGEMENTS

A MACHINE LEARNING APPROACH TO DIFFERENTIATE STABLE FROM UNSTABLE TOTAL KNEES FOR DATA MINING

Erica M. Ramirez [1], Kathrin Ebinger [1], Christopher Ferrigno [1], Denis Nam [1], and Markus A. Wimmer [1]
[1] Department of Orthopedic Surgery, Rush University Medical Center, Chicago, USA.
Email: markus_a_wimmer@rush.edu

INTRODUCTION

Joint instability after total knee arthroplasty (TKA) is a common observation and has been associated with activity limitations, pain and poor quality of life. From a mechanical perspective, joint stability is preserved when the joint can recover from subtle perturbations. However, establishing objective measurements for knee stability has been difficult [1]. Here, we propose a semi-supervised approach using clustering techniques to separate stable from unstable knee joints based on gait pattern and to subsequently data mining of the kinematic, kinetice and electromyographic (EMG) features. For the purpose of this abstract, we focus on EMG features and hypothesized that co-contractiction indices may differ.

METHODS

TKA subjects with occasional or frequent instability of the knee joint during daily activity underwent gait analysis in the Human Motion Lab. All subjects were evaluated with a point cluster (PCT) marker set and EMG surface electrodes. The ratio of mean EMG rectus femoris and biceps femoris was determined for each of the eight phases of the gait cycle according to Perry. Additional TKA subjects, who were tested under identical protocols, were added from an IRB approved data repository. As a comparator group, a healthy, elderly subject group, whose gait features should be different from those with self-reported and/or suspected TKA instability, was included as well.

Fourteen different gait variables, previously discussed as potential objective knee instability parameters [2], were applied to cluster subjects. Each combination was processed through a self-organizing map (SOM) with the neurons distributed in a two-dimensional grid. The SOM was tuned to different topographies, learning rates, and epochs; then each SOM output was used as input for the k-means. In our approach, the optimal number of clusters was investigated (between 2 and10). The solution reliability was evaluated through the Fleiss' Kappa index, and the clusters' consistency was assessed with the Silhouette coefficient. To identify differences between groups, one-way ANOVAs were performed. Post-hoc tests between groups were done using Bonferroni or Games-Howell.

RESULTS AND DISCUSSION

The final cohort comprised 91 TKA subjects and 34 healthy control subjects. Several combinations reached an almost perfect agreement, suggesting that clustering did not occur by chance. However, regarding the clusters' consistency, only two combinations gave reasonable results with one seemingly addressing 'instability'. A split based on dynamic joint stiffness (DJS) lead to a 'high stiffness' group with a minority population (12%) that included all but one of the known unstable subjects. The remaining TKA subjects showed a lower stiffness that was comparable with that of the healthy group. Hence, data mining was conducted on the DJS based clustering.

The EMG coactivity ratios throughout the gait cycle are shown in Figure 1. During the periods of initial contact, loading response and terminal swing the biceps femoris was dominant. During the remaining periods, for both the 'low stiffness' and 'healthy' subjects, the rectus femoris had a relatively higher activity than the biceps femoris, with a peak during initial swing. In contrast, for the 'high stiffness' subjects, biceps femoris activity was dominant ($p=0.033$ during initial swing).

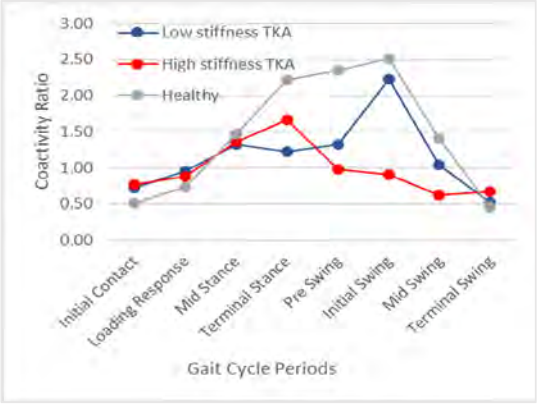

Figure 1 EMG Rectus Femoris to Biceps Femoris coactivity ratio.

CONCLUSIONS

Gait analysis in conjunction with machine learning provides a rich resource for discovery. Using a clustering approach that split the TKA cohort, we found differences in co-contraction indices between stable and unstable total knee joints.

ENGAGEMENT OF THE CRUCIATES AND MEDIAL MENISCUS IS RELATED TO ANTERIOR-POSTERIOR KNEE LAXITY BUT NOT CRUCIATE LIGAMENT VOLUME

INTRODUCTION

Rupture of the anterior cruciate ligament (ACL) is a debilitating injury with increased prevalence among young, active individuals[1]. Clinical studies have identified intrinsic factors that are associated with increased risk of non-contact ACL injury to guide interventions in these high-risk groups, including ligament properties and joint kinematics[2]. In particular, heightened anterior-posterior (AP) laxity is a risk factor for first time non-contact ACL injury, especially in females[3]. The anterior and posterior cruciate ligaments (ACL and PCL) are the primary ligamentous restraints to anterior and posterior tibial translation. Moreover, the ACL and medial meniscus (MM) work in concert to resist applied anterior tibial loads[4,5]. However, biomechanical factors that explain heightened AP laxity in the native knee are poorly understood. It is also not well understood how these parameters of tissue engagement relate to tissue geometry. The purpose of this biomechanical study was two-fold: to determine 1) whether AP laxity of the native knee is related to the biomechanical function of the ACL, PCL, and the menisci as quantified by the parameters of tissue engagement and 2) whether ACL and PCL volume is related to these tissue level properties of engagement.

METHODS

Thirteen, unpaired, fresh-frozen human cadaveric knees were acquired for testing (age: 37 ± 9, range: 25-54; 7 female) and MR scanned. Specimens were mounted to a robotic manipulator (Kawasaki ZX165U). Using the robot, AP forces of ±100 N were applied at 30° of flexion to simulate a clinical test of AP laxity. The force carried by the cruciates and menisci as a function of the applied AP loads was calculated via the principle of superposition. Subsequently, engagement parameters of the ACL, PCL, MM, and lateral meniscus (LM) were quantified. These parameters were: (1) in situ slack, (2) in situ stiffness, (3) tissue force at the peak applied anterior and posterior loads[5]. Subsequently, net in situ slack, defined as the difference between in situ slack of the ACL and PCL and of the PCL and MM was calculated. Finally, we measured cruciate volume using manual segmentation of the MR scans (Fig. 2). To address our goals, simple linear regressions were performed to identify correlations between (1) AP laxity and net in situ slack (mm) of the ACL/PCL, the PCL/MM and (2) AP laxity and in situ stiffness (N/mm) for each structure and (3) ACL/PCL volume and the parameters of tissue enagement. Finally, ACL and PCL volume were related to net in situ slack via multiple linear regression.

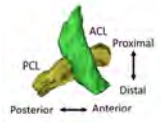

Figure 2: Representative segmentation of the ACL and PCL.

RESULTS AND DISCUSSION

The net in situ slack of the PCL/ACL and PCL/MM averaged 4.2 ± 2.2 ranging from 0.1 to 7.6 and 4.9 ± 2.7 mm ranging from 0.1 to 8.0, respectively (Fig. 1). AP laxity was positively correlated with the net in situ slack of both the ACL/PCL and the PCL/MM ($p \leq 0.008$) and to in situ stiffness of the ACL and the PCL ($p \leq 0.001$). ACL and PCL volume averaged 2430 ± 586 and 2670 ± 502 mm^3, respectively. ACL and PCL volume did not correlate with any parameters of engagement ($p>0.6$).

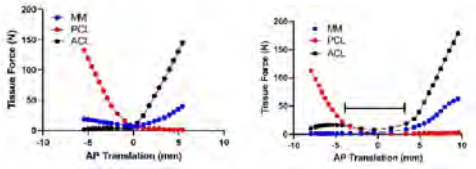

Figure 1: Representative plots of two knees with the least (left) and greatest (right) net in situ slack of the PCL and ACL. The black bar indicates net in situ slack.

We introduced a novel biomechanical measure, net in situ slack, which describes how force is passed between the major AP stabilizers as the knee undergoes AP translation. Our findings suggest those with heightened AP laxity may require specialized neuromuscular training to ensure their muscles effectively resist AP loads. This novel relationship may also inform surgeons how to tension ACL and PCL grafts intraoperatively. In knees with elevated AP laxity, the cruciates and medial meniscus provide minimal restraint to AP loads over a substantial range of AP translation. Therefore, individuals with highly lax knees must be more reliant on the muscular and articular anatomy to maintain joint stability, which may leave them at elevated risk of injury.

CONCLUSIONS

The net engagement of the PCL and ACL and the PCL and MM provide a framework for understanding why those with heightened AP laxity are at elevated risk of non-contact ACL injury. This framework provides the underpinnings for more focused injury prevention algorithms targeting muscular stabilizing mechanisms to compensate in the AP direction.

INTRODUCTION

Despite leading to joint discomfort in up to a third of players with total knee arthroplasty (TKA) [1], golf remains one of the most recommended sports by orthopaedic surgeons after knee replacement [2]. Among the potential solutions proposed to address this problem is the recommendation to modify a golfer's stance. This investigation therefore aims to assess rotational knee kinematics during the golf swing in three different foot positions of the leading leg. Our approach differs from that of previous research primarily in its focus on elderly TKA patients over young healthy participants, thereby serving as a better representation of the affected population.

METHODS

Eleven recreational golfers (age 69.6 ± 8.8 years; 2 females; weight 83.6 ±15.5 kg; height 1.78 ± 0.08 m; BMI 26.3 ± 3.8; months post-op 43.7 ± 11.9) with TKA in the lead leg were analysed at least two years post-operatively. Six subjects had Fixed-Bearing Persona TKA (Zimmer Biomet), while five had Mobile-Bearing Attune™ TKA (DePuy Synthes) implants. The golf swing using an 7 iron golf club was evaluated for three different foot positions of the lead leg: 1) self-selected, 2) 0° external rotation, and 3) 30° external rotation from stance set up to the end of follow-through. Motion capture used a marker-based optical system and the IfB marker set [3]. Rotational knee kinematics were evaluated using a linear mixed model analysis of variance ($p<0.0005$), with different foot positions as fixed effects (self-selected condition excluded), and implant design and subject as random effects.

RESULTS AND DISCUSSION

For the left knee, an angled lead foot significantly increased maximum tibial external rotation, while decreasing maximum internal rotation. Overall range of motion (ROM) in this plane was increased by a 30° foot position. In the frontal plane, ROM was not significantly affected, although maximum abduction decreased, and maximum adduction increased. For the right knee, an angled foot decreased ROM in the sagittal plane, while in the transverse plane maximum internal rotation decreased.

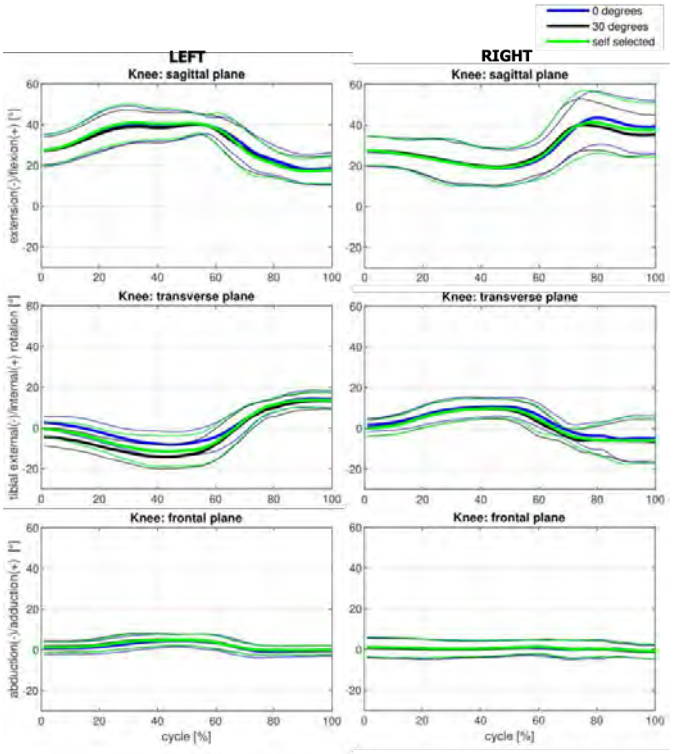

Figure 1 Angle progressions in three planes for left and right knees normalised to the golf swing cycle. Results presented as the mean (thick line) ± 1 SD (thin lines) over the subjects (n = 11).

CONCLUSIONS

Varying the position of the lead foot in the golf stance influences knee kinematics during the golf swing.

INCLUSION OF DISTAL FIBULAR TRANSLATIONS IN MULTI-SEGMENTED FOOT MODELING FOR LATERAL ANKLE LIGAMENT STRAINS

Renee Alexander[1], Rui Ding[1], and Tim Derrick[1]
[1] Department of Kinesiology, Iowa State University / Ames, Iowa, United States.
Email: rma24601@iastate.edu

INTRODUCTION

Ankle sprains account for over 80% of ankle injuries in sports with ankle injuries reported as 10-30% of all sports injuries [2]. Musculoskeletal models can be used to assess the strain in individual ligaments if the kinematics of the relevant bones are known. Input to these models are typically segment or joint angles, however, the distal fibula is known to translate relative to the tibia during plantar flexion and dorsiflexion [5]. It is unknown how these translations will affect the resulting ligament strain. Damage to the anterior talofibular (ATFL), posterior talofibular (PTFL), and calcaneofibular (CFL) ligaments characterize a lateral inversion ankle sprain. Thus, any movement of the fibula may impact the lateral ankle ligament strains and, therefore, the potential for an ankle sprain. The purpose of this research was to use a musculoskeletal model to estimate the effects of fibular translation on resulting lateral ankle ligament strain during plantar flexion and dorsiflexion at the tibiotalar joint.

METHODS

A musculoskeletal model of the foot [4] was implemented in MATLAB. The vertical and mediolateral translation of the distal fibula relative to the distal tibia were estimated from [3] for a typical range of motion during slow running of -20° plantar flexion to 20° dorsiflexion [1]. Anteroposterior translations were small and inconsistent and therefore not modelled. Anatomical position strains were estimated to be 3, 8, and 7% for the ATFL, PTFL, and CFL ligaments respectively [6]. Two models were developed, one without and one with tibiofibular translations.

RESULTS AND DISCUSSION

In both models, as the tibiotalar joint became more plantar flexed, strain increased in the stretched ATFL, decreased in the relaxed PTFL and remained relatively constant in the CFL (Figure 1). Fibular translations increased strain in the ATFL and the CFL at -20° plantar flexion. PTFL strains decreased. However, PTFL and CFL strains increased at 20° dorsiflexion (Table 1). Between the models, the inclusion of fibular translations increased the ATFL and PTFL's strain change per degree of plantar flexion/dorsiflexion at the tibiotalar joint, and hence increased their maximum strain and laxity at the ends of the tested range of motion. The strain in the CFL, however, did not change much between the models.

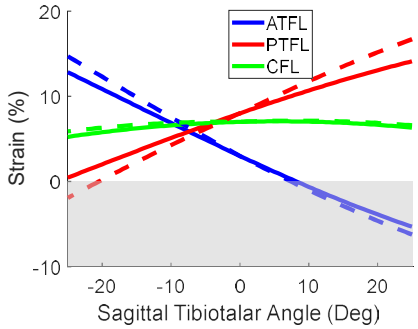

Figure 1 Ligament strain estimates for the ATFL (blue), PTFL (red), and CFL (green). Dashed lines represent the model including fibular translations as compared to the model without (solid lines).

CONCLUSIONS

Fibular translations were included in a musculoskeletal model to estimate their effect on resulting lateral ankle ligament strains during plantar flexion and dorsiflexion. Ligament laxity and strains increased based on the ankle position within the range of motion. Our musculoskeletal model can become more accurate by including fibular translations; however, it is not clear if these small values can be estimated in vivo when skin marker movement is included.

INTRODUCTION

The elasticity of skeletal muscle is defined as the length-tension relationship for modeling the muscle [1]. The length-tension relationship should be biomechanically accurate for every muscle because it substantially influences the simulation of musculoskeletal model. However, prior models are limited in muscles on the two-dimensional (2D) joints, such as the ankle and knee, unable to address the muscle across the three-dimensional (3D) joint, such as the shoulder. The reason behind this is an ill-posed problem as formulating many-to-one correspondence between joint postures and muscle tension. Here we demonstrate a novel method to model the 3D posture-tension relationship of the human skeletal muscle by identifying the passive properties.

METHODS

Data were obtained from five healthy men. The posture of upper limb and the shear modulus of pectoralis major muscle passing across the shoulder joint were simultaneously measured using motion capture system and ultrasound elastography respectively, while the upper limb was passively and slowly moved to the horizontal extension direction by a dynamometer (2 degree/s) to lengthen the pectoralis major muscle. These measurements were systematically performed on nine movement planes at 10 to 90° abduction, and consequently a large amount of data on the shear modulus and its corresponding postures was obtained (Figure 1 A).

The shear modulus corresponding to postures was represented in the polar coordinates. Subsequently, we performed the dimensionality reduction to transform the data points of shear modulus from the polar coordinates into a one-dimensional space by minimizing the area enclosed by the boundary of data points of shear modulus (Figure1 B). Finally, the conventional linear and exponential function previously used to model the passive muscle properties in the 2D joint [2] was fitted to the experimental data on the low-dimensional space using a least square method. The fitting accuracy was assessed by calculating the coefficient determination (R^2).

RESULTS AND DISCUSSION

Interestingly, the shear modulus corresponding to 3D postures in the polar coordinates presented an analogical geometric distribution to that in the 2D joint. Consequently, the R^2 in terms of fitting accuracy ranged from 0.75 to 0.93 in all participants, indicating the conventional linear and exponential model can be accurately fitted to the experimental data (Figure1 C). Figure1D shows the modeled relationship between 3D postures and shear modulus in Cartesian space. In this figure, as a representative of the many-to-one correspondence between postures and shear modulus, the dashed red line indicates the so-called muscle slack postures on which the passive tension begins to increase.

In this study, we hypothesized that the 3D posture-tension relationship could be represented in the low-dimensional space by the conventional model, given the comparable biomechanical properties of muscle between 2D and 3D joints. Our results showed that this analogy between 2D and 3D joints holds.

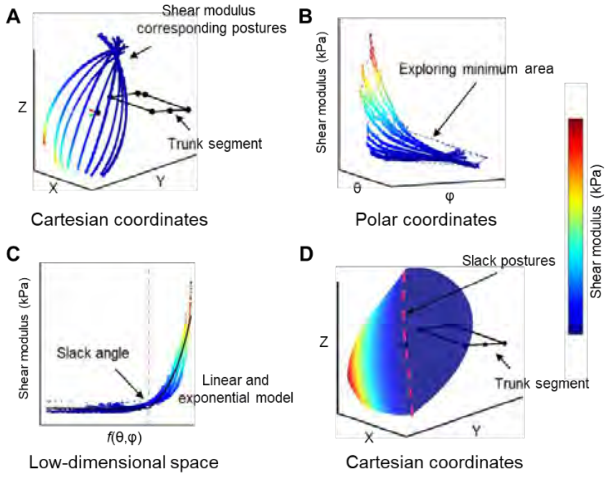

Figure 1 Modeling of 3D posture-tension relationship.

CONCLUSIONS

This study demonstrated that the 3D posture-tension relationship of skeletal muscle could be represented using the conventional model by identifying the passive properties in the low-dimensional space.

INTRODUCTION

Scaled generic musculoskeletal models are commonly used to analyze the movement of human subjects. However, such models do not represent the unique characteristics of individual subjects. To maximize model fidelity, one can use personalization techniques to minimize the errors between experimental measurements and model predictions. This study describes an easy-to-use software toolset for personalizing joint, muscle-tendon, neural control, and ground contact model properties for OpenSim [1,2] musculoskeletal model.

METHODS

We have developed four model personalization tools and a data preprocessing tool to integrate with the OpenSim GUI and run from XML settings files similar to other OpenSim tools [1, 2]. Running a tool starts a Matlab process that performs the actual calculations. The toolset accepts a scaled OpenSim model along with marker motion, ground reaction, and EMG data collected during gait and/or other movements and calculates personalized joint, muscle-tendon, neural control, and ground contact model parameter values. The tools in typical order of use are:

1) Joint Model Personalization (JMP) – personalizes parameters defining joint positions/orientations within bodies and, optionally, body scaling and marker locations within bodies in a scaled OpenSim model.

2) Data Preprocessing - organizes OpenSim inverse kinematics, inverse dynamics, and muscle analysis results calculated after JMP, as well as EMG data, into trial- and data-specific formats to facilitate faster computation and organization for subsequent tools.

3) Muscle-tendon Model Personalization (MTP) - personalizes parameters defining Hill-type muscle-tendon models and estimates muscle activations and forces for muscles with EMG data.

4) Neural Control Model Personalization (NCP) - personalizes parameters defining muscle synergy control models for all muscles and personalizes parameters defining Hill-type muscle-tendon models and estimates muscle activations and forces for muscles without EMG data.

5) Ground Contact Model Personalization (GCP) - personalizes parameters defining deformable foot-ground contact models.

The flow of data and parameter values through the toolset is outlined in Figure 1.

RESULTS AND DISCUSSION

The Matlab-based Model Personalization toolset for OpenSim is freely available on SimTK at https://simtk.org/projects/nmsm. The project includes tutorials that demonstrate how to use each tool based on sample video motion capture, ground reaction, and EMG data collected from an individual post-stroke walking on an instrumented treadmill.

CONCLUSIONS

The Model Personalization toolset described here will make it easier for the research community to develop personalized neuromusculoskeletal models of individual subjects or patients and may eventually help facilitate the design of optimized personalized interventions for various movement impairments.

COMBINED STATISTICAL SHAPE MODEL CAN PREDICT LOWER LIMB BONE SHAPE VARIATION IN A PAEDIATRIC POPULATION

Julie Choisne[1], Laura Carman[1] and Thor Besier [1]

[1] Auckland Bioengineering Institute, The University of Auckland, Auckland, New Zealand
Email: j.choisne@auckland.ac.nz

INTRODUCTION

The skeletal anatomy of children differs significantly from adults, yet musculoskeletal models were mainly developed from adult datasets. Subject-specific models from medical imaging are costly and time-consuming [1]. Ideally, we would scale musculoskeletal models using an atlas built from a population of paediatric bones that captures morphological variation of the growing skeleton. The aims of this study were to: 1) characterise lower limb bone shape variation in a typically developed paediatric population aged 4 to 18 years old and 2) evaluate bone shape prediction error using a combined shape model.

METHODS

Post-mortem CT scans of 333 children (137 F, Age: 12 ± 5 Y, H: 148 ± 24cm, M: 49 ± 22kg) [2] were obtained from the Victorian Institute of Forensic Medicine (VIFM, Australia). The pelvis, femurs, and tibias/fibulas were segmented. Each bone was non-rigidly registered and fitted to a template mesh, using radial basis functions to achieve nodal correspondence. Each pelvis, femur, and tibia/fibula were then rigidly aligned to a selected template case with a neutral pose. The bones were then combined and the shape model was characterized using principal component analysis [2]. The predictive power of the combined statistical shape model was assessed with a leave one out (LOO) analysis using height, ASIS width, femur length, and tibial length, which were found to be the best predictive factors. Further optional inputs to the model can include partial medical imaging and motion capture marker location.

RESULTS AND DISCUSSION

The first 3 principal components (PCs) captured 92.5%, 2.07%, and 0.53% of the variation in the dataset (Figure 1). The first PC described combined size and shape variation and the second and third PCs described shape variation and the aspect ratio of the long bones. The results from the LOO analysis gave an average RMSE of 2.94 ± 0.83mm and a Dice score of 0.8.

CONCLUSIONS

This unique dataset characterises morphological variation in lower limb bones in a paediatric population aged from 4 to 18 years. It allows for prediction of new bone shapes with lower errors than typical scaling for use in clinical settings and musculoskeletal modelling. Future work will add articulation to the model for incorporation into the MAP client for building personalised OpenSim models.

INTRODUCTION

Measuring muscle force during gait can provide critical knowledge in the field of gait biomechanics; however, noninvasive measurement of muscle force is difficult. Muscle force is estimated using a musculoskeletal model. In previous studies, muscle force estimation was assisted by electromyography (EMG), such as %MVC [1]. However, the effect of the electrophysiological characteristics of muscle force exertion, such as changes in joint angle, on the EMG amplitude [2] and electromechanical delay (EMD) of muscles [3] still have not been considered for muscle force estimation using EMG. The purpose of this study was to estimate muscle forces during gait using the angle–EMG–force (muscle activity level) relationship (a.-E.-f. relationship) and EMD of muscles.

METHODS

One healthy adult (male, 21 years old, 169 cm, 59.2 kg) participated. Gait kinematic, kinetic, and EMG data were measured by a motion capture system, force plates, and wireless surface EMG sensors, respectively.

To obtain the a.-E.-f. relationship of the leg muscles, a static force measurement task was conducted for each muscle with a custom-made measurement device. The knee and ankle joint angles were set under five conditions for the tasks. The participant adjusted the EMG amplitude of each muscle to target values (0–150% of the maximum values during gait, every 30%) with visual feedback. The muscle activity level during the task was estimated using a musculoskeletal model (AnyBody Technology). A regression model (a.-E.-f. relationship, quadric surface fitting) under a static condition was constructed.

The EMD was calculated using the estimated muscle force and the EMG signals. The EMD time was calculated with a cross-correlation function [3] using all the data from contraction to relaxation during the task (*ccEMD*). Another EMD time was calculated using the intervals of the EMG and muscle force onsets (*onsetEMD*) and offsets [4] (*offsetEMD*).

The muscle force during gait was estimated using the musculoskeletal model and a Hill-type muscle model with and without the a.-E.-f. relationship and the EMD.

RESULTS AND DISCUSSION

The EMG–force relationship changed with the joint angle. Figure 1 shows the estimated muscle force during gait. The rectus femoris and the tibialis anterior did not generate muscle force during the stance phase in the estimation without EMG but were activated with the a.-E.-f. relationship. These results suggest that muscle force estimation with EMG can include agonist and antagonist muscle co-activation. In addition, the a.-E.-f. relationship provides more accurate estimation compared with previous studies using EMG.

The timing of the estimated muscle activation differed with and without the EMD. Moreover, the onset of *ccEMD* was approximately 7% of the gait cycle later than *onset–offsetEMD,* on average, through the muscles. The peak force difference with and without the EMD was 138 N for the tibialis anterior. The contraction velocity affected the force estimation values.

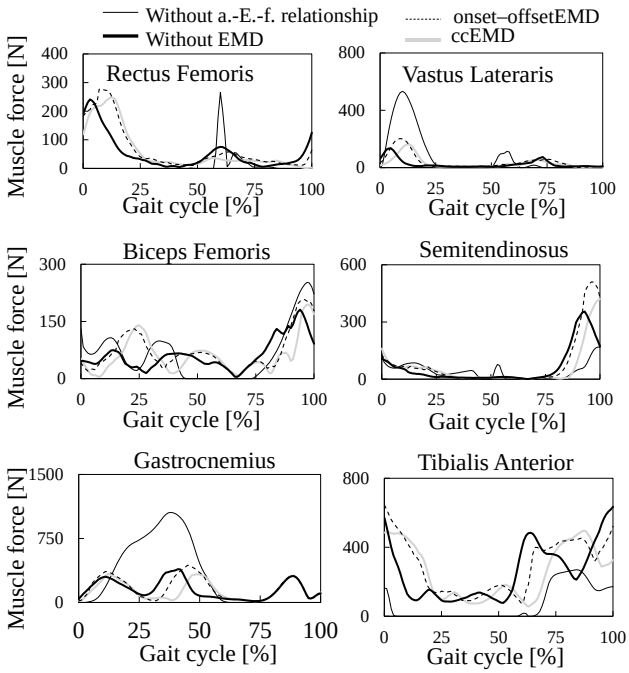

Figure 1 Estimated muscle force

CONCLUSIONS

The muscle force during gait was estimated with and without the a.-E.-f. relationship and EMD of leg muscles. The results showed differences in the activation timing and peak force values. The present method using the a.-E.-f. relationship and the EMD provides more accurate estimation for individuals compared with the methods used in previous studies.

RELATIVE ENERGY COST OF THE GAIT PHASES ACROSS WALKING SPEEDS

Israel Luis[1], Maarten Afschrift[2], Friedl De Groote[3] and Elena M. Gutierrez-Farewik[1,4]

INTRODUCTION

The swing phase was estimated to account for 29% of the total metabolic cost at a preferable walking speed, which lies within the experimental inferences that suggest a relative cost from 10% up to 33% [1]. Yet, little is known about the relative cost of the swing phase across walking speeds. Energy expenditure may be estimated using metabolic cost models, which consist of equations describing the relationship between muscle-tendon mechanics and heat dissipation at various contraction conditions. A comprehensive understanding of the relative cost of the gait phases might support rehabilitation programs and the design of assistive devices. In this study, we performed inverse dynamics musculoskeletal simulations informed with EMGs to estimate the relative energy cost of muscle activity during stance and swing phases across walking speeds.

METHODS

Eight able-bodied adults were asked to walk at 100%, +/-15%, 30%, and 45% of their preferred walking speed, during which gait kinematics (Vicon V16, CGM2.4), ground reaction forces (AMTI), and EMGs in one leg were recorded in biceps femoris long head, semitendinosus, vastus lateralis and medialis, tibialis anterior, gastrocnemius lateralis and medialis and soleus, using bipolar surface wireless electrodes (myon/Cometa). Vastus intermedius excitation was estimated as the average of vastus lateralis and medialis excitations. A musculoskeletal model [2] was scaled to each subject's dimensions, and maximum muscle force was scaled according to muscle volume, estimated based on body weight and height [3]. Inverse kinematics and inverse dynamics were computed for all trials using OpenSim 4.1. The passive force-length characteristics of the muscle actuators were calibrated to match experimental passive torque-angle relationships reported by Silder et al. [4]. An algorithm based on direct collocation was used to solve the muscle redundancy [5]. Recorded time-series EMG data were used to constrain the excitations of the corresponding muscles in the musculoskeletal model. Remaining muscle excitations were computed by minimizing muscle excitations squared assuming optimal motor control. Achilles and patellar tendon stiffness were optimized so that the muscle-tendon actuators' torque better reproduces the inverse dynamics solution. The energy expenditure was computed using a metabolic cost model proposed by Uchida et al. [6], and repeated measure correlation was used to compute the relationship between the relative energy cost of gait phases and walking trials.

RESULTS AND DISCUSSION

Of the total energy cost at self-selected speed, 31.5% occurs during the swing. The major contributor to energy cost in the stance was the plantarflexors during push-off, and in the swing, the hip flexors during initial and mid-swing. Relative energy cost during gait phases correlated with walking speed ($p<0.05$); proportionally, more energy was consumed during stance than during swing as walking speed increased.

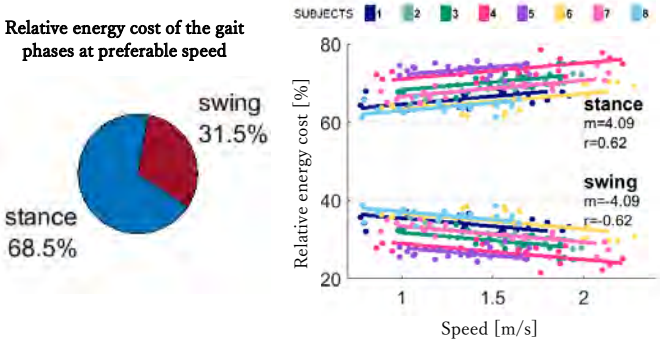

Figure 1 Average relative energy cost of the gait phases among all subjects at the preferable speed [left] and repeated measure correlation of the relative energy cost of the gait phases at each subject across walking trials [right].

CONCLUSIONS

Almost 1/3 of the total metabolic cost during normal walking occurs in the swing phase, and this proportion decreases as speed increases. It is suggested that an increase in the walking economy might be achieved by supporting primarily the plantarflexors during the stance phase and hip flexors during the swing phase.

INTRODUCTION

The passive 6 degree-of-freedom tibiofemoral joint (TFJ) kinematics can be predicted via parallel mechanisms, which are composed of rigid analytic representations of articular contact surfaces and ligamentous constraints [1]. Medical imaging can be used to personalized these mechanisms, but requires extensive manual processing thus limitting widespread use. Automatic identification of feduciary antomy via geometric analysis or atlas deformation has been proposed. However these approaches do not include ligamentous attachments, and thus cannot be used for automatic generation of personalized knee kinematic models. This study aimed to: (1) automatically identify geometrical parameters required to generate personalized TFJ kinematic models and compare them against manually identified equivalent; (2) compare TFJ kinematics from automatically and manually generated models; and (3) validate these models using *in vivo* knee kinematics from medical imaging.

METHODS

Three-dimensional models of lower limb bones as well as TFJ ligaments and cartilages were created using magnetic resonance imaging (MRI) of 8 healthy youths (4 females; 14.0±2.6 years) taken at ~0° TFJ flexion. Thirty geometric parameters (e.g., TFJ articular surface centres, ligament attachments) were both manually and automatically identified. Anatomic landmarks and articular surfaces were estimated via geometric analysis (e.g., principal inertia axis, cross-sectional area, primitive shape fitting) using the STAPLE toolbox (https://github.com/modenaxe/msk-STAPLE) [2]. Ligament attachments were embedded into an anatomic atlas (i.e., median-size bone) and non-rigidly registered to novel bones, thus approximating their ligament attachments [3]. Automatically and manually identified geometric parameters were compared using Euclidean distance (mm) for landmarks and ligament attachments (centroid), and root mean square error (mm) (RMSE) of vertices for articular surfaces.

RESULTS AND DISCUSSION

Compared to manual identification, automatic approach identified bone landmarks and joint articular surfaces with mean (SD) error of 5.6 (3.7) and RMSE of 3.4 (1.0) mm, respectively (Table 1). Compared to manual identification, ligament attachment centroids were automatically identified with mean (SD) error of 6.9 (4.0) mm (Table 1). Manually identified ligament attachment surfaces from MRI were 4.7 mm in average radii when approximated as circular.

Table 1. Tibiofemoral joint geometric parameter error (Euclidean distance (mm) for landmarks and ligaments centroid; RMSE for articular surfaces).

Estimation method	Mean (SD) error	Range
Landmarks	5.6 (3.7)	1.9, 12.9
Articular surfaces	3.4 (1.0)	1.5, 5.4
Ligament attachments	6.9 (4.0)	2.6, 19.5

SD-standard deviation; RMSE-Root mean square error.

Ligament attachments estimations using atlas registration had lower accuracy than bone landmark estimations which were computed via geometric analysis (Table 1). Ligament centroids were 6.9 mm from manual identification, or ~1.5 times average radius of ligament attachment surfaces (4.7 mm). Identification of ligament attachments might be improved by adjusting bone atlas (e.g., averaging multiple atlantes) or directly deriving from segmentation of ligaments on MRI. Knee articular surfaces were estimated with low error (Table 1). The worst-case estimate the articular surface on femoral condyle had RMSE of 5.2mm when compared to manual identification. The resulting approximated spheres based on the articular surfaces had radii of 17 (manually identified) and 19 (automatically identified) mm and a minor difference of 1.2 mm between sphere centres. The effect of the parameter estimation errors on the predicted TFJ kinematics is unknown and will be investigated further.

CONCLUSIONS

Geometric parameters required to construct TFJ kinematic model can be estimated from subject-specific bone geometry. At the conference, aims (2) and (3) will be fulfilled by constructing the TFJ mechanism from the auto- and manual-generated geometrical parameters and comparing their predicted TFJ kinematics.

INTRODUCTION

Post-stroke gait recovery is one of the primary rehabilitation goals. In clinics, observational gait assessments and instrumented 3D gait analysis are the standards for functional assessments of residual motor capacity. While the first is limited to its subjectivity, the second requires a fully equipped laboratory with pricey instrumentation and time-consuming setup and data processing. Moreover, current clinical assessments do not give quantitative metrics on muscle strength and how it affects gait performance throughout the rehabilitation. In this regard, equipped gait laboratories together with neuromusculoskeletal (NMS) modeling techniques can provide objective evidence of the patient's musculoskeletal function. However, this technology is not compliant with the restricted time limit in clinical practice. We developed a unique pipeline that integrated a fast-to-wear modular 64 textile-embedded EMG leg garment, a generalized and automated EMG clustering algorithm for the fast localization of leg muscles, and an EMG-driven NMS model for the estimation of muscle-specific activation, ankle muscle-tendon forces and resulting torques during walking in post-stroke individuals.

METHODS

Seven hemiparetic stroke participants (age = 57 ± 8.7 years, height = 179 ± 5.1 cm, weight = 88.9 ± 16.5 kg) were recruited by the Sint Maartenskliniek (Ubbergen, The Netherlands). EMG, kinetic and kinematic data were recorded during two main tasks: walking at comfortable and faster speeds. A 64-channel EMG grid embedded in a stretchable garment was applied on the paretic leg. The 64-electrode space was reduced in a few muscle-specific clusters by applying two non-negative matrix factorization (NNMF)-based steps. Afterward, averaged muscle activations were computed for both speeds, and input to EMG-driven NMS model to estimate ankle torque. The automatically derived EMG-driven ankle torque estimation was compared with respect to experimental torque and manually derived EMG- driven torque estimates.

RESULTS AND DISCUSSION

The results showed the ability of NNMF-based EMG clustering to extract the position of the main muscles by using 64-electrode activations during a few gait cycles of slow walking speeds. We used the automatically derived muscle-specific clusters and obtained electrophysiologically consistent muscle-specific envelopes during both walking speeds. Finally, the EMG clustering algorithm provided muscle-specific EMG envelopes with the accuracy needed to drive an NMS modeling framework and estimate dynamically consistent ankle torques. This was visible for the unseen tasks (i.e., not used for the NMS model calibration, such as fast walking) and when using abnormal muscle activations from post-stroke individuals. We show the results of automatically derived EMG (Figure 1.A) and estimated torque (Figure 1.B) for one subject walking at a comfortable speed.

CONCLUSIONS

We show how to go from a multi-channel EMG-embedded leg garment to ankle plantar-dorsi flexion torque by means of automatic NNMF-based EMG clustering and NMS modeling techniques. The developments made in this study open new avenues for fast and quantitative musculoskeletal function assessment in post-stroke individuals and potentially for any injured population.

ACKNOWLEDGEMENTS

The work was supported by EFRO OP Oost GUTs (20913301). The smart garment was developed in collaboration with TMSi (Oldenzaal, Netherlands) and Bard.zo Proad (Ommen, Netherlands).

DIGITAL SOLUTION: A 3-DIMENSIONAL KINEMATIC RATING ALGORITHM FOR SINGLE-LIMB STANCE TEST

Yu Yuan Lee[1], Lena Fennen[1], Rosemary Dubbeldam[1]

[1] Institute of Sport and Exercise Sciences, University of Münster, Münster, Germany

INTRODUCTION

Single Limb Stance Test (SLST) is a reliable movement test to assess fall risk and balance [1]. Our aim is to automate the SLST performance assessment by developing a marker-based rating algorithm using the Balance Error Scoring System (BESS) [2].

METHODS

19 healthy young adults (25 ± 5 years, 10 males, 9 females) and 9 young adults with chronic ankle instability (25 ± 6 years, 6 males, 3 females) were included. The Qualisys motion capture system was used to record full body segment motions. The participants performed the SLST with eyes-closed and eyes-open for 60 seconds. Each participant performed two trials of each condition on each limb. Only the second non-dominant (healthy) or impaired (patients) limb SLST trial was analysed. The BESS (Table 1) was evaluated for each trial by 3 people and the balance of each participant was classified as good, moderate, or bad. *MATLAB*® was used to build the rating algorithm based on the BESS items. The algorithm used the marker positions of the toe, fore foot, hind foot, thigh, trunk, and wrist segments to calculate the balance errors in the BESS items. A paired t-test was used to study the relationship between human and digital BESS assessment.

Table 1: Balance Error Scoring System (BESS)

1.	Lifting forefoot or heel from the ground
2.	Pelvis movement more than 30 degrees of flexion or abduction
3.	Stepping, stumbling, or falling
4.	Arm movement
5.	Remaining out of the test position for more than 5 seconds
6.	Eye close count (not applicable in 3D segment motion capture system)

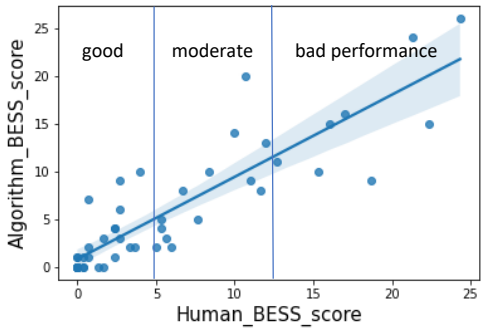

Figure 1: The comparison of the BESS score between the rating algorithm and human assessors.

RESULTS

49 trials including 26 eyes-closed and 23 eye-open SLSTs were analysed. Among them, 60% demonstrated good, 24% moderate, and 16% bad performance, which corresponded to a BESS of <5, 5-12 or >12 respectively. The BESS score assessed by the algorithm is highly correlated to the human assessed BESS score ($r = 0.88$, $p = 0.001$) (Figure 1). The Root Mean Square Error between the assessments is 2.1.

DISCUSSION AND CONCLUSIONS

The marker-based rating algorithm can efficiently and objectively assess SLST performance. The algorithm is repeatable and more accurate in small movement assessment than the subjective human observations. Furthermore, the algorithm can be further deployed in a 2-dimensional video-based motion capture system to provide a low-cost solution for the assessment of fall risk and balance.

ACKNOWLEDGEMENTS

We would like to thank V. Lima, A. Radetzky and O. Ojomo for their assessment of the BESS.

INTRODUCTION

Falls are a growing health concern in older adults. Interventions for fall prevention include exercises and sensory stimulation with textured surfaces [1]. Clinical monitoring of falls is a multipurpose task that is subjectively measured. Balance, related to unexplained falls, measured in gait labs, utilises centre of pressure (COP) excursion analysis on pressure or force plates. Traditional methods focus on evaluating stability through posture variability or magnitude of sway. However, recent research using non-linear analyses has led to a better understanding of the underlying physiology. Indeed, fractal analyses are considered useful tools to analyse postural control. Different frequency ranges can be analysed, revealing the role of proprioception and the visuo-vestibular system in neural control [2]. This paper focuses on a novel fractal analysis to extend the knowledge in this area and to aid the development of evidence-based insole interventions to reduce the incidence of falls.

METHODS

Twenty-one healthy females (age: 62.2 ± 3.7 yr; body mass: 73.0 ± 23.8 kg; stature: 1.58 ± 0.19 m) were recruited. Footwear grouping was randomly assigned in a single blinded manner. Shoe types included: a control with no texture (C; n = 6); full length texture with a dimpled midsole (T1, n = 7); and forefoot only texture with dimple in forefoot only (T2; n = 8) [Figure 1]. Participants were instructed on use of the shoe which included wearing for a minimum of 45 minutes, 3 times a week over a six-week period. Baseline COP data were recorded for 30 sec during quiet barefoot standing on a Footscan pressure mat (RScan International, Olen, Belgium) recording at 250 Hz pre- and post-intervention. Linear measures of COP included: anteroposterior (AP) range and mediolateral (ML) ranges. Fractal scaling of the COP velocity and positional data in AP and ML directions was quantified using frequency specific fractal analysis (FsFA; [2]) Frequency bands for proprioceptive and visuo-vestibular neural control were set at 20-2 Hz ($FsFA_{High}$) and 0.5-0Hz ($FsFA_{Low}$), respectively. A two-way repeated measures ANOVA (time x group) was used to test for differences in each of the dependent variables. Effect sizes were described in terms of partial eta-squared (ηp^2, with $\eta p^2 \geq 0.06$ representing a moderate effect and $\eta p^2 \geq 0.14$ a large effect).

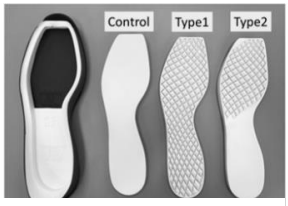

Figure 1. Construction of intervention footwear for each condition midsole.

RESULTS AND DISCUSSION

No time x group interaction effects were shown. A significant main effect for group was evident in AP COP range ($p = 0.034$, $\eta p^2 = 0.492$). A significant main effect was also demonstrated for time in $FsFA_{High}$ of the velocity in the ML direction ($p = 0.010$, $\eta p^2 = 0.763$). No further differences were identified between groups for fractal scaling measures. $FsFA_{High}$ and $FsFA_{Low}$ of COP velocities were closer to white noise ($1/f^0$). Conversely, FSFA of COP positional data was between Brownian ($1/f^2$) and pink (1/f) noise, values are in accordance with previous work [2].

Table 1: Tables that extend across both columns should be placed at the bottom of the abstract.

	Control (C)		Full-length (T1)		Forefoot (T2)	
	Pre	Post	Pre	Post	Pre	Post
COP Position						
$FsFA_{High}$ ML	1.16 ± 0.22	1.28 ± 0.64	1.38 ± 0.36	1.25 ± 0.30	1.22 ± 0.34	1.34 ± 0.29
$FsFA_{High}$ AP	1.48 ± 0.34	1.65 ± 0.35	1.65 ± 0.33	1.64 ± 0.24	1.63 ± 0.26	1.53 ± 0.38
$FsFA_{Low}$ ML	1.26 ± 0.97	1.28 ± 0.99	1.22 ± 0.16	1.27 ± 0.30	1.22 ± 0.16	1.21 ± 0.17
$FsFA_{Low}$ AP	1.22 ± 0.08	1.23 ± 0.10	1.43 ± 0.14	1.29 ± 0.17	1.31 ± 0.07	1.28 ± 0.11
COP Velocity						
$FsFA_{High}$ ML *	0.64 ± 0.39	0.47 ± 0.32	0.87 ± 0.54	0.47 ± 0.16	0.44 ± 0.22	0.45 ± 0.22
$FsFA_{High}$ AP	0.41 ± 0.25	0.41 ± 0.28	0.46 ± 0.34	0.31 ± 0.12	0.39 ± 0.29	0.29 ± 0.11
$FsFA_{Low}$ ML	0.49 ± 0.09	0.47 ± 0.12	0.53 ± 0.19	0.47 ± 0.19	0.58 ± 0.14	0.53 ± 0.21
$FsFA_{Low}$ AP	0.39 ± 0.12	0.43 ± 0.20	0.35 ± 0.10	0.44 ± 0.14	0.52 ± 0.18	0.43 ± 0.17

Values are expressed as Mean ± SD. ML, mediolateral; AP, anteroposterior. * denotes a significant main effect for time ($p < 0.05$).

This work demonstrated a significant decrease over time in $FsFA_{High}$, representing a shift towards white noise. $FsFA_{High}$ is indicative of how movement is regulated by somatosensory feedback mechanisms [2]. In the linear measures, a significant group effect was noted between the midsole conditions, with AP COP range greatest in the two experimental groups (T1 and T2). This could render the user of the midsole more adaptable over time.

CONCLUSIONS

The marked decrease in scaling exponent in the novel midsole over time, shows the potential utility of this intervention to alter short-loop postural regulation.

DYNAMIC OPTIMIZATION OF HUMAN GAIT TO SOLVE KINEMATIC-KINETIC MISMATCH

Zuming Xiao[1], Xinyue Wang[1], Jianqiao Guo[1], Qiang Tian[1]
[1] Key Laboratory of Dynamics and Control of Flight Vehicle, School of Aerospace Engineering, Beijing Institute of Technology, Beijing, China
Email: guojianqiao@bit.edu.cn (J. Guo)

INTRODUCTION

Dynamic modelling of human gait has been widely used to investigate the biomechanical alternations due to musculoskeletal pathology. However, numerous factors, including the measurement errors of the spinal curve flexions, the inertial differences between the musculoskeletal model and the corresponding subject, etc., can cause a mismatch between the kinetic and kinematic measurements. Therefore, using the measured joint kinematics as model inputs, the human gait model cannot keep upper body balance. This study proposed a dynamic optimization method to eliminate this mismatch by introducing an interpolation function to rectify the measured errors of spinal kinematics.

METHODS

The study has been approved by the ethics committee of Beijing Institute of Technology. A healthy male subject (29 years, 175 cm, 59 kg) was recruited and instructed to walk at a certain speed. Nineteen reflective markers were placed on the following anatomical landmarks: the left/right anterior superior iliac crest, the midpoint of the posterior superior iliac spine, the front side of the left/right thigh, the left/right lateral femoral condyle, the left/right medial femoral condyle, the left/right tibial trochanter, the left/right lateral malleolus of the fibula, the left/right medial malleolus of the tibia, the left/right toe, and the left/right heel.

A multibody musculoskeletal model with a detailed lumbar structure was developed using our in-house code [1]. During the simulation, the lower limb joint movements were constrained based on the measured data, and only the pelvic sagittal posture was calculated via forward dynamics. Foot-ground reaction forces were determined using a contact model for soft tissues [1].

To rectify the mismatch between kinematic and kinetic data, a three-order Fourier series was used to define the lumbar spine flexion angle in the sagittal plane, and the range for Fourier coefficients was determined based on the measured spinal curve in literature [2-3]. The posture of L1-L5 vertebrates was distributed according to the lumbopelvic rhythm [4]. The Fourier coefficients were then obtained through dynamic optimization. The cost function minimized the errors of the sagittal pelvic posture along with the spinal flexion angle during a gait cycle. The periodicity constraint was also utilized to decrease the deviation between each gait cycle. The optimization process was implemented in MATLAB using the fmincon function. A total of ten local optimizations were performed since the model parameter optimization was sensitive to the initial guess.

RESULTS AND DISCUSSION

As shown in Fig. 1, the predicted gait can keep balance without falling. Increasing the weight of the spinal flexion in the cost function can reduce its variations. The optimized spinal movements were in qualitative agreement with the literature. However, the predicted range of spinal bending (43 deg) was slightly larger than that in the literature [2] (40 deg). Moreover, the predicted spinal bending curve obtained still performed a deviation of 12 deg between the beginning and end of the gait cycle, which could be related to the form of the interpolation function or the failure to find the global optimum. Further investigations would extend the proposed method to three-dimensional cases.

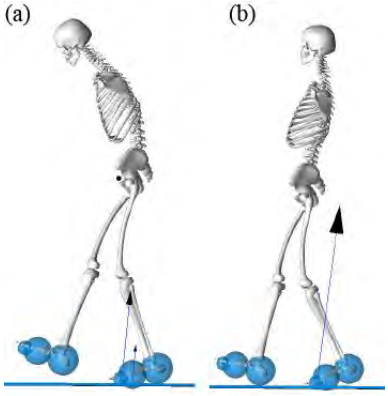

Figure 1 Comparison of the predicted spine flexion before (a) and after (b) dynamic optimization.

CONCLUSIONS

The proposed method successfully predicted feasible solutions of a two-dimensional spinal curve without falling, highlighting the possibility of quantifying the patient-specific spinal motions without attaching infrared reflective markers.

INTRODUCTION

The centre of mass (COM) is widely used to evaluate postural control, as it provides a measure of the distribution of body mass in relation to the base of support. Postural control is a critical aspect of balance and stability, and its assessment is crucial in evaluating the functional abilities of individuals. The measurement of postural sway has widely been studied in individuals following stroke to understand the effects of neurological impairment on balance[1][2]. COM however, cannot be directly measured and is estimated through stereophotogrammetric methods such as motion capture or centre of pressure (COP) measurement using force plates. Traditional marker-based motion capture methods are cumbersome due marker placement and thus, a more straight forward approach using COP from force plates has been adopted[3]. Although force plates are less time consuming and require less technical expertise than marker-based methods, their use poses a barrier to clinical integration as they are expensive, non-portable, and require special installation. Markerless motion capture is a novel solution that utilizes a deep learning approach to estimate anatomical landmarks and calculates 3D pose from video, allowing for estimation of COM from a full body model. The markerless solution removes the need for specialized labs, minimizes technical requirements, and is more portable allowing easier integration into clinical settings. The objective of this study was to determine if COM derived from markerless motion capture is sensitive enough to detect differences in postural control between stroke and healthy age matched controls.

METHODS

Inpatient stroke participants were introduced to the study by physiotherapists. Each participant performed a quiet standing balance task with the instructions of standing with their toes pointed forward, arms by their side, eyes open looking straight ahead. Participants with no known history of neurological or musculoskeletal impairments served as a control group. Each participant preformed a quiet stand with the same instructions as above. All participants wore the shoes and clothing they came in with that day. The trials were recorded at 60 Hz using eight commercially available time-synchronized Sony RX0II (Sony Corporation, Minato Japan) video cameras. Video data were processed using Theia3D (Theia Markerless, Kingston, ON) to obtain COM kinematics. Data were filtered at 5 Hz using a low pass Butterworth filter in Visual3D (C-motion, Germantown, MD). All data were normalized by COM height[4] and the range of COM excursion was calculated. Group differences in the medio-lateral (ML) range were compared using a Mann-Whitney-Wilcoxon test. Significance was set at 0.05. All statistical analyses were performed in R (v.4.2.2, R Core Team).

RESULTS AND DISCUSSION

16 participants were include in the analysis, 8 stroke (2 female, 6 male; mean(SD) age 77(13), range 58-93) and 8 healthy controls (4 female, 4 male; mean(SD) age 68(8.1), range 60-83). Compared with healthy controls, participants who had a stroke had higher postural sway in the ML direction (median(IQR) excursion (mm): stroke 29.2(12.6), controls 18.0(5.4), p = 0.01, Figure 1). These findings are consistent with the literature[1] where individuals with stroke where shown to have a larger sway in the ML direction.

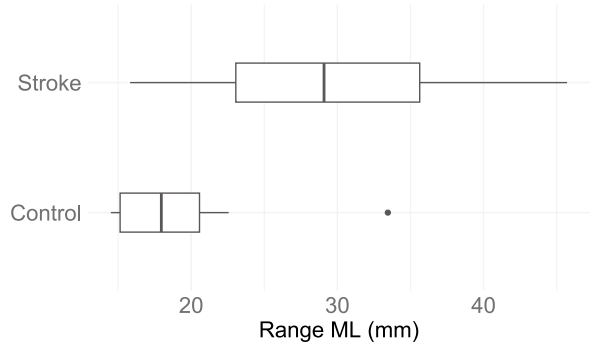

Figure 1 Range of COM excursion in the ML direction of a stroke population versus an age matched control.

CONCLUSIONS

Markerless motion capture is sensitive to differences in postural sway characteristics between individuals following stroke and healthy age matched controls. The increased accessibility of the technology compared to historical methods make it a promising tool for clinical integration.

INTRODUCTION

Proprioception enables the conscious and unconscious perception of the spatial and mechanical status of the musculoskeletal system, providing essential information for the production of coordinated movements and to control balance. However, as people age, the proprioceptive sensors and their neural pathways undergo alterations that lead to a decreased sensitivity, acuity, and integration [1]. These alterations reduce efficiency of balance control, leading to an increased reliance on visual inputs and increased agonist-antagonist coactivation [2]. Our study aimed to investigate the relationship between proprioceptive function at the ankle level and postural control across lifespan.

METHODS

Thirty participants divided into three groups of age: Group 1: < 18 years, Group 2: 18-40 years and Group 3: > 40 years. The evaluation of postural control was performed on a force platform to compute the center of pressure (CoP) displacement in four different sensory conditions: open eyes and close eyes, stable and unstable surface (foam). The mean velocity of the CoP excursion in antero-posterior and medio-lateral direction was computed to quantify the postural sway.
The evaluation of ankle proprioception was performed using unilateral and contralateral tests of sense of position during both plantar flexion and dorsiflexion. The ipsilateral test consisted in placing for 15 s the ankle in a target position that the participant had to retain and subsequently reproduce, while the referenced contralateral test involved placing one ankle in a reference position that the participant had to reproduce with the contralateral ankle. The mean absolute error was used to provide an index of the real difference between the performance produced and the target.

RESULTS AND DISCUSSION

Among the different groups, Group 2 presented the lesser CoP velocity while Group 1 exhibited the greatest CoP velocity ($p < 0.05$). Similarly, the Group 2 displayed less mean absolute error (greater proprioception), only in the contralateral test of plantar flexors while the Group 1 presented the greatest mean absolute error ($p < 0.05$). Additionally, a significant correlation was observed between contralateral test of plantar flexors only with the eyes-open condition in stable surface (the greater the error, the greater the postural displacement).

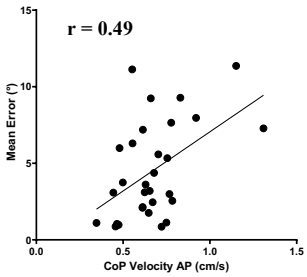

Figure 1 Relationship between contralateral plantar flexion sense of position test with Center of Pressure velocity in the anterior-posterior axis.

CONCLUSIONS

A better proprioceptive acuity is associated with lower CoP displacement during postural control tasks. Our study highlights the importance of proprioception in maintaining postural stability throughout lifespan. This has important implications for the development of interventions aimed at improving balance control, particularly in populations with compromised proprioceptive function, such as older adults or individuals with neurological disorders.

INTRODUCTION

Cerebral palsy (CP) is a permanent movement disorder that affects muscle tone, with symptoms such as poor coordination, tremors, muscle stiffness and muscle weakness. Impaired balance contributes to gait deficits and earlier studies have documented that children with CP are less stable when performing static tasks with and without visual feedback [1]. This suggests that children with CP are likely to present deficits in integrating sensory inputs from other sources such as proprioception. Local tendon vibration (LTV) is a means of increasing muscle spindle afferents activity, distorting the proprioceptive signal [2]. Perturbations induced by LTV during standing are compensated by postural adjustments, as reflected in muscle activity. However, whether CP leads to specific postural compensation in response to LTV remains unknown. The purpose of this study was to examine the stability and leg muscle activation through electromyography (EMG) of children with CP and typically developed (TD) children, before, during, and after LTV, when standing with eyes closed.

METHODS

Ten children with CP (13.0±1.7 yrs, 147.3±0.5 cm, 48.1±0.9 kg) and 16 TD children (14.0±3.8 yrs, 161.2±1.2 cm, 54.8±0.9 kg) were asked to stand with eyes closed for 60 s (three trials), while bilateral LTV was applied over the Achilles tendon for 15 s. The velocity of the center of pressure [CoP; on the anterior-posterior (AP) and mediolateral (ML) direction] and trunk (Tr) were calculated with data from a force platform and an accelerometer respectively. EMG responses from the soleus (SOL), gastrocnemius medialis (MG) and tibialis anterior (TA) muscles were measured. All data were analyzed in 5-s windows before LTV (pre-LTV), after the LTV onset, during LTV (i.e., last 5 s of LTV) and after the end of LTV (post-LTV). The rate of change of the variables after the onset, during and after the offset of LTV was expressed as the $\log_2$ ratio relative to values before LTV onset. A linear mixed model was used to compare the differences between the LTV conditions, groups, and their interaction.

RESULTS AND DISCUSSION

Both groups increased their CoP-AP, CoP-ML and Tr velocity, when LTV was introduced, with greater increase for the CP than TD group in Tr velocity ($p=0.005$). This shows that although LTV was applied distally, on the Achilles tendon, its effects were more pronounced over the trunk for children with CP, indicating a more general destabilization. EMG amplitude increased in all muscles at the onset and during LTV in children with CP ($p<0.001$) but not TD children, except for TA at the onset and during LTV (Figure 1).

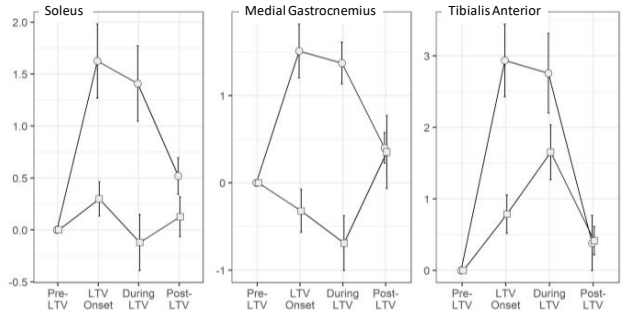

Figure 1 Change in EMG activity for children with CP (circles) and TD children (squares) relative to the values before LTV.

CONCLUSIONS

The main finding of this study is that in the presence of LTV, children with CP have different neuromuscular response compared to TD children, by activating both plantar- and dorsiflexors and resulting greater destabilization at trunk level. This indicates greater dependency from proprioceptive feedback in CP and illustrates one possible underlying cause of their motor disability. This dictates the need to implement interventions that promote somatosensory integration.

Relative importance of the visual system for balance control is reflected in the continuous margins of stability while walking

INTRODUCTION

The adaptability of the locomoter system to respond to environmental changes such as perturbations during walking is based on the interaction of the muskuloskeletal and central nervous system. Aging is associated with a degradation of these systems and overreliance on visual feedback, which diminishes the capability to react to challenges to stability during walking, leading to balance deficits and falls. Perturbation-based balance training (PBT) mimics the accidental and unpredictable nature of slips and trips in daily life in a safe environment and allows reactive gait adjustments. While PBT demonstrates efficacy in reducing fall risk, the underlying mechanisms is unclear. One candidate mechanism is a recalibration of the sensory weights away from latency- and attention-heavy processes such as vision. We here investigate the interaction between visual contribution to balance control and margin of stability (MoS) during walking.

METHODS

Within this study, we investigate 20 healthy adults over 60 years of age who receive three blocks of eight minutes of multidirectional perturbation training on a Computer Assisted Rehabilitation Environment (CAREN). Prior and after the training, a virtual Sensory Integration Test (vSIT) [1] is administered to assess visual contribution to balance control. Within the training, a total of 32 perturbations are applied in medio-lateral (2.25-18cm displacement) and anteroposterior (0.5-2.25 m/s^2 acceleration) direction while walking at a comfortable walking speed. Perturbation magnitude is personalized based on the maximal perturbation successfully resisted during standing. For this analysis, the MoS are calculated for all steps within block 1 of the training and is compared to the visual weights from the vSIT taken just prior.

RESULTS AND DISCUSSION

Of the currently analysed elderly population (n=8), there is a slightly increased visual weight compared to young healthy controls (0.42% vs 0.39%). More strikingly, the elderly participants converge into two discrete clusters. The MoS analysis shows that participants with greater visual weight are the ones with smaller MoS. This also correspond to greater temporal variability and more variability in foot motion patterns (Figure 1).

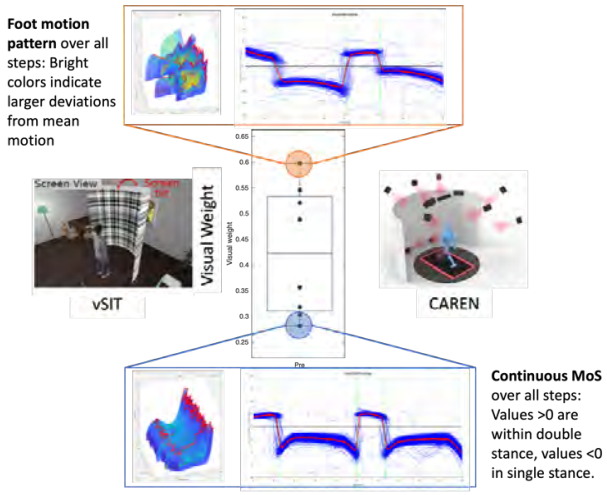

Figure 1 Visual weights and representative continuous margins of stability for two elderly participants. Note the difference in MoS at initial single stance and the difference in foot trajectory consistency. vSIT depicted on the left, CAREN on the right (credit: Stefan Schneller).

CONCLUSIONS

This preliminary analysis supports our expectation that there is an interaction between visual contribution to balance and MoS during walking. We are currently extending the analysis to include all 20 elderly and contrast steady walking with individual responses to single perturbations. In a next step we will evaluate how the MoS change throughout all three training blocks and whether this is equally reflected by a change in visual weight and perturbation resilience. This approach may provide some insight into the underlying mechanisms of PBT and will hopefully contribute to the field of fall prevention.

INTRODUCTION

Recent advances in leg exoskeleton technology have allowed for the augmentation of human locomotion by reducing metabolic power during walking and running [1,2]. However, the additional mass of these devices can increase metabolic power and alter joint kinematics and kinetics, necessitating consideration of the effects of added mass magnitude and distribution in exoskeleton design. The effects of added foot and leg mass on metabolic power during running have been extensively studied, but the effects on joint kinematics and kinetics have yet to be investigated. The present study analyzes the kinematic and kinetic effects of running with added mass on the feet, shanks, and thighs. This analysis is important for the design of wearable assistive devices and for gaining a better understanding of locomotion.

METHODS

Fifteen participants (7 females and 8 males) completed treadmill running trials ($3\ m \bullet s^{-1}$) normally and with lead mass (300–1350 g) attached bilaterally to the thighs, shanks, or feet. We quantified the lower limb biomechanics with motion capture and ground reaction force data using standard inverse dynamics analysis.

RESULTS AND DISCUSSION

Only moderate kinematic changes occurred in response to the distal added limb mass. Maximum hip flexion and maximum knee flexion angles during the swing phase increased by approximately 9% and 6%, respectively, for each kilogram added to each foot. However, adding even small masses to the legs caused dramatic changes in joint moment and power, particularly during the swing phase. For example, adding 1 kg to each foot increased maximum joint moment by as much as 42% (knee extension in late swing) and maximum joint power by as much as 50% (hip generation in late swing) (Figure 1). These changes have implications for shoe design, for people who run with added mass on their legs for sport or strength training, and for the design of wearable devices. These effects might be leverageable when designing particular exoskeletons—such as energy harvesters [3–8], which heavily rely on negative work (which increased at swing) with regenerative braking to generate electricity.

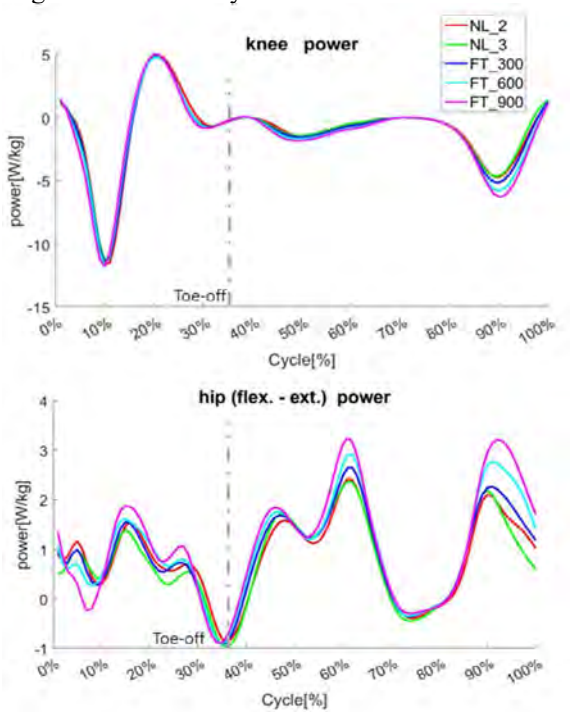

Figure 1 Participants' average power profiles under different loading conditions of the feet; 0% of the gait cycle is defined as the initial foot–ground contact; FT_300, FT_600, and FT_900 represent the added mass at each foot of 300 g, 600 g, and 900g, respectively; NL_2 and NL_3 represent no load running at 3 $m \bullet s^{-1}$.

CONCLUSIONS

Leg joint kinematics were largely conserved in response to adding mass to the legs. Adding mass to the legs more distally increased joint power mainly at the knee and hip joints during the swing phase, whereas proximal loading mainly affected the ankle joint mechanics during the stance phase.

EFFECTS OF GAIT VARIABILITY AND ENCOURAGED EXPLORATION ON ADAPTATION TO ANKLE EXOSKELETONS

Gillian Phillips[1], Anthony Chen[1], Megan J. McAllister[1] and Jessica C. Selinger[1]
[1] School of Kinesiology and Health Studies, Queen's University, Kingston, Canada

INTRODUCTION

Exoskeletons have potential applications in the rehabilitation and enhancement of human gait. In the past decade, numerous exoskeletons have reduced the energetic cost of walking[1], potentially allowing users to walk for longer durations before fatiguing. However, acheiving these benefits often requires hours of walking time, during which the user must adapt to the novel and complex dynamics created by the assistive device[2,3]. This is a nontrivial feat, as gross characteristics, joint level kinematics and kinetics, and individual muscle activities may all need to be adjusted to optimally move in concert with the device. Recent work by our group[4] and others[3] suggests that high gait variability may facilitate this adaptation process by providing experience with different-cost gaits. Here, our purpose is to test how gait variabilty, whether naturally occuring or created through encouraged exploration, effects the rate and magnitude of a users' adaptation to ankle exoskeletons. We hypothesize that individuals who display high natural (implict) gait variability will more readily adapt to the device and that verbal (explict) encouraged exploration will expedite adaptation.

METHODS

We will test 10 healthy adults with no prior experience walking in an exoskeleton and no lower limb impairments. To date, we have tested 2 participants. We instrumented participants with bilateral ankle exoskeletons (Humotech) that provide assistive plantar flexion torques. We controlled the timing and magnitude of the assistive torques using a custom real-time angle-based controller. We also instrumented participants with 22 reflective markers for optical motion capture (Qualisys), 9 dominant limb EMG sensors (Delsys) to measure muscle activity, and a portable indirect calorimetry system to measure metabolic energy expenditure (Cosmed). All walking occurred on a fully instrumented split-belt treadmill (Bertec). Participants completed a total of 102 minutes of walking on a single testing day. During a baseline trial the exoskeletons were unpowered, allowing participant habituation and qualification of natural gait variability. Next, the exoskeletons were turned on and we assessed the level of adaptation both before and after an exploration trial where we incited high gait variability by encouraging participants to explore different ways of walking using verbal prompts.

RESULTS AND DISCUSSION

Our preliminary findings suggest that encouraged exploration may facilitate adaptation toward more energy optimal gaits. In one example participant, net metabolic cost reductions of 12% were achieved pre-exploration, but these savings more than doubled post-exploration to 30%. These cost savings were accompanied by a 20% reduction in soleus average integrated EMG, a 15% reduction in ankle angle range of motion, and no change in step frequency. Next steps include collecting data from the remaining participants and evaluating the relationship between an individual's implicit and explicit variability and their adaptation.

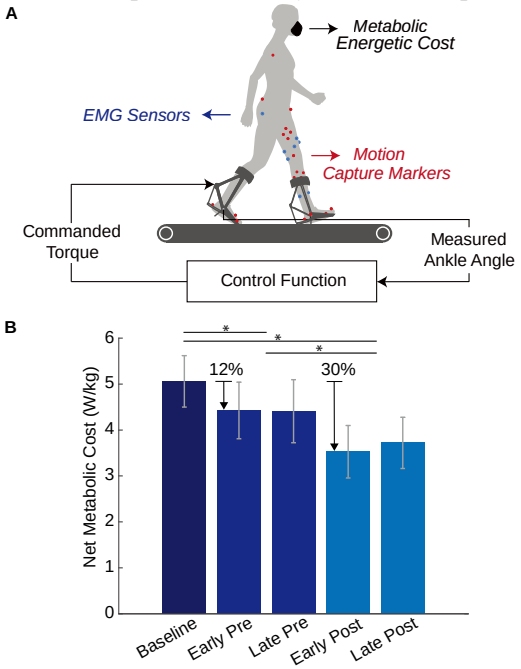

Figure 1 A) Schematic of participant instrumentation. **B)** Metabolic cost reductions from one example participant. Cost reductions, compared to the unpowered condition (Baseline), were evident prior to the encouraged exploration trial (Early Pre and Late Pre), but more than doubled afterward (Early Post and Late Post).

CONCLUSIONS

Our work will help elucidate the role of implicit and explicit gait variability during adaptation to lower limb exoskeletons. This may provide insight into how we can best facilitate and expedite the adaptation process when a user is learning to walk with a novel assistive device.

Design of a 2-DoF Soft Ankle Exoskeleton for People with Dropfoot and Excessive Inversion

Xiaochen Zhang [1], Yi-Xing Liu [1], Ruoli Wang [1] and Elena M. Gutierrez-Farewik [1,2]
[1] KTH MoveAbility Lab, KTH Royal Institute of Technology, Stockholm, Sweden.

INTRODUCTION

Dropfoot, or inability to lift the foot due to muscle weakness and/or atypical motor control, is a common secondary gait disorder after a stroke or other neurological injury. Dropfoot can negatively impact one's walking independence and confidence [1], and make daily activities less convenient and more challenging. Ankle-foot orthoses are frequently prescribed to assist in daily life [1]; they passively supplement for deficient dorsiflexor strength, but they also disrupt natural ankle motion and muscle recruitment. Exoskeletons made of soft and/or compliant components to compensate for atypical motor control have been frequently explored in the past decade [2]. The purpose of this study is to design a lightweight, soft 2-DoF active ankle exoskeleton specially intended to compensate for dropfoot and excessive inversion and test its performance and feasibility in simple ankle movements.

METHODS

The design consists of four components: waist belt, calf wrap, a pair of shoes, and sensors (EMG sensors and load cells). A controller with two different control modes was designed to assist ankle joint motion in sagittal and frontal planes: 1) position control to track the desired ankle joint angles; 2) forcefree control [2] to compensate for the device's intrinsic friction during ankle plantarflexion by extracting the cable tensile force. The device's feasibility was preliminarily evaluated on two able-bodied subjects (1 male: 25 y/o, 54.9 kg; 1 female: 30 y/o, 53.0 kg). Ankle joint angle was computed based on the 3D movement analysis (Vicon V16, markers as per CGM2.4). Each subject conducted three case studies, from a seated position and relaxed ankle joint muscles (verified by EMG signals): Case 1: position control of the foot, from a plantarflexed and inverted position: the foot first rested on two wedges in different angles and directions and moved to a neutral position (target angle = 0°) during a 0.75s duration; Case 2: position control during plantarflexion: the foot moved from the neutral position to a plantarflexion position in a 0.3s duration (target angle = 9° by using wedge); Case 3: forcefree control during plantarflexion, from the neutral position to a plantarflexed position.

Tracking errors between the measured and the target ankle angles were determined in the first two cases. In case 3, the duration of plantarflexion from 0° to 20° was measured as an index to evaluate the restriction in the condition of Forcefree control, Free (no restriction by removing cables) and Friction (with passive exoskeleton).

RESULTS AND DISCUSSION

With position control, the exoskeleton assisted the ankle to reach the target angle with an error of 1.6° in the sagittal plane and 0.6° in frontal plane in case 1 (Fig. 1a) and with an error of 0.8° in the sagittal plane in case 2 (Fig. 1b). The Forcefree controller decreased the movement duration by 0.31s, which is 43% less than with the Friction condition (Fig. 1c).

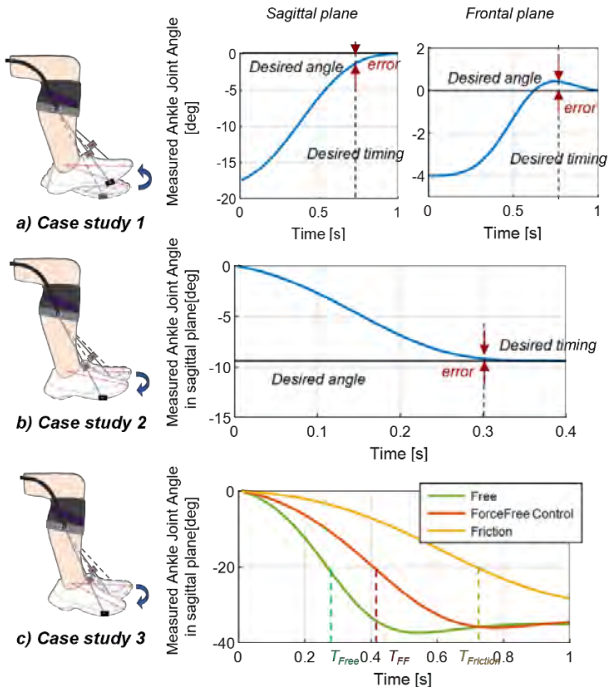

Figure 1 The measured ankle joint angles during three case studies from a representative subject.

CONCLUSION

In this study, we evaluated the performance of our 2-DoF active ankle exoskeleton on subjects' ankle joint response. Our preliminary results revealed that the use of a two-mode controller led to a good tracking performance and less restriction than passive exoskeleton, which supports its potential for assisting gait in persons with with dropfoot and excessive inversion. Our future work will t investigate the device's effect when subjects are not in a relaxed state.

GREEN EXOSKELETON BASED ON BIOMECHANICAL ENERGY HARVESTER

Yakir Knafo[1, 3], Yinjie Zhuo[2], Avi Manor[3], Alon Osovizky[3,4] and Raziel Riemer[2]*
[1]Mechanical Eng. School, Tel-Aviv University, Israel; [2]Industrial Eng. and Mgmt., Ben-Gurion University of the Negev, Israel, * rriemer@bgu.ac.il; [3]NRCN, and [4]Rotem Industries, Ltd., Israel

INTRODUCTION

Exoskeletons are designed to augment their users. There are two main types of exoskeletons, passive devices, which rely on elements such as springs and clutches to provide assistance and are limited to a single type of activity (e.g., walking) [1], and active exoskeletons, which use motors to provide assistance. Active exoskeletons typically use batteries as their energy source. Thus, the exoskeleton's operating time between charges is limited. This study presents a novel active exoskeleton without the need for a continuous external power source.

METHODS

The exoskeleton is based on harvesting biomechanical energy, which captures energy from the wearer's negative work movements (during which muscles act as brakes) and stores it in a battery or super-capacitor for later use. It returns the harvested energy when the joint is required to perform positive work (muscles working as a motor). Thus, provides assistance without the need for an external power source. To do this, an electronic circuit board with the active control of a brushless DC (BLDC) motor was developed and implemented on a knee exoskeleton. The main parts of the electronic circuit board are a low-power microprocessor, a digital logic circuit, an H-bridge, and super-capacitors. The control algorithms use three signals: rotation direction, desired operating mode (motoring or regenerating), and control signal (pulse-width modulation).

RESULTS AND DISCUSSION

We tested this technology on a Sit-To-Stand (STS) motion assistance task [2], which required the motion of going down from a standing to a sitting position. The exoskeleton aided in moving downward, while charging the super-capacitors (~10 Joules). Next, while the user was moving from a sitting to a standing position, the energy from the capacitors was used to drive the motor for assistance. In an experiment, a participant performed the STS motion (Fig. 1) while the torque applied by the device to the knee was measured using a torque meter (mini45, ATI Industrial Automation), and the participant's kinematics and kinetics were recorded using a motion capture system (Qualisys, Gothenburg, Sweden) with a force plate (Bertec, Columbus, Ohio). The joint angle and torques were calculated using Visual 3D. The results showed that the total knee torque was 65–70 Nm and the torque applied by the device ranged from 7–10 Nm.

CONCLUSIONS

The device's ability was demonstrated with the STS motion, yet with further development of the control system, it could also assist with movements such as walking.

ACKNOWLEDGEMENTS

The study was partially supported by the Israel Ministry of Science and Technology and the Helmsley Charitable Trust through the Agricultural, Biological and Cognitive Robotics Initiative of the Ben-Gurion University of the Negev.

INTRODUCTION

Difficulty in standing up and sitting down affects about two thirds of older persons in long-term care [1]. Effective robotic assistance can help this population lift out and into the chair, providing a more independent living. Investigations on robotic assistance in STS provide useful insights [2,3], but generally accepted, effective assistance trajectories are still unknown and its effects on biomechanical performance and stability are poorly understood. We propose a set of parametrized trajectories for sit-to-stand and stand-to-sit assistance, whose velocity profiles are based on experimental shoulder trajectories, and that can be scaled by subjects antropometry and motion duration. These trajectories will be investigated experimentally using a robotic lab device (Fig.1, bottom) in a ongoing study.

METHODS

Acromion marker trajectories were collected during 3-5 repetitions of standing up and sitting down for 10 younger (Yng, 28±5 yrs) and 7 older adults (Eld, 78±9 yrs). Data was filtered, divided by subject's thigh length (L), and scaled by motion duration T (seat off to stance on in sit to stand; stance off to seat on in stand to sit), resulting in normalized velocities in L/T, which were averaged resulting in an inverted C-shaped trajectory (Exp. Avg, Fig.1). Horizontal (i=x) and vertical (i=z) average velocities for sit to stand and stand to sit and for the younger and older adult groups were approximated by 2 gaussian curves according to

$$v_{i,n}(\tau) = a_{1i}\, e^{-[(\tau-b_{1i})/c_{1i}]^2} + a_{2i}\, e^{-[(\tau-b_{2i})/c_{2i}]^2}, \quad (1)$$

with τ=0/τ=1 *(seat off/stance on* or *stance off/seat on* for sit-stand and stand-sit) (iC-shape, Fig.1). This trajectory reproduces shoulder trajectory on the handles, providing natural support with arms stretched vertically. Shape variations to be investigated were obtained by slight manipulation of the parameters in (1): *i*) monotonically forwards and upwards motion with a_{2i}=0 (iL-shape, Fig.1); *ii*) simple straight trajectory by shifting velocities (b_{1i}) in x and z in time (Straight, Fig.1); *iii*) S-shape trajectory by manipulating c_{1z} for velocity in z.

RESULTS AND DISCUSSION

The average measured durations (T) are 0.91±0.01 s (sit-stand Yng); 1.02 ± 0.03 s (stand-sit Yng); 1.52 ± 0.21 s (sit-stand Eld); 2.31 ± 0.26 s (stand-sit Eld). Coefficients in (1) were obtained by optimization. The profiles for sitting up of younger adults are illustrated in Fig.1.

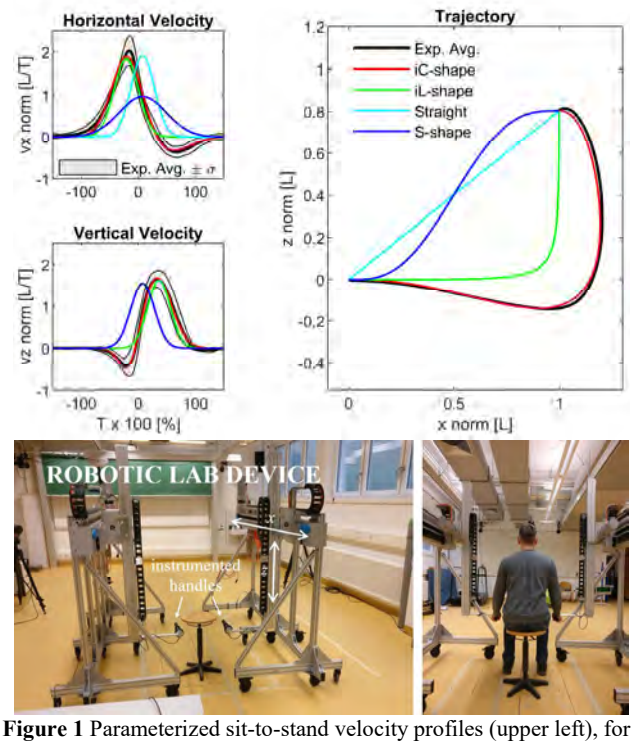

Figure 1 Parameterized sit-to-stand velocity profiles (upper left), for the corresponding different trajectory types (upper right), inverted C-shape (iC-shape), inverted L-shape (iL-shape), Straight and S-shape. Robotic lab device to impose handle trajectories (bottom).

CONCLUSIONS

This is the first study that proposes and systematically compares biologically inspired trajectories for robotic assistance of standing up as well as sitting down. From shoulder trajectories of younger and older adults, we determined straightforward parameterized assistance velocity profiles scaled by anthropometry and duration, which can be used as reference in future investigations. Results on the ongoing investigations on the biomechanics and stability effects of these trajectories with a robotic lab device will be reported in the congress.

EFFECTS OF FINGER FLEXION FORCE ON MEDIAN NERVE COMPRESSION

Shengwei Li[1], Ping Yeap Loh[2]
[1] Graduate School of Design, Kyushu University, Fukuoka, Japan.
[2] Department of Human Life Design and Science, Faculty of Design, Kyushu University, Fukuoka, Japan.
Email: li.shengwei.652@s.kyushu-u.ac.jp

INTRODUCTION

Work-related biomechanical stress on median nerve compression is critically relevant to carpal tunnel syndrome. Ultrasound imaging on the median nerve is useful for ergonomics intervention and prevention. Finger flexion force exertion causes gliding and displacement of the flexor tendons and compress the median nerve. [1] Previous study have shown that grip force leads to morphological changes in the median nerve and affects the cross-sectional area of the medial nerve (MNCSA). [2] The main objective of this study is to investigate the effect of individual finger flexion force exertion on the MNCSA.

METHODS

Five healthy right-handed young adults (3 males and 2 females; age = 26.8 ± 6.1 years old; height 167.5 ± 13.9 cm; weight = 72.3 ± 7.7 kg; BMI = 26.1 ± 3.7 kg/m^2) were recruited. Ultrasound examination of the median nerve was performed using a Toshiba Viamo Portable ultrasound system. The median nerve of the dominant wrist was examined in the proximal transverse plane. Four finger conditions were examined, including index finger (IF) only, middle finger (MF) only, ring finger (RF) only and total finger (TF, index, middle, and ring fingers together), while three finger flexion force levels were examined, namely, no force (Control), 50% force and 100% flexion force. Finger flexion force was measured by load cells (LTMS-25, Toyo Sokki, Japan) with PowerLab (ADInstruments, Australia) and ultrasound image was synchronized with LabChart (v7.3.8, ADInstruments, Australia). The load cells were connected to the second phalange of the volunteers through iron wires and soft webbings, while the angle of the proximal interphalangeal joints of the volunteers was approximately 65°. Ultrasound images were then exported for MNCSA measurement by a tracing method with ImageJ. The independent variable is the flexion force level and the dependent variable is the MNCSA at different flexion force levels. One-way repeated ANOVA and post hoc pairwise Bonferroni-corrected comparisons were conducted with flexion force levels as factors to examine the changes of MNCSA.

RESULTS AND DISCUSSION

The mean values of MNCSA for Control, IF50, IF100, MF50, MF100, RF50, RF100, TF50, and TF100 were summarized in Figure 1, and the corresponding flexion force were listed in Table 1. For IF, MF, and TF, the MNCSA at 50% flexion force showed no significant changes compared to Control condition, while MNCSA decreased significantly as TF flexion force changed from 50% to 100% flexion force ($p<0.05$). However, from Control to 100% flexion force, the MNCSA of RF increased significantly.

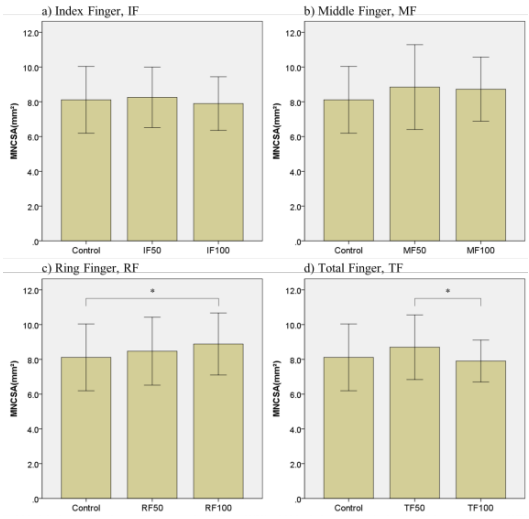

Figure 1 MNCSA changes with IF, MF, RF, and TF flexion force. (*, $p<0.05$)

CONCLUSIONS

In this study, both individual finger and total finger flexion force exertion cause differ compression stress to the median nerve, and results in MNCSA changes among young adults.

INTRODUCTION

Power flow has widely been investigated for gait analysis and sport movements such as baseball throw or tennis service. Such analysis provides insights about how much energy is flowing in or out of a segment and how energy transfers between adjacent segments [1]. However, only very few studies focused on energy transfer during a collective load transport. In our previous researches we showed a global alteration of the CoM pendular behaviour of the Poly-Articulated Collective System –composed of all the individuals acting together –and an increase of the cost of their movement (sum of joint moments) when increasing the load transported [2] that suggested change in power flow. In the present research we investigated the energy transfer occurring in the upper limbs of two participants carrying a stretcher-like object, with a particular focus on the differences between the right and left sides.

METHODS

Seven groups of two matched-participants (mean ± s.d.: age = 23,9 ± 2,2 year; height = 1,72m ± 0,09m; mass = 65,5 kg ± 8,3kg) performed three transports of a strecher-like object while looking at each other so that participant P1 performed a forward walking with a visual feedback of the external environment and participant P2 performed a backward walking with no visual feedback. Each was equipped with 42 spherical reflective markers. The 3-D kinematics of the upper limb and trunk was then recorded using 19 Vicon cameras sampled at 200 Hz. The carried object was equipped with four handles each including 6-axis force sensors (Sensix©, France) to record the external forces applied by the participants. The handles were synchronised and sampled at 2000 Hz. An inverse dynamic method enabled us to estimate the forces and moments at each joint of the upper limb [3]. Power flow analysis was then conducted following references 1 and 4:

$$Eq.\ 1:\ JFP = joint\ reaction\ force\ .\ \ linear\ joint\ velocity$$

$$Eq.\ 2:\ STP = segment\ torque\ .\ \ joint\ angular\ velocity$$

$$Eq.\ 3:\ SP_{seg} = JFP_{prox} + JFP_{dist} + STP_{prox} + STP_{dist}$$

Segment power: SP_{seg}, joint force power: JFP, segment torque power: STP , *prox* and *dist*: proximal and distal ends of each segments, i.e. C7, shoulder, elbow and, wrist [1, 4]. Energy transfer was computed as the difference between the time-integral of SP_{seg} for 2 adjacent segments (proximal-distal). Wilcoxon test was then performed to compare the means of right and left energy transfer.

RESULTS AND DISCUSSION

Figure 1 represent the energy flow of each of the four joints of the left and right sides of both participants.

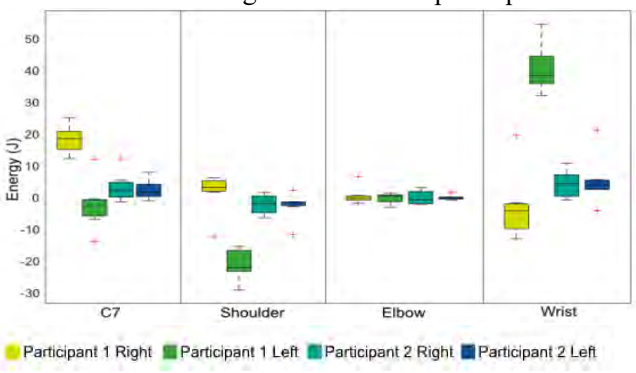

Figure 1 Boxplot of the average of delta energy transfer of participants 1 and 2. $p<0.05$

The results showed significant differences across the participants. Except at wrist, P1 created energy flow using his right side and counterbalance with his left side. P1 wrist acted in a contralateral and opposite direction. P2 energy flows were close to zero meaning it never created or dissipated energy but managed to be neutral. Moreover, a null delta energy around the elbow joint of both participants supports the idea of a locked joint with a very few degree of freedom. Therefore, the articulation being fixed can neither supply nor dissipate but transmits energy. P1 seeing in the direction of the displacement, he guided. P2 going backward was assisting well staying neutral and may be fixing all his joints. These results confirm [2] who observed that the sighted participant also guided and controlled when his partner only lifted and followed the movement.

CONCLUSIONS

This research gives insight into the energy transfer occurring during a collective stretcher transport, and confirm the guider-follower duality to be reproduced in collaborative robot.

INTRODUCTION

Military personal carry operational heavy loads, often consisting of a rucksack and body armour [1]. Heavy load carriage has been shown to change biomechanical variables during walking, standing and running e.g. [2]. There is limited understanding of the effects of rucksack design on these changes despite numerous commercial designs issued to service personnel worldwide. The effects of wearing a rucksack over armour as opposed to integrated armour are also unknown. The aim of this study was to quantify the effects of common rucksack features such as hip and chest strapping on the biomechanical changes associated with loaded running. The interaction of body armour and rucksack was also investigated.

METHODS

15 males who participated in regular resistance and cardiovascular training were recruited. Participants undertook four 1 km runs consisting of 50 x 20 m shuttles. Four loaded conditions were investigated: PC (5 kg plate carrier); LF (plate carrier + litefighter rucksack); BFMout (plate carrier + Camelbak BFM rucksack); BFMin (plate carrier + Camelbak BFM rucksack, rear plate moved from plate carrier to rucksack). The litefighter rucksack did not have any hip or chest strapping whilst the BFM had both; the litefighter had fixed shoulder straps whilst the BFM had back length adjustment. Rucksack loads were set at 20 kg such that total load was always 25 kg when wearing a rucksack and plate carrier. Retroreflective markers were used to identify the segments of the right lower limb, torso and head. Kinematic data was collected for one stace phase during each shuttle run using 15 Raptor cameras and Cortex software (version 7.02 Motion Analysis Corporation, CA). Peak knee flexion, peak forward torso lean and peak lateral torso lean timing were calculated for analysis, timings of peaks were also calculated. Variables were compared using a one-way repeated measures ANOVA. Bonferroni adjusted post-hoc t-tests were used where significant effects were identified.

RESULTS AND DISCUSSION

Discrete statistics and p values for all analysies can be seen in Table 1. Peak knee flexion timing was found to be different between conditions. Post hoc tests showed that peak knee flexion occurred significantly later in stance in the BFM_{out} condition compared to PC ($p = 0.024$). Peak forward torso lean during stance was found to be different between conditions. Post hoc tests showed that all three rucksack conditions had greater forward lean than PC (LF $p \leq 0.001$; BFM_{out} $p \leq 0.001$; BFM_{in} $p \leq 0.001$). Additionally, the BFM_{in} condition had significantly greater lean than the LF condition ($P = 0.004$). Peak forward torso lean timing occurred significantly later in stance for PC compared with the three rucksack conditions (LF $p = 0.009$; BFM_{out} $p \leq 0.001$; BFM_{in} $p \leq 0.001$). All three rucksack conditions had earlier peak lateral lean than PC (LF $p = 0.002$; BFM_{out} $p \leq 0.001$; BFM_{in} $p \leq 0.001$).

CONCLUSIONS

Results demonstrate that rucksack design has a significant effect on the biomechanics of heavy loaded carriage. Integration of body armour and rucksack can have significant effects on torso lean during stance and should be considered when combining these two pieces of equipment.

SUBJECTIVE AND OBJECTIVE EVALUATION OF SITTING-INDUCED SUSTAINED LOW-INTENSITY MUSCLE FATIGUE

Hui Lyu[1*], Jian Wang[2], Xiaoyan Dong[3]
[1] Ningbo Research Institute, Zhejiang University, Ningbo, China.

INTRODUCTION

Muscle fatigue is defined as an exercise-induced reduction in the capacity to generate the required force or power output (Vollestad, 1997). Muscle fatigue is task-dependent (Enoka, 1995), and the mechanisms behind it partly depend on exercise intensity. In today's workplace, heavy-labor work is becoming rare and replaced mainly by sustained low-intensity work. However, the knowledge of sustained low-intensity muscle fatigue and its evaluations is still limited.

METHODS

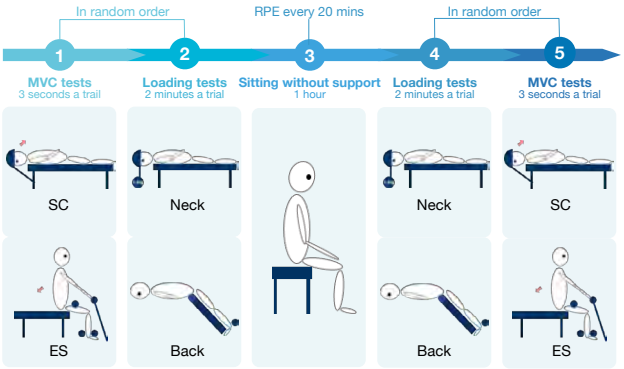

Figure 1 Experimental procedure

Ten male (20.6 ± 3.2 years) and ten female (19.3 ± 0.8 years) self-reported healthy students volunteered for the study. After outfitting and familiarization, subjects completed maximal voluntary isometric contractions (MVCs) of neck and back extension; loading tests of prone with neck loaded (1.5 kg) and Biering-Sorenson test on the roman chair. After 1-hour unsupported sitting, all the tests were repeated immediately (Figure 1). RPE was reported every 20 minutes during 1-hour sitting.
The right splenius capitis (SC) and erect spinea (ES) were recorded with the sEMG system (Delsys, USA). Root mean squared value (RMS), mean power frequency (MPF), entropy (EN), and DET% extracted from recurrence quantification analysis were computed during MVC and loading tests.

RESULTS AND DISCUSSION

RPE increased significantly during 1-hour sitting without muscle differences at any time point. As shown in Figure 2 (left, MVC tests), entropy decreased significantly after 1-hour sitting in SC and ES. Figure 2 (right, loading tests) found that for SC, RMS displayed a fatigue effect from 100 seconds in the females, and MPF showed a time effect from 60s post-sitting. For ES, there was no significant fatigue effect.

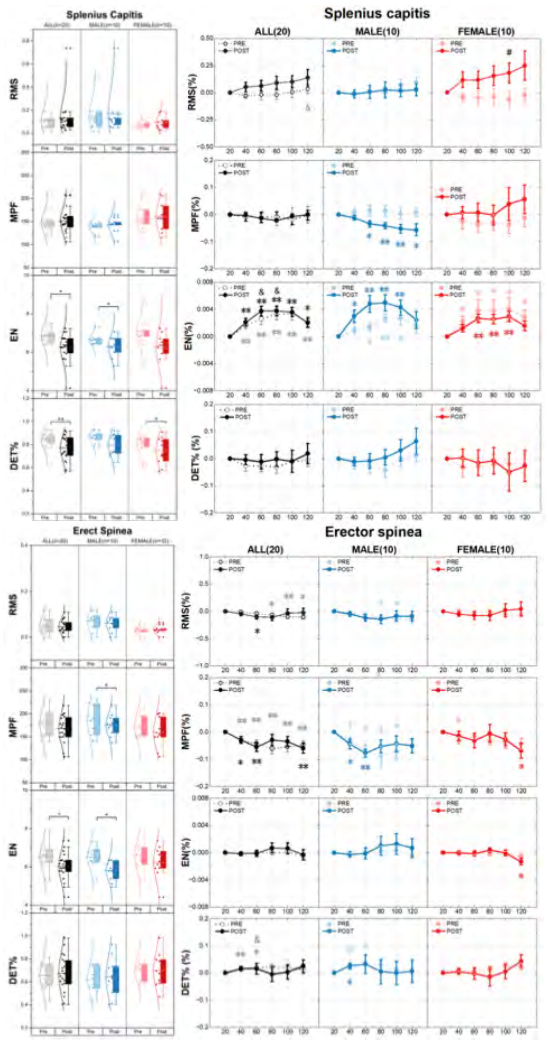

Figure 2 sEMG indexes during MVC (left) and loading test (right). Left: */** significant fatigue effect(<0.05, 0.01). Right: # significant fatigue effect (<0.05), & significant gender difference (<0.05), */** significant time effect (<0.05, 0.01).

CONCLUSIONS

For sitting-induced sustained low-intensity muscle fatigue: 1) females displayed higher subjective fatigue in the upper and lower back than males; 2) entropy of EMG from MVCs was effective in detecting fatigue in the neck and lower back muscles; 3) RMS and MPF were more sensitive than non-linear indexes from loading tests in detecting fatigue; 4) a better design of loading tests may serve as a new method to evaluate sustained low-intensity muscle fatigue.

INFLUENCE OF WALKING SPEED AND LOAD ON SPINAL CURVATURE AND PELVIC ORIENTATION DURING PUSHING TASKS

Daniel Körner[1] and Catherine Disselhorst-Klug[1]
[1]Department of Rehabilitation and Prevention Engineering, Institute of Applied Medical Engineering, RWTH Aachen University, Aachen, Germany.
Email: koerner@ame.rwth-aachen.de

INTRODUCTION

Manual pushing and pulling of heavy loads or equipment takes up a large part of the working day in many occupations in manifold sectors. Although often considered as trivial and common tasks, their non-ergonomic repetition can pose a biomechanical risk for the spine[1]. Despite ergonomic guidelines limiting load, task duration and frequency for manual handling tasks, the favourable stable and balanced posture of the upper body is often not maintained in everyday work. Although there are indicators that changes in spine curvature are related to excessive tissue stress and vertebral loading[2], so far the spinal curvature during pushing and pulling tasks is only sparsely explored. Marker-based optical measurement systems and inertial measurement units allow measurement of the trunk posture, but the accurate assessment of the spinal posture still poses a challenge. Scanning stereography provides a non-invasive, non-contact method to detect the position and pose of the spinal cord under static and dynamic conditions[3].
Therefore, the aim of this work is to study the effect of load and walking speed during pushing tasks on the spinal curvature for loads and walking speeds that are common in everyday occupational scenarios.

METHODS

The experimental set-up reproduces the pushing a load on a straight track (fig. 1). The subjects are walking on a treadmill at a selectable constant speed. They push a handle that is at individual hip height (60% of body height). The handle is mounted in such a way that it can only be moved back or forth. An exchangeable weight is attached to a cable that is redirected by a pulley and connected to the handle. This way the gravitational force acting on the weight is acting in the opposite direction of the subjects walking direction. The test subjects are pushing with different randomized combinations of load (*0N*, *80N* and *160N* force) and walking speed (*3km/h* and *5km/h*) that are adjusted between measurements.
The subjects are asked to lift the weight and hold it at a stable position while walking on the treadmill. Small fluctuations of the position are acceptable since this reflects a real pushing scenario. The subjects get about 30 seconds time to adapt to the conditions. When a uniform movement is established, the spinal posture as well as pelvic and trunk orientation are recorded over the course of five seconds. Afterwards the treadmill slows down and the weight can be dropped. The subjects get three minutes resting time between measurements.
The spinal posture of 15 healthy subjects pushing a load in a continuous and straight manner is measured. The mean values of kyphosis angle, lordosis angle, pelvic inclination and trunk inclination over three gait cycles are evaluated.

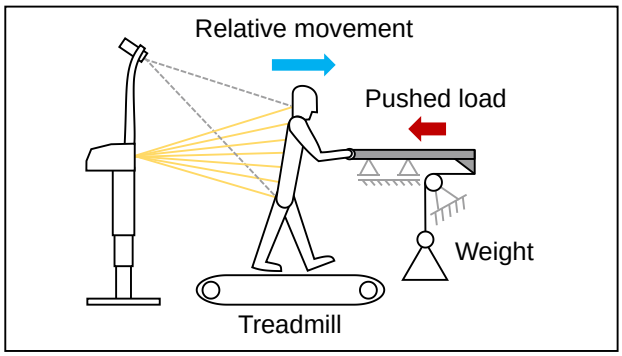

Figure 1: Experimental setup reproducing a pushing task

RESULTS AND DISCUSSION

Mean values of kyphosis angle and lordosis angle did not show a significant change with increasing load while pelvis and trunk inclination increased. This indicates an anterior tilt of the upper body with no significant signs of deformation of the spine in the sagittal plane. Since an anterior tilt of the upper body gives better support during pushing, an anterior tilt of the trunk could be expected with increasing pushing load while it is surprising that spine curvature is not affected.
Both kyphosis angle and lordosis angle decrease when walking speed increases. Trunk and pelvic inclination also increase with increasing walking speed. In contrast to higher pushing loads, higher walking speeds result in an alteration of the spinal curvature, resulting in a more excessive tissue stress and vertebral loading.

CONCLUSIONS

Results show that load and walking speed affect pelvis and trunk inclination while spine curvature is only affected by walking speed. The results suggest that walking speed should be considered when assessing the risk of pushing tasks if moving high loads.

Email: jestrazulas@uea.edu.br

INTRODUCTION

Work-related musculoskeletal disorders have been a major concern as they are the most common occupational diseases worldwide [1]. The literature indicates that psychosocial risk factors are related to MSD. They do not act in isolation, their effect combines (and often exacerbates) the effects of physical load factors [2,3]. This negative relationship goes both ways, that is, just as psychosocial risk factors can contribute to increasing the consequences of physical workload, physical workload can also enhance the perception of some psychosocial factors [3]. Thus, this study aimed to evaluate the correlation between psychosocial factors and the physical load of workers in an electronic components industry.

METHODS

This cross-sectional study evaluated 115 workers at a company in the electronics sector in the city of Manaus, Amazonas, Brazil. The jobs included in the study were manual activities in assembly, soldering, packaging and revision of electronic components. The assessment instruments used were: 1) the HSE Indicator Tool (HSE-IT) questionnaire, which assesses the worker's psychosocial risks through 35 items and seven dimensions, and 2) Strain Index, an ergonomic tool focused on physical load on hands and wrists, evaluating six parameters. Initially, a descriptive analysis of the instruments domains was performed. Then, the associations between the HSE-IT and Strain Index items were analysed using Spearman's correlation coefficient. All analyses were performed using Stata SE, version 15.0. The significance level adopted was 0.05. This research obtained ethical approval under CAAE number 58380122.6.0000.5016, Amazonas State University.

RESULTS AND DISCUSSION

The mean values of the dimensions of the HSE-IT and Strain Index are shown in Table 1. A significant association was identified between the intensity of effort and demands (r_s=0.25; p=0.006), managers support (r_s=0.22; p=0.021) and relationships (r_s=0.25; p=0.006). Associations were also identified between duration of effort and changes (r_s=-0.20; p=0.031), as well as the total score of the Strain Index instrument with the control dimension of the HSE-IT (r_s=-0.19; p=0.045).

Table 1 Descriptive analysis of the assessed instruments (n=115).

Variable	Mean	±SD
Strain Index		
Intensity of exertion	1.36	0.76
Duration of exertion	1.21	0.55
Exertion per minute	1.34	0.65
Hand/wrist posture	1.51	0.36
Speed of work	1.10	0.21
Duration of task per day	1.00	-
Total	3.34	2.97
HSE-IT		
Demands	3.28	0.42
Control	1.70	0.17
Managers support	4.53	0.16
Peers support	4.50	0.02
Relationships	3.68	0.16
Role	5.00	-
Change	3.57	0.32

The Strain Index total score was moderate. The control dimension of the HSE-IT, which assesses the autonomy of workers performing their activities, was the most critical. Although no significant correlation was observed between control and Strain Index parameters, an association with the total score was identified. The results showed that SI items correlated with different dimensions of the HSE-IT. Therefore, when using both tools, we can prioritize the workstations that require control for upper limb problems and also be indicative of the need to address psychosocial risks [2,3].

CONCLUSIONS

A relationship was found between physical load factors on hands and wrists and psychosocial factors, evidenced by the association of effort intensity with demands, managers support and relationships dimensions. The possibility of interaction between these aspects, potentializing the consequences through a bidirectional path, indicates the need for ergonomic analyses with holistic approaches in the assessment of occupational risks, since the recognition and interventions only in the physical load or psychosocial risks may not be enough to prevent future impairments to workers' health.

THE CHANGES IN BALANCE, LOWER EXTREMITY STRENGTH AND POWER OF COLLEGE TENNIS PLAYERS AFTER AGILITY TRAINING

INTRODUCTION

Tennis, a quick-moving explosive sport, requires a combination of strength, flexibility, agility, and tennis-specific skills to excel in a single game. Tennis players must serve, receive, or hit the ball several times. This process includes multiple sprints in different directions, rapid stops, sudden changes in direction, and vertical jumps, among other things. They need to maintain balance during the hitting process and effectively return the ball. The stability, coordination and sensitivity of the lower body are very important to them. Agility, or the ability to sprint and change directions quickly while running, is thought to benefit lower extremity function. However, agility training was sometimes skipped in the training protocol by student-athletes due to time-consuming and unclear effects on physical ability. The aims of this study are to determine whether agility training can improve the balance, muscle strength, and muscle power of local college tennis players or not.

METHODS

Thirteen college tennis players from Tzu Chi University were recruited in this study. Each participant underwent 30 minutes training protocols from the International Tennis Federation and/or United States Tennis Association twice a week. Outcome measurements, including the vertical jump test and the single hop test for power, the Y-balance test for balance, and the wall squat test for strength, were evaluated. The Wilcoxon Signed Rank Test was used to compare the differences before and after six weeks of the training program by using the Statistical Package for the Social Sciences software. A significant level of p-value < 0.05 was set.

RESULTS AND DISCUSSION

After six weeks of agility training, significant improvements were found in the Y-balance tests posterolateral reach with right leg standing (95% interval changes = 63.7~117.4 to 82.02~112.05) and the Y-balance test anterior reach with left leg standing (95% interval changes = 45.00~69.9 to 43.1~81.59). The Y-balance tests is related to lower extremity stability and postural control. In this study, two Y-balance test directions were found to be improved[1], which are movements that resemble the foot's position when striking a tennis backhand. The improvement in this findings may be explained by the fact that the subjects are student-athletes, who may not have trained their non-dominant side adequately[2]. This also applies to the backhand, which performs comparatively poorly as compared to the forehand. Foot dominance also affects support strategies. The dominant foot is usually related to stability and non-dominant foot related to mobility. The stability of the lower limbs will directly affect the power of hitting the ball and the accuracy of the hitting process. If agility training can improve the balance of the lower limbs in this direction, it may also improve sports performance. However, there were no statistically significant changes in muscle power or strength after six weeks of training(Table1). The overload principle suggests that agility training may not have significantly improved these players' muscle adaption.

Table 1: Y-balance tests Posterolateral reach and Anterior reach

	Pre-test	Post-test	*p-value*
Posterolateral reach (right leg stand)	90.54 ± 13.70	97.04 ± 7.66	$p = 0.036$
Anterior reach (left leg stand)	57.46± 6.36	62.35 ± 9.82	$p = 0.016$
vertical jump test	39.23±10.76	41.54±10.75	*P=0.248*
wall squat test(right)	37.23±17.82	37.33±9.34	*P=0.972*
wall squat test(left)	47.25±24.36	40.22±12.11	*P=0.552*

CONCLUSIONS

Six weeks of agility training may improve balance but not muscle strength and muscle power for college tennis players. Our results suggest that the six weeks of agility training may improve the balance ability, especially in posterolateral reach with right leg standing and anterior reach with left leg standing, which should be incorporated into the training protocol for tennis players.

INTRODUCTION

Changes in muscle metabolism due to sex, age, and maturation can impact youth sport performance [1]. While age-related changes have been well documented, the specific effects of maturation on muscle and sport performance are not well understood [1][2]. More studies are needed to compare performance differences between different age groups, especially in young athletes [4]. This current study aims to determine the differences in speed, change of direction, and explosive power between U-15 and U-18 soccer players.

METHODS

Thirty secondary school soccer players (n=30) participated in this study. The participants were divided into two groups: U-15 (n=15; aged 13-15 years) and U-18 (n=15; aged 16-18 years). Each participant underwent three physical tests: 20 m sprint test, arrowhead agility test, and counter-movement jump (CMJ) test. A speed timing gate system was utilized to record the time of the sprint for the 20 m sprint test and the arrowhead test in order to minimize any potential biases in the testing. The Counter-Movement Jump Test was conducted using the "My Jump 2" application on a smart mobile phone.

RESULTS AND DISCUSSION

An independent T-test revealed a significant difference ($p<0.05$, $p=0.043$) in explosive power performance between the U-15 and U-18 soccer players (Table 1). In addition, a trend towards significant in speed performance ($p=0.05$) was also observed. This can be attributed to the difference in age, as the U-18 soccer players are older and therefore capable of producing greater muscular power. As the individual transitions from childhood to adulthood, numerous physiological changes occur in the neuro-muscular system, including muscle-tendon development, muscle activation, circulation of androgens, and motor unit recruitment [5]. Additionally, as players mature, they tend to display increased maximal force production and improved muscle capabilities, specifically regarding their muscle's stretch-shortening cycle (SSC) and the strength of the lower limb muscles crucial for executing jumps [3].

	U-15	U-18			
	Mean ±Std	Mean ± Std	df	t	p
20 m sprint test	3.23 ± 0.09	3.16 ± 0.11	27.43	2.01	0.05
Arrowhead test (right)	8.45 ± 0.30	8.28 ± 0.29	27.98	1.51	0.14
arrowhead Test (left)	8.49 ± 0.30	8.39 ± 0.30	28.00	0.95	0.35
CMJ Test	36.66 ± 4.48	40.37 ± 5.10	27.54	-2.12	0.04*

Table 1. Performance test comparison between U-15 and U-18.
*Indicate significant difference.

CONCLUSIONS

The findings of this study demonstrate a faster speed and higher power performance in U-18 players compared to U-15 players. These findings may suggest that in youth players, differences in age and maturity may have a significant impact on sport-related performance. This is due to the interplay of various physical and physiological variables that are related to age, growth, maturation, and sex. Typically, earlier-maturing players are taller, heavier, and more muscular than later-maturing players. However, these differences may be altered by specific training interventions.

ACKNOWLEDGEMENTS

The author expresses appreciation to Sultan Idris Shah II Secondary School, Malaysia for allowing the recruitment of participants for this study. The author also thanks all those who helped in the completion of this project with their invaluable contributions and cooperation.

Influence of Penn State University on the International Society of Biomechanics

Brian L. Davis, Ph.D[1]
[1] Department of Mechanical Engineering, Cleveland State University, Cleveland, Ohio, 44115, USA
Email: B.L.Davis@csuohio.edu

INTRODUCTION

The International Society of Biomechanics (ISB) was founded in 1973, with its first president being Dr. Jurg Wartenweiler from Switzerland. The creation of the ISB was on the campus of Penn State University, where Dr. Richard (Dick) Nelson had established a lab in 1967, initially focusing on sport biomechanics. This humble beginning in a circular water tower would later result in groundbreaking research into human gait, ergonomics, muscle mechanics and biomechanical instrumentation.

METHODS

This historical review is based on published literature, ISB archives, and communication with ISB pioneers.

RESULTS AND DISCUSSION

In is first 50 years, the ISB has had 23 presidents, with the first two (Wartenweiler and Nelson) each serving 4 years. Of these presidents, 7 (Table 1) have had close ties with Penn State (three as faculty members, and four who obtained doctorates, two advised by Nelson, and two by Cavanagh). Nelson's first doctoral graduate was Doris Miller, who was a member of the first Executive Council and the first woman to serve on ISB's Council. The next woman elected to the Executive Council (Micheline Gagnon) was also one of Nelson's students. Her research on sprinting was completed in 1976, 13 years before she became an ISB Council member.

The ISB organization depends on multiple volunteers. Dewey Morehouse and Nelson served as Treasurers for 9 years, and other Penn State alumni have served multiple terms as Secretary General or Newsletter Editor. Challis is the current archivist who oversees the collection of ISB documents at Penn State.

Figure 1. A historical marker on the campus of Penn State University. It highlights the formation of the Biomechanics Lab in 1967, and the founding of the ISB 6 years later. https://hhd.psu.edu/news/2010/biomechanics.html

CONCLUSIONS

Students and faculty such as Nelson and Cavanagh and others associated with Penn State have played key roles in both the initial development of the ISB as well as the continued growth around the world.

ACKNOWLEDGEMENTS

The author acknowledges the role of Penn State in his own professional growth, and the network of colleagues that is the hallmark of ISB.

Email: hlchen@ntu.edu.tw

INTRODUCTION

Early detection of cognitive decline in older adults has become increasingly important. Cognitive and motor dysfunction were found in patients with mild cognitive impairments (MCI). The kinematic features of alphabetical handwriting have been reported as a potential indicator for discriminating between adults with and without MCI [1]. In Chinese handwriting, the spatial arrangement of characters was more diverse than words in alphabetic writing. Exploring kinematic features of copying characters with 1 to multiple components may reflect different cognitive and motor dysfunction in patients with MCI [2]. Thus, this study aimed to investigate the Chinese handwriting performance of adults with and without MCI.

METHODS

Fourteen participants with MCI (5 males, mean age: 76.0) and 14 healthy controls (HC) (5 males, mean age: 73.3) were recruited to copy Chinese characters with 1 to 5 components (Figure 1(A)). The stylus trajectories were collected by a digitalized tablet and pen (Figure 1 (B)). The kinematic parameters calculated in this study include: (1) The sill time during each stroke, (2) the ratio of in-air to on-paper trajectory length (length ratio) and (3) the ratio of in-air to on-paper time (time ratio). The generalized estimated equations were conducted to confirm the kinematic differences in handwriting between the MCI and HC groups.

3	你、原
4	落、能
5	影、偷

(B) 
Figure 1 Experimental equipment and task. (A) Copying material of 1 to 5 components. (B) Digitalized tablet and pen.

RESULTS AND DISCUSSION

Table 1 summarizes the results for kinematic parameters. Significant interactions were found in length ratio (p=.015), time ratio (p=.023) and still time (p<.001). The MCI group showed a significantly larger time ratio than the HC group in all copying tasks (p=.001-.013). Furthermore, the MCI group showed a significantly larger length ratio (p=.004-.022) and a longer still time (p=.004-.017) than the HC group when copying characters with more than one component. Patients with MCI wrote strokes with more redundant trajectories and longer pauses, indicating difficulties in processing writing movements with complex spatial configurations. Those results indicate patients with MCI performed writing movements less efficiently than those in the HC group. Copying characters with more than one component may exhibit that patients with MCI have impaired visuospatial skills.

CONCLUSIONS

Patients with MCI showed more characteristics of impairments when copying characters with the increased number of components. Using Chinese characters with complex spatial arrangements as copying material is necessary to detect both motor and visuospatial dysfunction.

Novel Spring Cleat Testing with Custom-Built Shoe Test Device Yields Null Result

Gregory Chingas, MS[1], Andrew Kraszewski, PhD[1], and Howard Hillstrom, PhD[1]
[1] Leon Root, MD Motion Analysis Laboratory, Hospital for Special Surgery, New York, USA.
Email: chingasgreg@gmail.com

INTRODUCTION

The player-shoe-surface interface is a complex, variable system [1]. Though traction at the shoe-surface interface is implicated in lower extremity injury, studies suggest flexible cleat components lessen rotational stiffness, affecting injury type and risk [2-4]. A deformable, dual spring-loaded cleat (Cleat Assembly, or CA; Patent No.: US 11,213,101 B2) could affect lower extremity injury similarly through coupled compression and bending. The purpose of this study was to quantify repeatability of a custom-built shoe test device in producing torsional friction parameters (TFPs) and differentiate between CAs with stiff and soft compression and bending springs. Barring strong test device reliability, it was hypothesized that TFPs would decrease from standard cleats to stiff CAs, and from stiff to soft CAs.

METHODS

Test device reliability testing

Ten cleats with rigid spikes were rotated by two testers (GC and AK). Cleat, tester, and test options (test-retest and remove-replace) orders were randomized. Cleats were rotated 10 times for each of three test options, and each cleat was rotated 30 times per tester, or 60 total times. Rotations were performed using prosthetic feet over artificial turf adhered to a force plate. Cleats were positioned in foot flat prior to rotations, and turf position was consistently changed to reduce wear. Rotations were performed with a compressive force and rotational pressure of about 50 lbf and 70 psi, respectively.

Cleat Assembly testing

Soft and stiff CAs were prepared using commercially available springs matching CA specifications. Seven cleats were tested by one tester (author GC), and each cleat was rotated 20 times – 10 times per CA type (soft or stiff). Otherwise, procedures from test device reliability testing were followed.

Motion analysis

An eight-camera motion capture system and one force plate were used. Reflective markers were placed on all cleats at toes, heel, and proximal and distal lateral and medial locations.

Statistical analysis

Rotations 4 through 10 from all tests were analyzed. Stiffness (torque linear regression from 0 to 5° rotation), peak torque (torque taken at 15°), and release coefficient (moment-to-vertical force ratio) were computed from test device reliability (control) and CA testing. Cronbach's alpha (α) values were computed to quantify test device internal consistency. Wilcoxon signed-rank tests were used to compare TFPs produced in control, soft CA, and stiff CA conditions, and p values less than 0.05 were considered significant.

RESULTS AND DISCUSSION

The test device was excellent ($\alpha \geq 0.875$) at consistently producing TFPs (Table 1). For CA testing, data from one cleat were omitted from analyses given outlier behavior in soft and stiff conditions. There were no significant differences for stiffness and peak torque between all conditions ($p > 0.05$). Though a decrease in release coefficient from control through soft CA was expected, a significant increase in this TFP from control to stiff CA ($p = 0.018$) and stiff CA to soft CA ($p = 0.047$) was observed (Figure 1).

Table 1: Cronbach's alpha values for TFPs. Internal consistency was assessed as excellent ($1.0 > \alpha \geq 0.8$), good ($0.8 > \alpha \geq 0.6$), and moderate ($0.6 > \alpha \geq 0.3$).

	Stiffness	Peak torque	Release coefficient
Cronbach's Alpha	0.875	0.898	0.899

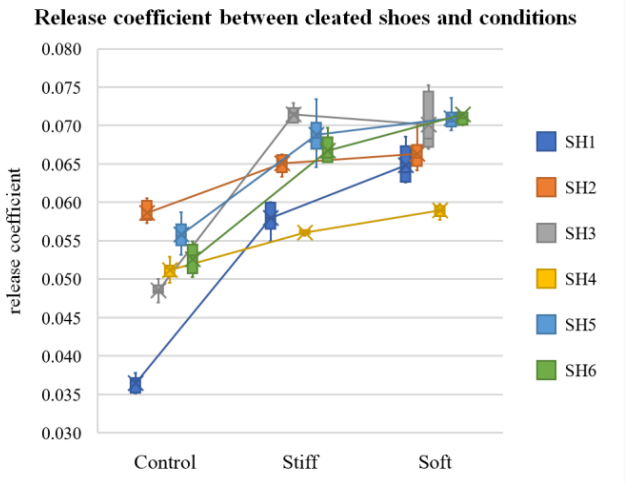

Figure 1: "X" marks indicate mean values, which are connected between condition for all shoes by lines.

CONCLUSIONS

Despite the test device's reliability in producing TFPs, CA testing yielded a null result, which necessitates vetting the current CA design. Understanding the test device's static response (i.e., peak torque timing and magnitude given a specific input) would be ideal for future testing to better define and assess TFPs. Lastly, future tests with the test device should be conducted using real-world forces and moments.

Tracking golf swing trajectory using a single IMU by applying biomechanics and machine learning

Myeongsub Kim and Sukyung Park
Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea.
Email: myeongsub@kaist.ac.kr

INTRODUCTION

Human motion monitoring services using wearable devices are becoming popular, but the information from most golf-related devices is limited to operation-related and club kinematics. Recently, golf wearable devices have shown a trend to provide kinematic details on the body, but the amount of information and accuracy is still limited. Therefore, in this study, we applied biomechanics and machine learning to improve the tracking accuracy of the upper limb's trajectory using a single IMU.

METHODS

Three technical issues should be addressed in order to enhance the swing tracking accuracy: segmentation, orientation calibration, and trajectory calibration.

Before addressing the issues, to collect the golf swing data, nine professionals and eleven amateur golfers with an average handicap of 15.3 were recruited. A 6-axis IMU was attached to the wrist, and data was collected from the IMU and the motion capture system, swinging 10 times each with a driver and a 7-iron.

First, we segmented the golf swing data from the IMU signal into swing phases using a heuristic approach [1]. The indicators of minimum, maximum, or zero-crossing of the IMU signal were manually selected to segment the address (ADD), backswing top (BST), impact (IMP), and finish (FIN) points.

Then we applied a convolutional neural network (CNN) to calibrate the initial sensor orientation. The sensor orientation during the entire swing was calculated using the angular velocity from the IMU.

Finally, we calibrated and estimated upper limb trajectories. The wrist speed was calibrated with the traits that the speed comes to 0 at ADD, BST, and FIN. The wrist trajectory was calibrated to approximate a circle. The elbow and shoulder trajectories were estimated from the wrist trajectory by modeling the elbow flexion using trigonometric functions.

RESULTS AND DISCUSSION

Tracking accuracy using the methods at each step described above was calculated and compared.

Using a heuristic method, we segmented the golf swing phases with a mean absolute error (MAE) of approximately 60ms on average (Figure 1A).

Without using any additional calibration motion, the suggested CNN-based method calibrated the initial sensor orientation with a MAE of about 7.5 degrees (Figure 1B). This result shows higher accuracy than the baseline obtained using the averaging method and the N-pose and T-pose methods currently in use [2], which revealed errors of between 6 to 40 degrees.

The proposed method reduced the MAE by 70%, compared to the naïve integration, calibrating the wrist trajectory from the IMU with a MAE of about 0.15m. With a MAE of 0.11 m and 0.13 m, respectively, the proposed method estimated the trajectory of the unmeasured elbow and shoulder joints during the backswing and downswing phases (Figure 1C).

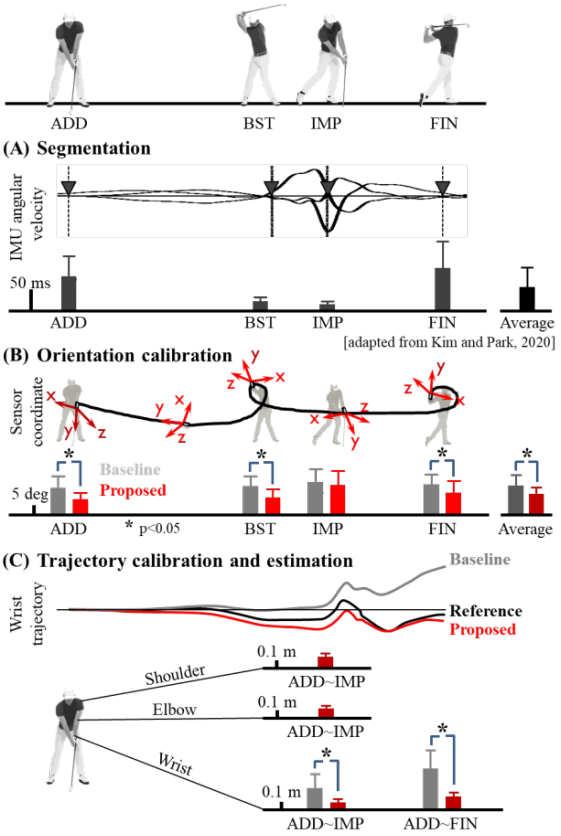

Figure 1 MAE of the (A) segmentation, (B) orientation calibration, and (C) trajectory calibration and estimation.

CONCLUSIONS

In this study, we enhanced the tracking accuracy of the upper limb kinematics from a single IMU by applying biomechanics and machine learning. It implies that we might be able to overcome the wearable devices' motion tracking limitations by comprehending the biomechanical characteristics of the movement.

INTRODUCTION

Adult spinal deformity (ASD) is a degenerative disorder resulting in three-dimensional (3D) spinal deformities [1]. ASD is known to alter spinal biomechanical parameters, like muscle geometry and physiology, yet these are still neglected by current treatment decision-making [2]. Musculoskeletal models (MSKM) are increasingly used to evaluate these parameters in many other musculoskeletal disorders. However, existing generic MSKM fail to account for the altered spinal biomechanical parameters in ASD [3] and to date, no biofidelic MSKM for ASD patients exist. The aim of this research is to develop an efficient image-based workflow for the definition of subject-specific muscle parameters in MSKM of ASD patients.

METHODS

MKSM of one representative ASD patient with subject-specific muscle parameters was defined in a workflow, using Mimics and 3-Matic, with python interface (Materialise, Belgium): 1) Semi-automatic multi-atlas segmentation of muscles in magnetic resonance imaging (MRI); 2) Landmark-based registration of previously developed OpenSim [4] spine MSKM, with personalized geometry and spinal alignment [5], to MRI; 3) Muscle parameter definition: attachment points and wrapping surfaces. Attachment points are defined automatically with a closest-point algorithm. Wrapping surfaces are used to prevent bone penetration and ensure a realistic anatomical muscle representation. These surfaces are defined with three different methods; Method 1: manual cylinders and spheres definition, Method 2: automated tori definition using an optimal fit to the vertebral geometry, Method 3: manual adjustment of the dimensions, 3D orientation, and position of the tori from Method 2 to visually correct for discontinuities in moment arms (MA). For all methods, the MA at the lumbar intervertebral joints spanned by respectively 22, 48, and 18 fascicles of the psoas, multifidus, and erector spinae muscles in the resulting personalized MSKM are compared to the MA of a generic MSKM [5] scaled to the anthropometry of the same ASD subject for the following range of motion: flexion-extension and lateral bending: -8° to +8°, axial rotation: -5° to +5°.

RESULTS AND DISCUSSION

The generic MSKM resulted in unphysiological behaviour with many fascicles penetrating bone, thus resulting in smaller MAs (Fig. 1). In addition, some fascicles had the opposite action compared to the personalized MSKM, highlighting the inability of generic MSKM to account for the 3D malignment. However, the wrapping surfaces in the personalized MSKM introduced small discontinuities in MA, compared to the generic MSKM (Fig. 1). Method 1 usually resulted in the least and smallest discontinuities, but required almost twice as many wrapping surfaces as Methods 2 and 3, thus increasing the computational cost. Method 2 generally resulted in the largest discontinuities, albeit still relatively minor. Method 3 often reduced and even removed these discontinuities.

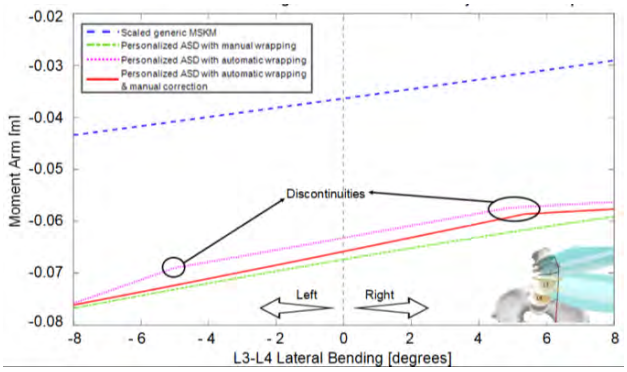

Figure 1 Moment arms at the L3-L4 intervertebral joint during lateral bending for fascicles of the left psoas muscle.

CONCLUSIONS

This novel workflow is the first to allow for an efficient definition of realistic subject-specific muscle parameters in MSKM of ASD patients, with an anatomically correct muscle geometry, while preventing bone penetration during the representative range of motions. The workflow will be validated for a larger set of patients, but is already promising to provide accurate biomechanical analyses of ASD.

INTRODUCTION

Numerical models of the musculoskeletal system are an integral part of biomechanical and clinical research. Multibody modeling allows the consideration of biomechanical systems from a holistic perspective, and thus, takes into account multiple influencing factors of mechanical loads. Being the source of major health issues worldwide, the human spine is subject to a variety of studies using these models to investigate and understand healthy and pathological biomechanics of the upper body. Models usually consider muscle mophology from cadaver studies or imaging data from a single individual. However, muscle morphology is highly individual, depending on various factors, such as age, fitness, genome, or pathological changes of the musculoskeletal system of the respective subject. To this date, only few studies exist, that systematically investigate the effects of altering muscle morphology on spinal loading[1].

METHODS

We used our validated pipeline for automated generation of individualized models of the torso with detailed lumbar spine[2] to assess the influence of altering muscle physiological cross sectional area (PCSA) on spinal loading in 93 patients. For abdominal muscle force estimation, we used a combination of inverse dynamics and static optimization (*global search, fmincon, Matlab*). The cost function was defined as the sum of cubed muscle stress and maximum muscle stress was set to 1MPa. We simulated static upright standing, 30° flexion, and symmetric lifting of 10kg close to the chest and with stretched arms. The PCSA of single fascicles of erector spinae (ES) and multifidus muscle (MF) were each set to 0%, 30%, and 50%. Resulting spinal loads were compared to results from simulations with full muscle architecture considering the patient's individual upper body weight and spinal alignment.

RESULTS AND DISCUSSION

Depending on individual lumbar alignment, effects were most evident in upper (T12/L1) and lower levels of the lumbar spine (L5/S1) in loading tasks with a 10 kg weight lifted with stretched arms. Normalized anterior-posterior shear loads increased to 128 % on average, with a maximum of 208 % at T12/L1 for ES PCSA reduced to 30%. Simultaneously, compression forces were increased up to 120% (Figure 1).

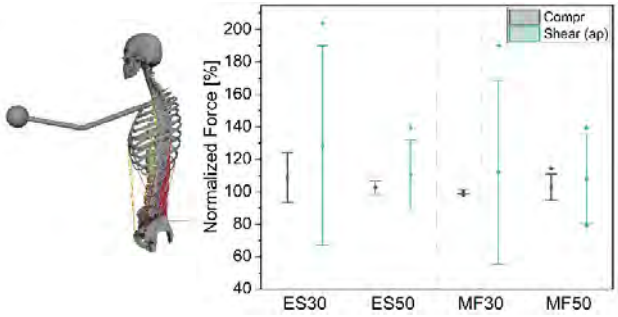

Figure 1 Normalized anterior-posterior shear and compression forces in T12/L1 during lifting of 10 kg with stretched arms under consideration of individual anthropometry and spinal alignment.

Static equilibrium conditions could not be met for the vast majority of models with disabled ES or MF. With increasing body weight or lumbar malalignment, models with reduced MF were less likely to meet static equilibrium conditions for challenging loading tasks.

CONCLUSIONS

Our results indicate that the loss of functional muscle cross sectional area, e.g. due to muscle atrophy or intramuscular fat, leads to increased spinal loading with a pronounced effect on anterior-posterior shear forces. Furthermore, our study emphasizes the relevance of paraspinal musculature for spinal stability and associated malalignment[3] to prevent potentially pathological overload.

Quantifying Spinal Parameters for Scoliosis Using A Low-Cost 3-Dimensional Motion Capture System

Pitchaya Rayothee[1,2] and Professor Philip Rowe[1]
[1] Department of Biomedical Engineering, University of Strathclyde, Glasgow, Scotland.
[2] Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.
Email: Philip.rowe@strath.ac.uk

INTRODUCTION

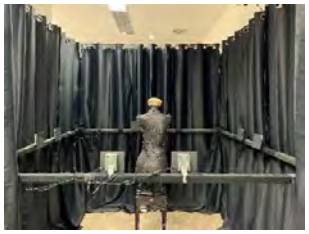
A lateral deviation of the spine of more than 10° is considered scoliosis [1]. Adolescent idiopathic scoliosis accounts for 80% of cases and is more common in girls than boys [2]. Scoliosis treatment options include non-surgical and surgical correction. Spinal orthosis is recommended as a treatment option to delay the curve progression [1]. Radiography is a standard method for quantifying outcomes [1]; however, it can be harmful and cannot be described in three dimensions (3D). A motion capture system is another option; however, current systems are expensive and not available in clinics [3]. Therefore, the study objective was to develop an alternative method to quantify the spinal parameters (SP) for scoliosis using a low-cost 3D motion capture system.

METHODS

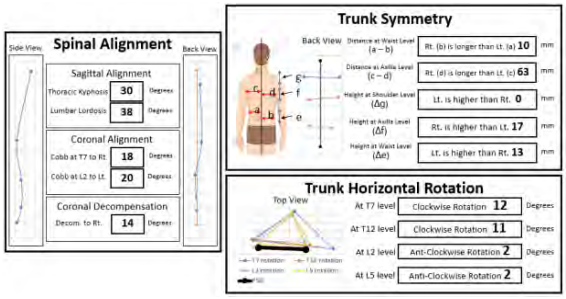
We developed a low-cost 3D motion capture system. Which utilised eight Raspberry Pis (3B+) each with a camera which streamed to a local network real time images wirelessly. A central, windows based computer running a purpose written C++ programme in Visual Studio 2019 collected and analysed the video frames from the cameras. White markers were used to track key anatomical landmarks. Twenty-five passive markers were attached using double sided wig tape to the spinous processes of C7/T7/T12/L2/L5; acromion processes; axilla level; inferior angle of scapula; waist level; at the same level as T12/L2/L5; PSIS; xyphoid process; umbilicus; middle distance between xyphoid and umbilicus; and middle distance between ASIS.
In the initial test phase, a scoliotic manikin was used to quantify relevant spinal parameters and check for accuracy and precision. After calibrating the camera and attaching the marker, the manikin was positioned in the center of the camera frame (Figure 1.a). The developing software then determined the locations of the markers prior to calculating the SP during the data processing method. The system was then used to measure before and after orthotic casting in a series of patients to determine the amount of change produced in spinal curvature during casting.

RESULTS AND DISCUSSION

The graphical user interface (GUI) displayed fourteen SP, including the level of shoulder, axilla, and waist; distance between left and right side to the central line at the axilla and waist level; thoracic kyphosis; lumbar lordosis; Cobb angle at T7 and L2; trunk horizontal rotation at T7, T12, L2 and L5 level; and coronal decompensation (Figure 1.b). Moreover, there were another sixteen SP for further evaluation, including upper and lower thoracic, upper and lower lumbar in sagittal, coronal, and 3D angles with respect to the horizontal plan. The results displayed on the GUI were the most common SP observed by clinicians during the assessment process. Additionally, another set of SP were previously studied by Jane [3] and included in this study for further analysis.



a)



b)

Figure 1 a) A low-cost 3D motion capture system and b) Results of spinal parameters and a graphical representation of the trunk.

CONCLUSIONS

A low-cost 3D motion capture system technique can be developed to quantify appropriate SP in clinics. In a clinical situation, the clinician normally observes by eye; however, the motion system developed could assist in quantifying and reporting the result and hence provide a scientific basis on which to develop future practice.

ACKNOWLEDGEMENTS

I would like to thank the University of Strathclyde for my Ph.D. study and thank the Faculty of Medicine Siriraj Hospital, Mahidol University, for my PhD scholarship.

INTRODUCTION

Human neck range of motion (ROM) during researcher-initiated movements reduces with age [1], but neck behaviour when the muscles are relaxed (i.e. passive) has only been reported for young and mid-age adults [2, 3]. Passive ROM and stiffness data is needed for computational modelling and surrogate neck design. Therefore, the aim of this study was to measure passive neck stiffness and ROM in flexion, extension, lateral bending and axial rotation, and to examine if these outcomes were dependent on age and sex.

METHODS

Two custom low-friction testing apparatus were used for bending (flexion/extension, lateral bending) and axial rotation tests. Participants were strapped to each apparatus lying in the prone or lateral position, and their head was slowly rotated by the researcher to their maximum ROM. An electromyography system (Trigno, Delsys, USA; 2 kHz) with real-time audio feedback was used to alert participants if they exceeded a "passive" muscle activation threshold. Reflective markers were placed on the participants' head, neck, and upper torso to provide instantaneous moment arm and head/neck kinematic data, via a 13-camera motion capture system (Vantage, Vicon, UK; 100 Hz). Bending moments were calculated by multiplying the tangential pulling force (9327C, Kistler, SUI; 2 kHz) by its instantaneous moment arm. Axial rotation moments were recorded by a six-axis load cell (MC3A, AMTI, USA; 2 kHz). Three trials were performed for each motion. Moment-angle plots were generated for each trial, and divided into three zones via an automated cubic and tri-linear fit process. Neck stiffness was calculated as the gradient of the moment-angle data in each zone. The effect of age, sex, and their interaction, on ROM and stiffness were examined with linear regression models (flexion, extension) and linear mixed models (lateral bending, axial rotation; fixed effect: left/right side, random effect: participant). Post-hoc tests were completed if the age-sex interaction was significant (SPSS, IBM, USA; $p < 0.05$). For brevity, stiffness and ROM for lateral bending and axial rotation are reported as the mean of left and right.

RESULTS AND DISCUSSION

40 males and 40 females participated (age: 20 – 80 years). ROM for flexion, extension, lateral bending and axial rotation were 46 ± 11, 63 ± 14, 37 ± 11 and 66 ± 17 degrees, respectively, and were not dependent on age ($0.05 < p < 0.49$) or sex ($0.21 < p < 0.97$). Age effects on extension (zone 3) and lateral bending (zone 1-2) stiffness were sex dependent ($p < 0.01$), with 3.16, 4.56 and 9.08 Nmm/deg/yr increase for males and 1.10, 2.13 and 3.94 Nmm/deg/yr increase for females (Figure 1). Stiffness increased with age, independent of sex, in extension (zone 2: 1.32 Nmm/deg/yr, $p < 0.01$), lateral bending (zone 1: 0.37 Nmm/deg/yr, $p < 0.01$) and axial rotation (zone 1-3: 0.19, 0.58, 1.11 Nmm/deg/yr, zone 1: $p = 0.045$, others $p < 0.01$).

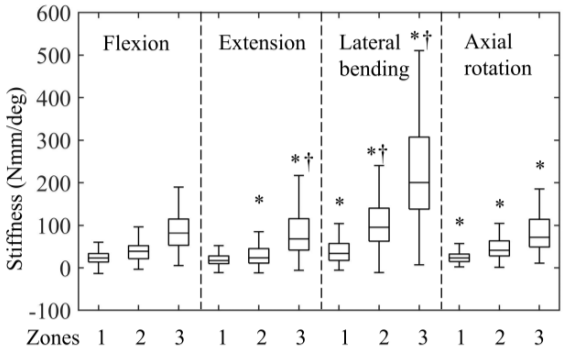

Figure 1: Neck stiffness in each zone, for all motions. All ages and both sexes are presented together for brevity. *Significant age effect ($p < 0.05$). †Significant age-gender interaction ($p < 0.05$). Box: median, 1st and 3rd quartile. Whiskers: indicate minimum and maximum data points that are within 1.5 interquartile range from the box.

CONCLUSIONS

Unlike seated researcher-initiated neck ROM reported previously [1], passive lying neck ROM was not dependent on age or sex. Passive neck stiffness generally increased with age in extension, lateral bending, and axial rotation, and the "rate" of this increase was sometimes sex dependent. Stiffness in flexion was not age dependent in this cohort. These data enhance understanding of the effects of age and sex on cervical spine mechanics and provide data for computational and surrogate neck modelling.

INTRODUCTION

Virtual reality systems constitute a new and interesting approach to the assessment and treatment of musculoskeletal musculoskeletal disorders, particularly chronic neck pain [1, 2]. The objective of this work was to evaluate the concurrent validity and test-retest reliability of the measurements of neck range of motion (ROM) and cephalic repositioning (CR) using a commercial virtual reality system, the Virtualis®, in order to be able to integrate it in clinical routine.

METHODS

Thirty healthy subjects (aged 18-70 years) volunteered to participate in our study. Each subject performed two measurement sessions, 5 to 7 days apart. During the first session, the Virtualis® system, via a virtual reality headset (VIVE Cosmos Elite), and a 14-camera VICON® system tracking reflective markers were placed on anatomical landmarks were used simultaneously to evaluate the validity of the measurement. During the second session, only the virtual reality system was used. The sessions, in standardized seated position, consisted of measurements of cervical ROM in the three planes followed by a neutral CR test after right and left rotation. Six trials were executed for each task and the average value was computed. ICC(2,k) and Bland & Altman method were used to compare systems and sessions.

RESULTS AND DISCUSSION

Reliability: The ICC(2,k) for the ROM analysis ranged from 0.74 to 0.92, corresponding to levels of agreement ranging from moderate to excellent [3]. Mean differences (MD) between sessions did not exceed 3.2°. The ICC(2,k) for CR was 0.35 corresponding to a poor level of agreement (MD = 0.2°, Figure 1).

Validity: The results obtained in the analysis of ROM showed a moderate to excellent agreement (ICC(2,k) >0.67) for flexion/extension ROM with a MD between instruments of 1° for flexion and 7° for extension.
Validity was poor for left/right rotation with a mean difference larger than 24° (ICC(2,k) >0.19), and fair for left/right lateral bending (mean difference > 7°; (ICC(2,k) >0.52). Larger ROM was measured by the Virtualis system for axial rotation and lateral bending.

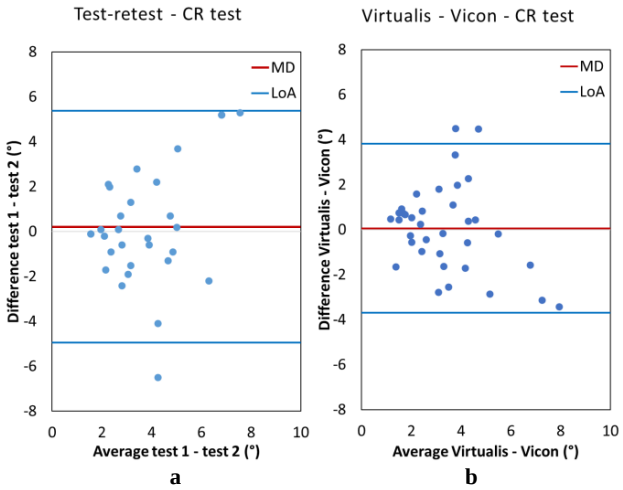

Figure 1 Bland & Altman plots for CR. a) reliability; b) validity.

Regarding the CR test, validity of the Virtualis® was found to be moderate with a mean difference between systems of 0.1° and an ICC(2,k) of 0.67 (Figure 1).

CONCLUSIONS

Virtualis® was shown to have a good reliability for cervical ROM measurements. Concerning concurrent validity, the results indicate acceptable agreement for sagittal plane motion. However, for lateral bending and especially axial rotation, Virtualis overestimated ROM significantly. This bias is linked to the contribution of the upper thoracic spine. Work is in progress to propose a resolution of this source of bias.
On the other hand, cervical repositioning errors measured by Virtualis® displayed negligible differences between repeated sessions and compared to Vicon reference measurements, pointing at a good reliability [4] and validity of Virtualis, despite low ICC values, probably linked to the low dispersion of measurements [5].

INTRODUCTION

Spinal cord injury (SCI) may lead to sensory-motor impairment, including diminished muscle control, muscle weakness, and paralysis. Lower leg muscles, crucial for daily activities like walking and maintaining balance, are often affected due to their innervation in the lumbar and sacral segments of the spine. There is potential for partial recovery during the acute phase of SCI due to numerous neurophysiological changes [1] that may persist during the sub-acute and chronic SCI. However, the knowledge of these neurophysiological adaptations in the dorsiflexor muscles is still limited. High-density electromyography (HD-EMG) allows non-invasive observation of muscle activation and motor unit behavior *in vivo*, helping to understand these adaptations and aid in developing effective treatment and rehabilitation strategies for individuals with SCI.

METHODS

HD-EMG data (64 channels) were collected from the *tibialis anterior* of eleven participants (7 male, age: 56.0 ± 10.8 yrs., BMI: 25.9 ± 3.1) with sub-acute or chronic (> 7 months) SCI and ten age-matched control participants (4 male, age: 55.5 ± 9.4 yrs., BMI: 29.1 ± 4.6). The subjects were asked to perform four repetitions of isometric dorsiflexion at 20% and 50% of their maximum voluntary contraction (MVC) while seated on a chair, with their hip and knee fixed at 90º and ankle fixed in the neutral position. Participants were given visual feedback to guide the contraction intensity. The torque was measured simultaneously using an ankle dynamometer. The HD-EMG data was decomposed into separate motor unit firing events using convolutional kernel compensation [2]. Parameters, such as maximal torque (normalized to body weight), variability of sustained torque (CoV_{TRQ}), normalized EMG amplitude ($NRMS_{EMG}$), motor unit discharge rate and variability (CoV_{ISI}), and motor unit recruitment thresholds were calculated for each person. Between-group comparisons were made, and the statistical significance was determined with independent samples t-test (normally distributed data, $p < 0.05$) or the Man-Whitney U test (non-normal distribution, $p < 0.05$).

RESULTS AND DISCUSSION

The preliminary results showed a slightly decreased dorsiflexor strength (SCI: 0.49 ± 0.14 Nm/ kg; control: 0.57 ± 0.08 Nm/kg; p = 0.105) in the SCI group. We found that participants in both groups could maintain the torque with similar variability (at 20% MVC SCI: 0.06 ± 0.06, control: 0.05 ± 0.03, p = 0.81; at 50% MVC SCI: 0.05 ± 0.05, control: 0.05 ± 0.03, p = 0.61). However, the SCI participants needed a higher $NRMS_{EMG}$ to achieve the same level of torque as the control participants (Fig. 1A), indicating an altered strategy in force generation. At 50% MVC, the motor units were recruited at lower torque thresholds (Fig. 1D) and continued firing at lower discharge rates (Fig. 1C) in individuals with SCI, but with similar variability as in the control group (Fig. 1B). These alterations in motor unit behavior observed in persons with SCI may contribute to their muscle weakness and reflect altered force modulation strategies after the impairment.

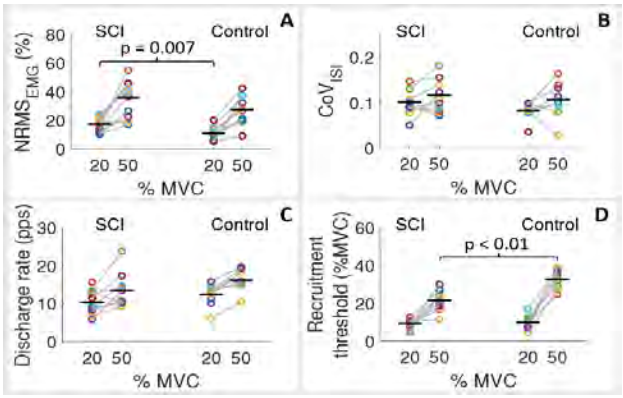

Figure 1 (A) EMG amplitudes, (B) variation of motor unit firings, (C) motor unit discharge rates and (D) recruitment thresholds. The horizontal bars indicated the group means, and the brackets with p values indicated statistical significance.

CONCLUSIONS

Torque, EMG, and motor unit parameters were observed in SCI and control groups. Most notably, we found increased EMG activation and decreased motor unit recruitment thresholds following SCI. The results indicated altered neural control strategies for force generation and gradation in individuals with SCI. Knowledge of these neuromuscular adaptations may aid the future research in SCI rehabilitation and treatment.

INTRODUCTION

The oral and maxillofacial tumor has become one of the ten most common tumors worldwide. Most patients can recover their mandibular bone anatomy with the help of digital surgical planning; however, nearly half of them cannot open their mouths wide (i.e., trismus) after six months of recovery. Musculoskeletal modeling provides a systematic way to estimate jaw opening functions [1]. This study proposed a patient-specific modeling framework of the mandibular musculoskeletal system based on medical imaging and jaw kinematics measurement. It was utilized in jaw opening predictions and validated by postoperative measurements.

METHODS

This study's protocol was approved by the Institutional Research Board of Peking University School and Hospital of Stomatology (PKUSSIRB-201942015). Ten preoperative patients with unilateral mandibular tumors were included. As shown in Figure 1, subject-specific mandibular geometry was measured and reconstructed based on CBCT data, and the bone-cutting regions were prescribed by ProPlan software. Mandibular muscles were discretized by a flexible cable element with a typical Hill-type model [2]. Their insertions were registered based on the nonlinear iterative closest point method. The patients were required to perform three repetitive cycles of maximal jaw opening-closing movements, and their mandibular kinematics were measured by the WinJaw system. The desired fiber length of each muscle was calculated via inverse dynamics simulations. Their activations before the surgery were then obtained by a proportional-integral-derivative controller considering the differences in muscle cross-sectional area. The changes in muscle biomechanical parameters in the postoperative stage were estimated based on the average value of spiral CT data. These values were used to predict the postoperative jaw opening functions, validated by the six-month follow-up measurements of the mandibular kinematic data.

RESULTS AND DISCUSSION

As a validation, the average root-mean-square error (RMSE) of the predicted mandibular opening magnitude averaged by the recruited patients was 3.5mm. The predicted mandibular incisor trajectories were highly correlated with the postoperative measurement of each patient (R^2=0.95 ± 0.05). Using 25mm of maximal jaw opening as the inclusion criteria of severe trismus [3], the proposed framework successfully predicted the jaw opening functions of 80% of recruited patients. The sensitivity in predicting severe trismus was 66.7%, and the prediction specificity was 85.7%. The performance of estimating trismus was influenced by the patient's age, tumor classification, and tumor-involved regions. The current modeling approach did not consider the biomechanical influence of the scar tissue, potentially reducing the active force generation. The activation patterns of the masticatory muscles were assumed unchanged after the surgery since the observed EMG data were patient-specific and could not be averaged. Moreover, the proposed model performed poor accuracy in estimating jaw deviations. Further investigations should include a more detailed model of the temporomandibular joint.

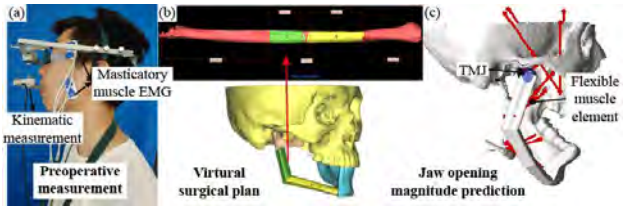

Figure 1 Schematics of the jaw opening function predictions. (a) Preoperative measurement of jaw kinematics & EMG data; (b) Virtual surgical planning based on jawbone anatomy; (c) Predictions of jaw opening magnitude based on patient-specific modeling.

CONCLUSIONS

The proposed musculoskeletal modeling framework successfully predicted the sagittal jaw opening functions before mandibular reconstruction surgery, highlighting its potential use in surgical planning.

INTRODUCTION

Reverse total shoulder arthroplasty (RSA) is an established treatment for irreparable rotator cuff tears of the glenohumeral (GH) joint. However, this procedure can be associated with a relatively high complication rate, with joint instability being the most common complication. Scapula anatomy and a deficient rotator cuff are known to affect the inherent stability of RSA, but there have been few studies exploring this topic. The aims of this study were twofold. Firstly, to develop a virtual clinical trials modelling framework for the GH joint after RSA; and second, to use this framework to quantify the effects of scapula size, glenoid version, and rotator cuff tears on joint stability after RSA.

METHODS

A previously published statistical shape model (SSM) was used to generate an average 50th percentile adult scapula and a 98th percentile scapula [1]. This was achieved by applying the mode of variation for size to the mean shape with 0 standard deviation and +2 standard deviation, respectively. Similarly, four glenoid versions (6° anteversion, neutral, 6° retroversion and 16° retroversion) were generated for each scapula size. The mean geometry of an age-matched humerus was also generated using a published SSM [1].

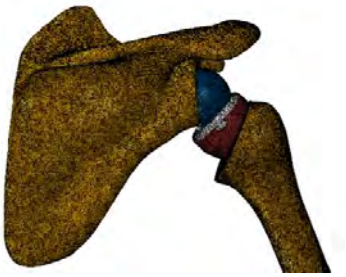
For each anatomy, RSA was virtually performed in an automated manner using Zimmer Biomet components according to the recommended surgical technique.

A previously published rigid-body model was modified to match each post-operative joint anatomy and used to calculate joint reaction forces for 45° arm abduction with an (i) intact rotator cuff (ii) supraspinatus tear (iii) combined supraspinatus and infraspinatus tear (iv) combined supraspinatus and subscapularis tear [2].

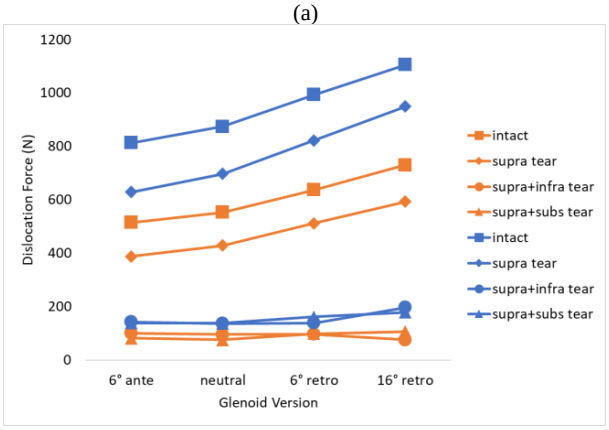
Finite element (FE) models (Figure 1a) were then developed for each post-operative joint anatomy. For each anatomy, joint reaction force calculated from the rigid-body model was applied as joint compressive load in the FE model, and then the joint was anteriorly dislocated in the FE simulation. Dislocation force, the force required to dislocate the joint anteriorly, was calculated for each post-operative joint anatomy and used as a proxy for joint stability (Figure 1b).

RESULTS AND DISCUSSION

Larger scapula size led to increased dislocation force (1105N vs 730N as peak dislocation force for each size), thus higher GH joint stability. Larger retroversion of glenoid also yielded higher dislocation force and joint stability. Rotator cuff muscle tears significantly reduced dislocation force, especially when two muscles were torn. For example, a tear to the supraspinatus and infraspinatus resulted in an average 84% drop in dislocation force relative to that in the intact rotator cuff.



(a)



(b)

Figure 1 FE model (a) and calculated joint dislocation force (b) for shoulder joint after RSA. Orange lines represent 50th percentile anatomy while blue lines represent 98th percentile anatomy. Acronyms are as follows: anteversion (ante), retroversion (retro), supraspinatus (supra), infraspinatus (infra) and subscapularis (subs).

CONCLUSIONS

This study developed a virtual clinical trials modelling framework to investigate shoulder joint instability after RSA. The results show that a combined supraspinatus and infraspinatus (or subscapularis) tear significantly reduced joint stability after RSA, while larger scapula size yielded a more stable joint. The findings may help to guide surgical planning and rehabilitation to patients with rotator cuff tear to avoid early joint dislocation.

A pipeline to morph the finite element model of lumbar spine and generate personalised spinal implant

Yihang Yu[1], Dale Robinson[1], David Ackland[1] and Peter Vee Sin Lee[1]
[1] Department of Biomedical Engineering, University of Melbourne, Melbourne, Australia.
Email: yihangy@student.unimelb.edu.au

INTRODUCTION

Lumbar interbody fusion (LIF) with interbody cages is an established treatment for degenerative disc disease, however, generic cages comprising standardised shapes and sizes still encounter complications such as cage migration and subsidence. Preoperative planning of LIF surgery incorporating biomechanical analysis provides the possibility to address post-operative complications by optimising implant positioning and customising its 3D geometry to suit a specific patient. However, current customisation processes involve excessive time and expense to develop patient-specific finite element (FE) models to validate bespoke implant designs [1]. Therefore, our project aims to build an automated pipeline to generate patient-specific FE model and interbody cage for the lumbar spine.

METHODS

A template lumbar spine FE model was established in ABAQUS 2017 based on an average-sized healthy male. The surface mesh of the FE model was non-rigidly aligned to a training set of 46 lumbar spines, from which a principal component analysis was performed [2]. By choosing the weightings of these principal components, the FE model surface mesh could be fit to a new spine. The full FE model could then be generated by the following: (a) generation of solid meshes based on the updated surface mesh, (b) assigning bone material properties using computed tomographic scans for the new subject, (c) removing overclosures between facet joints, and updating facet joint ligaments, and (d) since all boundary conditions, constraints and interactions were defined by the surface mesh, hence, these were automatically updated when the surface mesh was fit to the new subject. Once the spine mesh was fitted to the new subject, a customised cage was created by extruding a 2D cage template in the axial direction then trimming it via a boolean function with the adjacent endplates. Adjustment of cage material, type, size, position and orientation was set as built-in functions of the pipeline.

RESULTS AND DISCUSSION

To evaluate the performance of intact lumbar FE models, the flexion-extension range of motion (ROM) was simulated for the template model, morphed models for four patients, and a morphed model with a customised cage (Figure 1A). The facet joint forces (FJF) of intact spine models under extension and torsion were also computed (Table 1). The predicted ROM for each model compared well with published data [3], while the addition of the cage reduced the total ROM (Figure 1B). Overall, the FJF appeared to be at the lower range of that reported in the literature, which is likely due to modelling differences affecting the facet joint contact stiffness such as their initial contact area, their assumed thickness or the orientation/properties of surrounding ligaments.

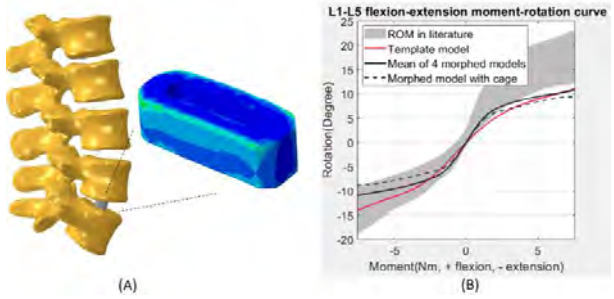

Figure 1. (A) Morphed lumbar FE model with cage. von Mises stress contours for the cage in flexion is indicated. (B) ROM of morphed and template models compared to models in literature [3].

CONCLUSIONS

In conclusion, the pipeline can generate FE models and customized spinal cages with predictive outputs that compare well to reported data. The pipeline's automatic capability reduces the manual effort involved in FE model development, making it viable for use in spinal surgery planning and interbody cage customisation. In future work the pipeline will be verified with more subjects, and expanded to incorporate optimisation of cage material properties.

EFFECT OF PELVIC TILT ON FEMORAL HEAD COVERAGE AFTER PERIACETABULAR OSTEOTOMY

INTRODUCTION

Developmental dysplasia of the hip (DDH) leads to early-onset of hip osteoarthritis due to the presence of a shallow acetabula and poor femoral coverage. It causes structural instability, decreased load-transferring area, and abnormal joint stress distribution on articular cartilage. Periacetabular osteotomy (PAO) has been a successful procedure to correct these morphological abnormalities and subsequently improve hip biomechanics, delaying or even preventing the development of osteoarthritis. Success of the operation is dependent on optimal positioning of the acetabular fragment, so surgeons frequently plan for these operations using 2D parameters derived from radiographs to estimate joint coverage, yet it is unclear if these are reliable metrics. Additionally, previous studies investigating hip joint biomechanics evaluated the joints in a standardized position, which does not apply to most patients given the inherent and positional variability of pelvic tilt, which has a significant effect on acetabulum orientation [1-2]. Therefore, the objective of this study was to quantify the effect of pelvic tilt on femoral head coverage after PAO.

METHODS

Hip models of 22 patients (25 hips) with DDH were created using pre-operative CT images (Materialise Mimics, Materialise, Belgium). The pelvic tilt was measured in pre-op standing X-ray using the method proposed by Tannast et al. [3]. Then, each model was positioned in the ISB coordinate system and the pelvic tilt was adjusted to the pre-op neutral position. Next, a simulated PAO was carried out by laterally rotating the acetabular fragment until the lateral center edge angle (LCEA) reached 35°, followed by 10° anterior rotation of the fragment. A custom MATLAB program was built to measure the femoral head coverage under different pelvic tilt conditions (Figure 1). Specifically, the measurements were repeated at 0°, ±5°, ±10°, and ±15° pelvic tilt. At each position, the 2D projection of the lunate surface on the transverse plane was measured and divided into four quadrants. Statistical significance was evaluated through a paired, two-tailed Student's t-test ($p=0.05$).

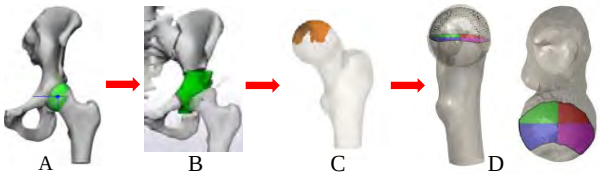

Figure 1 Measurement of load-bearing coverage. A) 3D hip models from CT scans. B) Simulated PAO. C) 3D coverage. D) 2D projection of femoral coverage on the transverse plane.

RESULTS AND DISCUSSION

As the pelvic tilt increased from neutral (i.e., 0°) to 15° anteriorly, there was a significant increase in the coverage in the anterolateral (AL) quadrant and a significant decrease in the posterolateral (PL) coverage ($p<0.0001$). On the other hand, posterior pelvic tilt led to a significant decrease in total coverage ($p<0.04$). Moreover, there was a significant decrease in the AL coverage ($p<0.0001$) and a significant increase in the PL coverage ($p<0.0001$). No significant differences were detected in the posteromedial (PM) or anteromedial (AM) coverage across all levels of pelvic tilt.

CONCLUSIONS

The findings of this study demonstrated the effect of pelvic tilt on femoral head coverage after PAO. More anterior tilt results in increased load-bearing coverage, and more posterior tilt results in decreased load-bearing coverage. These findings indicate that natural pelvic tilt should be considered when planning a PAO.

Differentiating activity of forearm finger flexors and extensors for SEMG biofeedback training

Christian Sure[1], Sascha Selkmann[1], Marc Neumann[1] and Beate Bender[1]
[1] Chair of Product Development, Dept. of Mechanical Engineering, Ruhr-University Bochum, Germany.
Email: sure@lpe.rub.de

INTRODUCTION

Surface electromyography (SEMG) based biofeedback training is a common approach in the therapy of motor dysfunctions of the hand. Usually, methods for SEMG-Biofeedback rely on simple measurement setups, where only a few large and roughly positioned electrodes are used to discriminate combined hand and finger flexor from extensor activity [1]. For the training of complex hand movements like grips however, a finer degree of muscular differentiation could be beneficial. In our efforts to develop new strategies for differentiating muscle activity in the forearm during SEMG biofeedback training, we are currently evaluating the feasibility of analyzing and comparing the SEMG amplitude measured at small, strategically placed electrodes to estimate the activation state of individual finger flexors and extensors. The goal of the presented study was to identify suitable electrode sites and assess the correlation as well as the selectivity of the respective SEMG amplitude to the activity of individual muscles for finger movement.

METHODS

Subjects performed isolated, as well as combined isometric finger flexions and extensions while incrementally increasing the applied finger force. During contractions. SEMG signals were recorded across a wide area of the forearm. Finger forces were measured using a custom hand force meter (Fig 1a, bottom). Applied finger forces, as well as force targets, were visualized to the subjects. In a first session, isolated finger extensions and flexions were performed while subjects were instructed to increase finger force in steps of 0.5 N from 0 to 8 N. In a second session, an additional constant force of 3 N in the same direction was to be applied to an adjacent finger. The monopolar SEMG signal was recorded at 96 electrode sites with a measuring system from DeMeTec. Electrodes were applied with the help of a custom forearm sleeve equipped with 6 electrode rings, each containing 16 equally spaced dry electrodes (Fig. 1a). Measurement sites were prepared according to common standards. The signal was recorded with a sample rate of 1024 S/s and filtered using a high pass at 10 Hz and a notch at 50 Hz. SEMG amplitude was evaluated by calculating root-mean-square (RMS) within a time window of 1 s.

RESULTS AND DISCUSSION

During isolated finger activation, characteristic signal hotspots formed at specific areas across the forearm (Fig. 1b). Based on these hotspots, sites with potentially high correlation to individual finger muscle activity could be identified (Fig. 1c). Signal amplitude at these sites show the typical [2], approximately linear correlation to the applied finger force. Gradients differ between fingers and muscle groups, with gradients of extensors being generally lower than flexors (Fig. 1d). During combined movements, selectivity at the sites varied depending on the distance between hotspots of the active muscles. Electrode sites in non-overlapping hotspots, like e.g. the extensors of fingers IV and V, show a high degree of selectivity, with RMS amplitude being nearly constant on one site and incrementally increasing in the other. In the case of overlapping hotspots, such as the extensors of fingers III and IV, an increase of amplitude due to crosstalk can be observed on the site of the stationary finger.

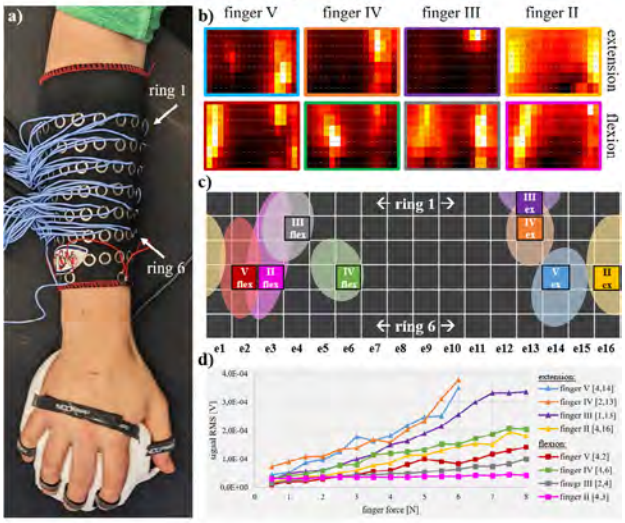

Figure 1 a) SEMG-sleeve with hand force meter. b) SEMG amplitude (RMS) across electrode matrix in heatmap view. c) identified hotspots with high correlation to isolated finger activation d) relationship between finger force and RMS amplitude at chosen electrode sites during isolated finger activation

CONCLUSIONS

The study reinforces our assumption, that evaluating and comparing SEMG amplitude measured at small, strategically placed electrodes might be a suitable approach for estimating activity of individual finger flexors and extensors. Further strategies for differentiating activity of muscles with overlapping hotspots must be developed though.

LOWER LIMB AMPUTEES HAVE SIMILAR UPPER LIMB FUNCTION 8Y POST INJURY AS UNINJURED GROUP: THE ADVANCE COHORT STUDY

Fraje Watson[1], Angela E Kedgley[1], Alexander Bennett[2] and Anthony M J Bull[1]
[1] Department of Bioengineering, Imperial College London, London, UK.

Email: f.watson@imperial.ac.uk

INTRODUCTION

Increased biomechanical load on the upper limb (UL), and subsequent injury has been identified in wheelchair users [1]. We hypothesised that lower limb (LL) amputees make similar biomechanical compensations with their ULs through crutch use, balance and coordination needs, transfer activities and UL bodyweight loading.

ADVANCE is a 20yr prospective cohort study collecting medical and psychosocial data from 1145 military servicemen, half of whom sustain combat injury [2]. The aims of this study are to compare UL disability at baseline assessment (a mean of 8yrs post-injury) in (1) LL amputees and the uninjured comparison group, and (2) the full cohort.

METHODS

Disability of the Arm, Shoulder, and Hand (DASH) questionnaire data was collected from injured and uninjured ADVANCE participants frequency matched for deployment, age, and rank. DASH scores range from 0-100, with a higher score denoting more UL disability.

DASH data was non-parametric, and appropriate statistical tests were used with an alpha level of 0.05.

RESULTS AND DISCUSSION

DASH data was available and valid for 1092 participants (mean age: 34yrs).

DASH was higher for the injured group compared to the uninjured group (p<0.001). Major and partial UL amputees (p<0.002), triple amputees with a unilateral major UL amputation (p<0.002), and LL amputees with partial UL amputation (p<0.002) all had higher DASH scores than the uninjured group (Table 1, Figure 1).

DASH was not significantly different between unilateral LL amputees, bilateral LL amputees, and the uninjured group. This finding suggests minimal UL disability 8yrs post-injury that we hypothesised might result from high reliance on the ULs. Similarly, DASH was not significantly different for triple amputees (with a unilateral major UL amputation) compared to unilateral major and partial UL amputees only. This further supports the finding that LL amputation did not increase UL disability (Table 1, Figure 1).

Injury type	n	DASH (SD)
Uninjured[abcd]	562	3.6 (8.3)
Injured	530	9.7 (14.2)
Non-amputee[ae]	363	9.8 (14.1)
Unilat LL amputee[fgh]	70	4.4 (7.0)
Bilat LL amputee[i]	38	5.9 (11.0)
UL amputee (major + partial)[befi]	14	21.7 (19.5)
Triple amput. (unilat major UL)[cg]	12	13.5 (13.7)
LL amputee + partial UL amp[dh]	32	17.6 (20.3)

Table 1: DASH scores for ADVANCE participants. [a-i]p<0.002 per Bonferroni correction

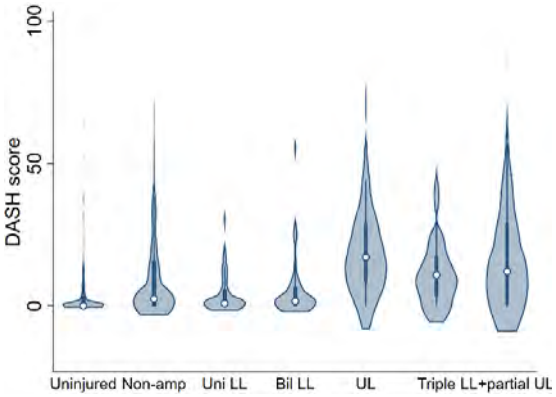

Figure 1: Violin plots for DASH scores of ADVANCE participants (LL=lower limb, UL=upper limb, uni=unilateral, bil=bilateral).

CONCLUSIONS

Contrary to our hypothesis, unilateral and bilateral LL amputees had similar DASH scores to the uninjured population, and triple amputees had similar DASH scores to UL amputees. These results suggest that assumed biomechanical compensations resulting from LL amputation did not increase UL disability, 8yrs post-injury.

Overall, the ADVANCE cohort have lower DASH scores than equivalent military and civilian populations [3,4]. The ADVANCE cohort is currently young, so longitudinal study of their UL disability will be of great interest, particularly for the LL amputees.

ACKNOWLEDGEMENTS

We thank the whole ADVANCE team and participants, and the ADVANCE charity for funding.

VALIDATION OF A MARKER CLUSTER-BASED APPROACH TO ESTIMATE SCAPULA MOTION

Jennifer Maier[1], Julie Muccini[2], Ellen Kuhl[1], and Scott L. Delp[1,2]

INTRODUCTION

Fast and dynamic motions of overhead athletes like volleyball hitters can lead to shoulder injuries. Measuring the in-vivo shoulder kinematics is necessary to analyze the biomechanics leading to injuries. The main challenge when recording shoulder motions with marker-based motion capture is the scapula, as it moves subcutaneously and its motion cannot be recorded with skin-mounted markers. Current approaches to measure scapula motion have mostly been validated on small ranges of motion and/or static poses [1, 2]. We present results of initial experiments that evaluate the accuracy of a method that uses an acromion marker cluster (AMC) to estimate scapula motions during large range of motion trials.

METHODS

Our proposed method is an extension of an approach presented in [1] and uses five instead of two calibration shoulder poses, see Fig. 1. In all five poses, at 0° abduction/flexion, 180° abduction, 180° flexion, and maximal horizontal adduction and abduction, we locate the scapula by palpation to define the relation to the AMC. We use this information to compute the scapula position in a new trial by interpolation in the three body planes based on the humeral elevation angle. The estimates in the three body planes are weighted by the length of the upper arm projected onto the respective body plane and summed to form the final scapula estimate. Using the measured AMC, we register the estimate to the subject's current position.

We evaluated the method on three subjects at static poses of different angles of shoulder abduction, flexion, and horizontal abduction, and on static poses of scapula elevation and depression, by comparing the estimated scapula positions to palpated measurements of the scapula. Furthermore, subjects performed dynamic full range of motion trials of abduction, flexion, and horizontal abduction, and we extracted frames of similar humeral angles as the static measurements and compared them to the palpated scapula positions of the corresponding static measurements.

RESULTS AND DISCUSSION

Results on the static trials show an average rotation RMSE of 4° and translation RMSE of 11 mm compared to palpation. Our method requires more calibration poses than the existing double calibration approach [1], but shows reproducible, accurate results over a larger range of motions, see Table 1. The deviations between static measurements and poses extracted from the dynamic trials are higher (6° and 27 mm), but within the acceptable range for most studies.

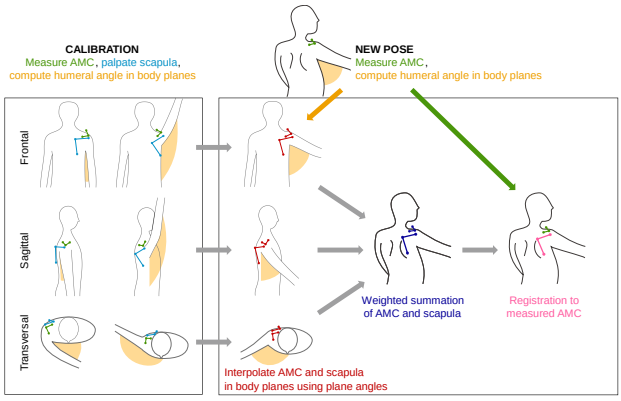

Figure 1 Schematic description of the scapula estimation method.

CONCLUSIONS

Our method for AMC-based scapula estimation shows promising results for an application in large range dynamic motions. Our next step is to combine this technique with a physically constrained biomechanical model to enable analyses of shoulder motions and provide guidelines to prevent shoulder injuries in overhead athletes.

Investigating the Torque-Velocity Relationship Within the Human Shoulder During High-Demand Tasks

INTRODUCTION

The shoulder complex may have evolved to produce high torques across a range of speeds – facilitating tasks with different torque-velocity requirements like carrying heavy loads and high-speed throwing [1]. In lower extremity joints, such as the knee, torque decreases as velocity increases, which is reflective of the force-velocity relationship in muscles [2]. We question whether the shoulder's complex architecture allows it to maintain high torque during low and high speeds, which is consistent with its functional requirements. While previous studies have provided insight into the shoulder's ability to produce torque under static conditions, unloaded tasks, or uni-planar motions [3], there is little research regarding loaded and dynamic functional tasks.

This study aims to address this gap by introducing a novel approach to perform inverse dynamics in the upper extremity to assess three-dimensional shoulder joint motion and torque. Here, we examine a loaded functional task performed across a range of speeds. We tested the prediction that shoulder torque would decrease as angular velocity increased.

METHODS

Five participants (1F/4M, Average age = 22) performed an isokinetic shoulder task. Participants started with their right arm overhead and pulled a cable across their body, ending the task at their left hip. They were tasked with applying maximal force at a prescribed cable speed and were allowed to execute the task in a manner that felt most natural to them. A motion capture system (Qualisys, Goteborg, Sweden) collected their 3D motion, and a controllable cable resistance machine (1080 Quantum) collected their force output. The cable machine was set to a maximum speed of 0.5 m/s and was increased by 0.5 m/s with each trial until the participant could no longer achieve the speed. Participants were allowed self-selected rest time between trials. The 1080 applied the resistance required to prevent the participant from exceeding the set speed. We computed the position and orientation (poses) for the pelvis, trunk, right upper arm, right forearm, and right hand in Visual 3D (C-Motion). The shoulder joint was modelled by computing the functional joint centre from a low-abduction circumduction task. We used inverse dynamics to compute the shoulder moment and angular velocity (Figure 1). For each participant, linear regression was performed on the peak moment at the shoulder as a function of peak angular velocity across cable speeds.

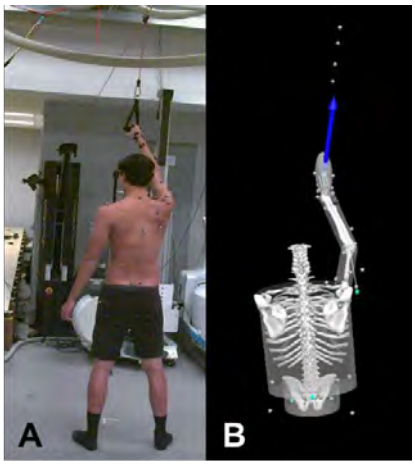

Figure 1 (A) Participant performing isokinetic task with 1080 Quantum cable machine. **(B)** The force vector was tracked with markers on the cable and applied to the hand. Inverse dynamics was performed on a link-segment model (Visual 3D, C-Motion).

RESULTS AND DISCUSSION

The slowest and fastest participants achieved angular velocities of 484 and 670 deg/s, respectively. Across participants, peak moments ranged from 18 to 92 Nm. Across cable speeds, participants achieved a wide range of angular velocities (min range: 216, max range: 466 deg/s). However, within each participant, peak shoulder torque remained relatively constant where slopes were not statistically different than zero ($p > 0.2$) and ranged from -0.1 to 0.02 Nm/deg/s. These results are consistent with the idea that the shoulder complex can maintain high torque over a wide range of speeds.

CONCLUSIONS

We found peak shoulder torque to be statistically independent of angular velocity during the tested unconstrained task. We do not doubt the shoulder muscles follow typical force-velocity constraints, but speculate that high-torque may be maintained through a combination of dynamically changing muscle moment arms, differential contributions of the scapulothoracic and glenohumeral joints, and/or differential activation of the complex muscle architecture. A future biplanar videoradiography study examining both constrained and unconstrained shoulder motion may allow us to tease out these potential factors. This approach may allow us to better understand how differences in person-specific anatomy influence shoulder function and dysfuntion.

INTRODUCTION

Reverse total shoulder arthroplasty (RTSA) alters biomechanics of muscles around the glenohumeral joint (GHJ). These changes are well documented for muscles like deltoids[1], but limited research has been performed on post-RTSA biomechanics of coracobrachialis (CBR) and short head of biceps (SHB). In this study, using computational models, we compared muscle moment arms and lengths of CBR and SHB between native and RTSA shoulders.

METHODS

The Newcastle Shoulder Model (NSM)[2], a pre-validated upper extremity musculoskeletal model was used for this study. The NSM was modified with bone geometries obtained from 3D reconstructions of 15 non-diseased shoulders, constituting the native shoulder group. Delta XTEND prosthesis, with a glenosphere diameter of 38mm and polyethylene thickness of 6mm, was virtually implanted in all the models creating the RTSA group. Moment arms were measured using the tendon excursion method and muscle lengths were calculated as the distance between the muscles' origin and insertion points. These values were measured during 0°-150° of abduction, forward flexion, scapular plane elevation, and -90 to 60° of external-internal rotation with the arm at 20° and 90° of abduction. Statistical comparison between native and RTSA group was analysed using spm1D.

RESULTS AND DISCUSSION

Forward flexion moment arms (Figure 1) had the greatest increase between RTSA (CBR:25.3±4.7 mm; SHB:24.7±4.5 mm) and native groups (CBR:9.6±5.2 mm; SHB:10.2±5.2 mm). CBR and SHB were longer in the RTSA group by a maximum value of 15% and 7% respectively. Both muscles had larger abduction (Figure 2) moment arms (CBR: 20.9±4.3 mm; SHB: 21.9±4.3 mm) in RTSA compared to the native group (CBR: 19.6±6.6 mm; SHB: 20.0±5.7 mm). Abduction moment arms were observed earlier in RTSA (CBR: 50º; SHB: 45º) compared to the native group (CBR: 90º; SHB: 85º). In the RTSA group, both muscles had elevation moment arms until 25° of scapular plane elevation motion, whereas in the native group the muscles only had depression moment arms. Both muscles had small rotational moment arms which were significantly different between RTSA and native shoulders during different stages of the motion.

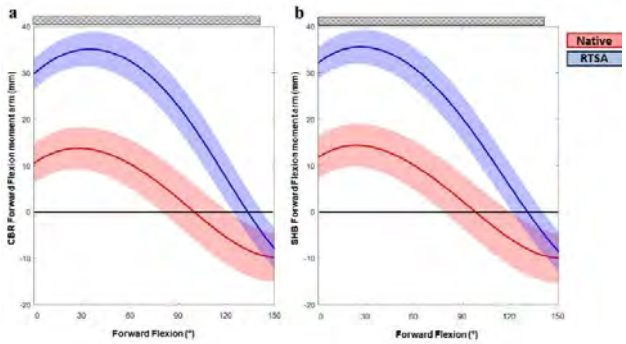

Figure 1: Forward flexion moment arms in RTSA and native shoulders for a) CBR and b) SHB. Statistically significant difference was observed for most of the motion.

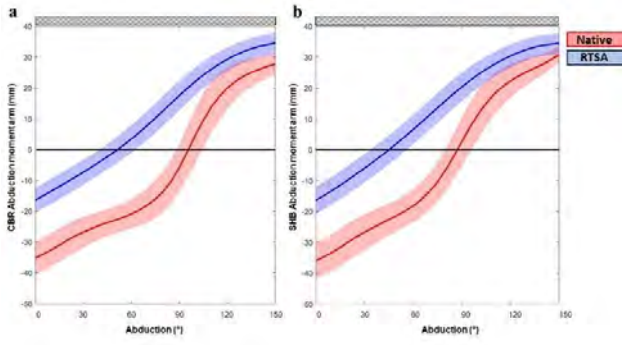

Figure 2: Abduction moment arms in RTSA and native shoulders for a) CBR and b) SHB. Statistically significant difference was observed for the complete motion.

CONCLUSIONS

RTSA makes CBR and SHB early abductors and stronger forward flexors. The surgery increases their length which might increase tension on the conjoint tendon.

Investigating Shoulder Muscle Coactivation Ratio Changes Following and Overhead Fatigue Task

Matthew S. Russell, Sam Vasilounis, Janessa D.M. Drake, and Jaclyn N. Chopp-Hurley
Kinesiology and Health Science, York University, Toronto, Ontario, Canada.
Email: msr@yorku.ca

INTRODUCTION

Subacromial Impingement Syndrome (SAIS) and rotator cuff tears account for 30-45% of all clinically presenting shoulder conditions [1, 2]. Mechanically, reduction of the subacromial space can be the result of alterations in shoulder muscle activation and subsequent kinematics, leading to SAIS [3, 4]. The effect of muscle fatigue on kinematics has yielded highly variable outcomes, with differential effects on the subacromial space. It is unclear whether fatigue leads to changes in scapular and rotator cuff muscle co-activity, which may provide insight into kinematic variability [4]. This study investigated fatigue-related changes in shoulder muscle coactivation following an overhead drilling task.

METHODS

18 healthy, right-handed adults (19-35yr; BMI 23.7 ± 3.2 kg/m^2) have initially participated in this research. Participants were instrumented with surface (sEMG) and fine-wire intramuscular (iEMG) electromyography (Delsys Trigno, Natick, MA), as well as right thoracal, scapular, and upper limb kinematics (Vicon MX, Hauppauge, NY). Participants completed a series of maximum voluntary contractions (MVC) to allow for EMG normalization [5-7]. In a standing position, participants were tasked with using a simulated drill to approximate overhead targets until volitional fatigue. This protocol has been previously validated in literature to effectively fatigue the rotator cuff muscles [8, 9]. Submaximal (15%) shoulder abduction and adduction exertions at 90° were completed after every 5 minutes of the fatigue task and immediately following failure. EMG signal time-varying normalization was implemented to remove the muscle fatigue-related amplitude artefact, making EMG amplitude comparisons between pre-fatigue and post-fatigue possible [10]. Scapular, rotator cuff, and deltoid-rotator cuff coactivation ratios for submaximal 90° abduction and adduction were compared at pre-, mid-, and post-fatigue using one-way ANOVAs. A chi-squared model evaluated the change in rotator cuff muscle dominance at pre-, mid-, and post fatigue.

RESULTS AND DISCUSSION

Preliminary results show coactivation changes between middle deltoid and supraspinatus consequent of global upper limb fatigue from overhead work. The ANOVA model between middle deltoid and supraspinatus ($F_{(2,48)}$ = 4.29; p = 0.02) revealed a significant LSD post hoc comparison between the pre-fatigue (μ = 28.3, σ = 22.3) and post-fatigue (μ = 33.5, σ = 72.8) state; p = 0.007 (Figure 1). Chi-squared model comparing muscle activity between supraspinatus and infraspinatus ($X^2_{(2,N = 36)}$ = 7.33; p = 0.026) indicated an increase in infraspinatus activity relative to supraspinatus activity associated with fatigue.

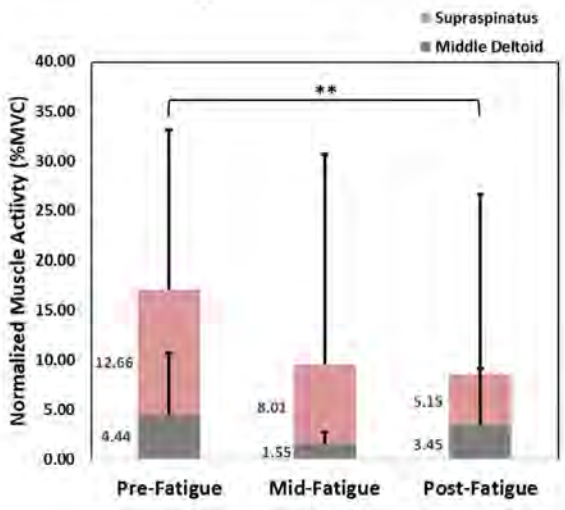

Figure 1 Middle Deltoid-Supraspinatus Muscle Coactivation Changes with Fatigue. ** denotes p<0.01.

CONCLUSIONS

Initial results of this research provide evidence to suggest that muscle fatigue consequent of occupationally relevant overhead work may produce transient changes to the coactivation ratio between middle deltoid and supraspinatus. Increases in middle deltoid activity relative to supraspinatus activity increase superior humeral head translation and are a known risk factor for SAIS and rotator cuff impingement [4, 11]. Relationships between these changes in muscle co-activation and kinematics are forthcoming.

Disentangling Allometry and Sex-Based Differences in Scapula Shape

Erin Lee[1], Rebekah Lawrence[2], and Michael Rainbow[1]
[1] Department of Mechanical and Materials Engineering, Queen's University, Kingston, Canada.
[2] Program in Physical Therapy, Washington University in St. Louis School of Medicine, St. Louis, USA.
Email: erin.lee@queensu.ca

INTRODUCTION

Sex is often a key determinant of musculoskeletal disease and can influence treatment. For example, sex-based differences in knee shape have inspired sex-specific implants [1]. It is unknown whether sex-based differences in scapula shape play a role in the pathomechanics of shoulder disease or injury. However, scapula shape features are strongly associated with soft-tissue injury [2]; thus, it is important to understand the role of sex in the scapula's highly variable morphology.

A caveat of measuring sex-based shape differences is that the male skeleton is, on average, larger than the female skeleton. Even after scaling structures to a common size, *allometry* (shape changes as a function of size) may persist as a source of morphological variation. While previous studies have reported sex-differences in scapula shape [3], they did not account for allometry; thus, apparent sex-based differences could instead reflect inherent differences in body size. If sex-based treatments are developed for the shoulder, this would disadvantage females and males whose body size is above or below their respective group means. Here, we used a geometric morphometrics approach to disentangle allometry from sex-based differences. We tested the null hypotheses that male and female scapulae would not exhibit different allometric relationships, and that shape changes due to allometry would not differ from shape differences associated with sex (Fig. 1).

METHODS

We acquired scapula surface meshes for 45 male (age=54±11) and 80 female (age=56±10) individuals [1,4]. The 3D coordinates of 29 anatomical landmarks were scaled and aligned via Procrustes superimposition, yielding $3 \times 29 = 87$ shape variables. We computed scapula centroid size as a proxy for body size.

We quantified directions of shape variation – called *shape vectors* – associated with sex (sex-distinction) and size (allometry). Allometry vectors were composed of the slopes calculated by regressing each of the 87 shape variables on centroid size. The sex-distinction vector was oriented from the mean female to mean male shape variables. Goodall's F-tests assessed the statistical significance of the vectors.

To disentangle allometric shape variation from sex-based variation, we computed within-sex allometry vectors and compared their directions to the sex-distinction vector by calculating the angle between vectors. Parallel vectors indicating identical shape changes would yield an angle of θ=0°. For visualization, we projected the vectors onto a lower-dimensional shape space via Principal Component Analysis (PCA).

RESULTS AND DISCUSSION

Scapula shape differed significantly between sexes ($F=6.62$, $p<0.0001$, Fig 1). While allometry explained a small amount of total shape variation (1.8% in males, 3.2% in females), the relationship was strong in female scapulae ($p=0.0013$). Contrary to the null hypotheses, male and female allometry vectors were distinct from each other (θ=86°), and from the sex-distinction vector (θ=88° for males, θ=128° for females, Fig. 1).

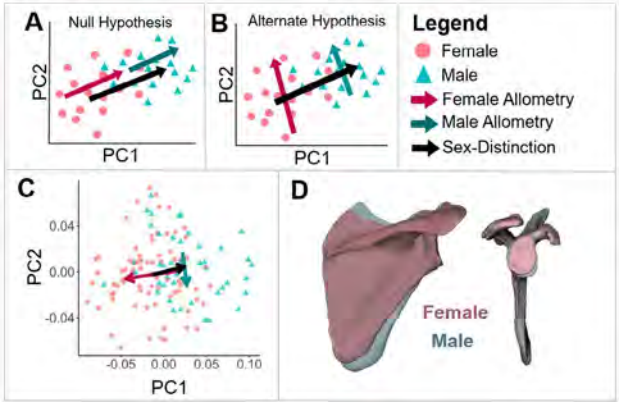

Figure 1 (A) Null hypothesis: allometry vectors align with sex-distinction vector, indicating sex-differences due to allometry. **(B)** Alternative hypothesis: allometry vectors are orthogonal to sex-distinction vector, indicating non-allometric sex differences. **(C)** Results: Individuals and shape vectors projected onto PC1-PC2 space. **(D)** Mean mesh warped along sex-distinction vector, with the magnitude of shape change doubled for visualization. Relative to the mean female scapula, the mean male scapula is more superior-inferiorly broad, has a less superiorly-inclined and more retroverted glenoid, and exhibits a wider supraspinatus attachment site.

CONCLUSIONS

Our findings suggest that sex differences in scapula shape cannot be attributed to inherent differences in body size. While future work is required to investigate the biomechanical effects, these shape differences have the potential to alter normal joint mechanics and contribute to sex-specific differences in mechanisms of injury.

ACKNOWLEDGEMENTS

We thank M. Bey and H. Henninger for providing access to scapula surface meshes.

A Study of Suitable Takeoff Motion of a Ski Jumper Using Principal Component Analysis and Computational Fluid Dynamics

Shin Ikeda[1], Keizo Yamamoto [2], Rahul Bale[3], Tokimasa Shimada [3], and Makoto Tsubokura[1,3]

INTRODUCTION

The motions of ski jumping is often divided into four parts: in-run, takeoff, flight, and landing. Of these motions, the takeoff motion in which largely change jumpers' posture in a short time of about 0.2~0.3 seconds is considered to strongly affect the flight distance. However, there is no consensus as to what an optimal take-off posture ought to be. Therefore, the purpose of this study is to analyse a large, markerless motion capture based, dataset of trials using principal component analysis (PCA) to find an optimal takeoff posture.

METHODS

First step of the obtaining trial data involves capturing the takeoff motions in the trial jumps from 10 directions. Using the video data with Theia3D, which is a markerless motion capture system with deep learning, we measure the takeoff motion data. Next, using the motion data with Visual3D, we calculate the jumper's trunk angles of attack at takeoff (TAKEOFF), 0.1 seconds after takeoff (AFT100), and 0.2 seconds after takeoff (AFT200). Using PCA with the time series data of the trunk angle of attack, the principal component scores of all trials are plotted on a scatter diagram to find the skilled group, and the takeoff motion representative of the skilled group is confirmed in Visual3D. Finally, we use Computational Fluid Dynamics (CFD) to analyse the aerodynamic characteristics of the takeoff motion. The CFD analysis was conducted using a framework developed by Nishino et al [1].

RESULTS AND DISCUSSION

The scatter diagram of the principal component scores of all the trials obtained by PCA is shown below (Figure 1). Skilled is defined as a trial jump with a distance of 90m or more, and normal as a trial jump with a distance of 80m to 90m, and unskilled as a trial jump with a distance of less than 80m.

From the scatter diagram, it is found that there are two types of good takeoff motions. The two types of good takeoff motions are defined as Type A and Type B, and the takeoff motions representing each type were checked in Visual3D. The results show that Type A gradually increases the trunk angle of attack from TAKEOFF to AFT200, while Type B increases the angle of attack from TAKEOFF to AFT100 and tilted forward from AFT100. And, the aerodynamic characteristics of Type A and B are confirmed by using CFD.

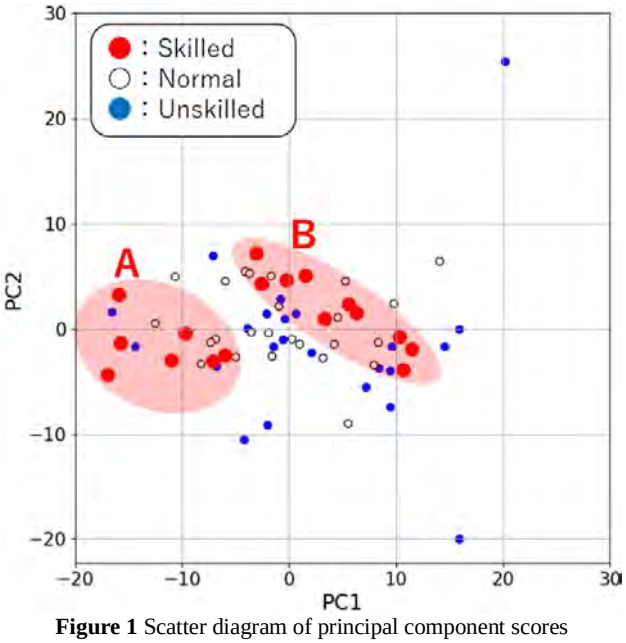

Figure 1 Scatter diagram of principal component scores

CONCLUSIONS

Through this study, we conclude that there are two types of appropriate takeoff motions in ski jumping. Furthermore, the aerodynamic characteristics of the two takeoff motions were analysed by using CFD.

INTRODUCTION

The performance of alpine skiing, a risky winter sport, has been benefited from mechanical simulation and analysis. The quantitative measurement and analysis on turning maneuvers is crucial to skill advancement of skiers in both training and match. Kinematics characteristics analysis was thus provided for alpine skiers[1]. The kinetic features, such as joint moments and muscle forces, however, are crucial and urgent for to improving training outcomes, the mechanical simulation model of alpine skiing is yet to be improve.

In the present study, a custom-designed wearable system was adapted to harvest the kinematic signals at each turning of the skiers. Based on these data, we built a skier's musculoskeletal model (Figure 1A) and successfully simulated the trajectory of the body mass center, the joint moments, the muscle activation patterns of the skier, and the friction between the ski and snow surface during the ski movements. The ski-turning technique of skiers were then evaluate quantitatively.

METHODS

Two ski volunteers (a coach and a beginner) were recruited to complete the ski turns under the same conditions. Seventeen inertial sensors were attached to the volunteers limbs to capture their posture and movement during each ski turning (Figure 1B); Ski geometry and dynamical parameters were detected by three-dimensional scanning and vibration tests and used to describe the ski-snow interaction behaviors in a dissipative contact model; Windward area of the skier was calculated by the projected area of the human body in the coronal plane to estimate the air resistance[2]. Upon using posture data as input, we coupled the ski-snow contact model and musculoskeletal model to simulate the mass center trajectory, the snow reaction forces, the joint moments and the muscle activation patterns of the skiers[3].

A global positioning system (GPS) collecting the skier's motion trajectory, a pair of plantar pressure measurement insoles measuring the ground reaction forces were adapted to evaluate the accuracy of the simulation results of the skier's musculoskeletal model.

With this model, the skiers' speed, body mass center trajectory, joint angle and moments, ski angle and position, and muscle activation at each time point were determined. The turning technology was thus evaluated based on these parameters.

RESULTS AND DISCUSSION

The simulation results of the skier's center of mass trajectories were consistent with the measurements, with a correlation coefficient of r=0.97. The normalized ski-snow contact forces were also compatible with the measured plantar pressure, with a correlation coefficient of r=0.94 (Figure 1C). Comparison between the coach and the beginner further demonstrated the technical errors of beginners (Figure 1D): The adductor magnus of the beginner was continuously activated during the turning maneuver, resulting in hip adduction. The unnecessary adduction posture increased the friction between the ski board and its underlying snow surface. The force of the hip extensor muscle group of the beginner was too small, resulting in a slight hip flexion angle. The center of mass tended to move backward of the pelvis, and led to a wrong ski posture.

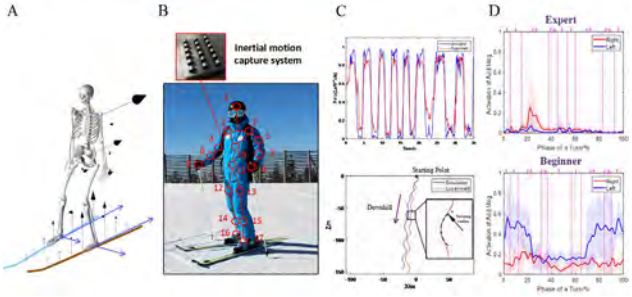

Figure 1 A Skier's musculoskeletal model; B Inertial sensors; C Validation of the model; D Activation of adductor magnus.

CONCLUSIONS

The proposed wearable measurement system successfully measured the kinematics and ski-snow interaction data during the alpine skiing maneuver. The skier's musculoskeletal model has been proved feasible to evaluate the performances of each skier, which shed a light to elevating the training outcomes with quantitative biomechanical data.

SEX DIFFERENCES IN NETBALL PLAYERS' FOOT SHAPE: IMPLICATIONS FOR SHOE DESIGN

Maddison M. Kirk[1], Joshua P.M. Mattock[1], Celeste E. Coltman[2] and Julie R. Steele[1]

INTRODUCTION

With the increasing professionalisation and popularity of men's netball, integrating males into a historically female-centric sport has raised important questions about the design and fit of footwear. Although there is a wide range of netball shoe models based on the foot dimensions of women, there is currently only one netball-specific shoe exclusively marketed for men [1]. This men's netball-specific shoe, however, is a hybrid-court shoe with design compromises so it can be used for both netball and volleyball [1]. Given the limited choice of netball-specific footwear for men, nearly 30% of male netball players have reported wearing female netball-specific shoes, and 70% wear shoes not designed for the sport [1]. Footwear designed using foot dimensions unrelated to the individuals likely to wear the shoes can lead to ill-fitting footwear. Of concern, 80% of male netball players have reported foot-related problems and pain in their last netball season [1]. Developing netball-specific footwear for males based on the foot dimensions of men is necessary to ensure proper shoe fit and to prevent foot-related problems. Therefore, we aimed to establish any differences in the dimensions and shape of the feet of male and female netball players to help inform netball shoe design recommendations for men.

METHODS

The feet of 251 representative male netball players (age: 26.1±8.3 yrs; height: 183.3±8.5 cm; mass: 87.7±21.5 kg) and the feet of 251 representative female netball players (age: 22.1±6.9 yrs; height: 172.5±13.8 cm; mass: 75.5±14.1 kg) were scanned using a Tiger full foot 3D scanner. The 3D foot scans were then analysed using a custom MATLAB script to derive eight measurements that characterised foot shape. Independent samples *t*-tests were then used to determine whether there were any significant differences in the foot dimensions derived for the left feet of the male compared to the female netball players ($p < 0.05$). We compared both the absolute foot dimensions and the foot dimensions normalised to foot length.

RESULTS AND DISCUSSION

The male netball players had significantly larger foot dimensions than the females, particularly at the ball of the foot, heel and instep (Figure 1). The foot dimensions normalised to foot length also significantly differed between the men and women, highlighting that men's feet are not simply a scaled-up version of females' feet; instead, the men and women's feet differed in several critical shape dimensions. This finding is consistent with previous findings in other cohorts, such as firefighters and young adults, which revealed that compared to women, men have much longer and broader feet that are different in shape, especially at the angle formed by the axis of the metatarsal heads and dimensions of the arch [2,3]. The sex differences in foot shape may explain the high prevalence of foot-related problems reported by male netball players and their dissatisfaction with the fit and comfort of the current shoes they wear during netball activity [4].

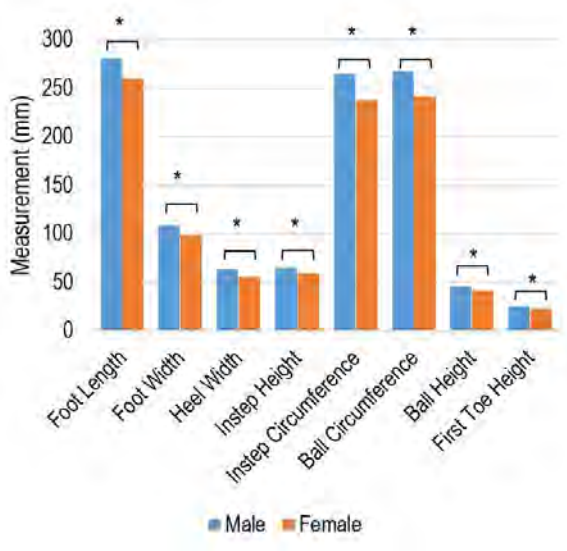

Figure 1 Differences in absolute foot dimensions, grouped by sex. * = $p < 0.001$.

CONCLUSIONS

The fit and functionality of netball-specific shoes must be improved to better cater for male foot dimensions. In addition, the sex differences in foot dimensions and shape must be considered when designing netball-specific footwear for men. Such improvements will help optimise shoe fit and comfort while minimising foot-related problems and pain associated with wearing ill-fitting footwear.

OPTIMAL ATTITUDE REORIENTATION OF FREE-FLOATING HUMANS BY RECTILINEAR JOINT ACTUATION

INTRODUCTION

Rotational dynamics (attitude dynamics) of a free-floating multibody has been investigated for a long time. It is known that the attitude motion of the multibody exhibits nonholonomic properties in which final orientation depends on its joint actuation procedure. Thus, properly designed body actuation process can generate arbitrary attitude reorientation even when total angular momentum of the system is kept zero. The typical research topics on this field are a righting reflex of falling cats [1] and reorientation of free-floating astronauts or aerial sports player [2,3]. In these systems, resulting attitude motion during joint actuation can be solved by numerical integration, but on the other hand, it is difficult to solve its inverse problem in which joint actuation process is designed to obtain arbitrary atititude reorientation. Previous studies have not generally solved the inverse problem, but instead, constrained most degree-of-freedom of control input to largely reduce exploration space for the solution. Thus, conventional methods have not made the most of potential attitude reorientation capability.

METHODS

This research proposes a novel method to solve the inverse problem of the attitude reorientation of a free-floating multibody. We refer to the proposed method as *rectilinear joint actuation* in which all m joints of the multibody are actuated along rectilinear path in m-dimensional joint angle space. The rectilinear path that connects starting and final joint configurations is iteratively modified to achieve target final attitude and self-collision-free constraints while optimizing total amount of joint angle displacement. The proposed method can handle large number of control degree-of-freedom and make the most of potential attitude reorientation capability of the free-floating multibody. In addition, each stroke of the rectilinear path results in concise attitude solution whereas the successive rectilinear stroke can yield sufficiently complicated attitude maneuver. In particular, this rectilinear joint stroke is suitable for humans because they can accomplish desired attitude maneuver simply by sequential posing of their body, not following complicated torque histories.

RESULTS AND DISCUSSION

The proposed motion planning method is validated by numerical simulation of free-floating human model. We used average physical properties of human body in this simulation. In the example simulation shown below, the target attitude rotation is set to be -30 degrees around x-axis (Figure 1). The human sequentially switches body poses and achieves target attitude after 5 strokes of joint actuation. The entire body actuation process does not cause self-collision and satisfies joint angle limit constraints. The resulting attitude maneuver is agile and efficient due to optimization.

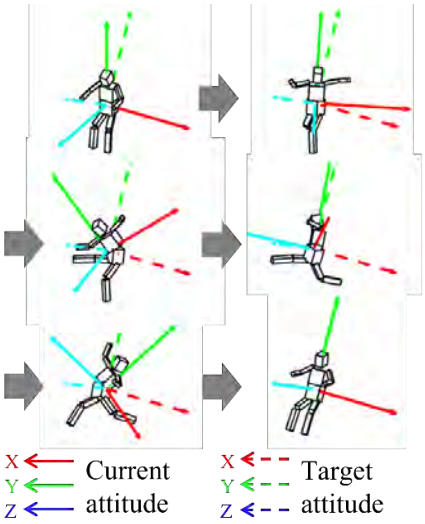

Figure 1 Example of optimized attitude reorientation of a human.

CONCLUSIONS

This research proposed a novel method for free-floating humans to achieve target body reconfiguration and attitude reorientation simultaneously. The proposed method greatly enhances attitude reorientation capability of large degree-of-freedom systems that conventional methods cannot make the most of its potential capability. Numerical simulation validated the proposed motion planning method effectively achieves agile attitude reorientation.

IMPACT OF MENSTRUAL CYCLE ON ANAEROBIC POWER AMONG YOUTH CRICKETERS

Vijay Dhamodharan[1], Shanmugapriyanka Ilangovan[1], Rajinikumar Palaniyappan[1]
[1] Center of Excallence in Biomechanics, TNPESU, Chennai, India.
Email: vijaydhamu5@gmail.com

INTRODUCTION

The single most difficult challenge for athletes, particularly female athletes, is avoiding low energy availability due to its known effects on menstrual function and bone health – as evidenced by the Female Athlete Triad. Many aspects of athletic performance may suffer as a result of these changes in physical functioning [1]. There is a general lack of understanding regarding the relationship between menstrual cycle (MC) phases and performance in elite athletes. The purpose of the study is to investigate whether the menstrual cycle phase influences the anaerobic power in young female cricketers.

METHODS

This study was formulated as a homogenous group design. For the purpose of this study twenty young female cricketers (n=20) who represented the district and state teams were selected as subjects purposely (purposive sampling). This is a two-group comparative study as shown in Figure 1. To collect necessary data, the following variables were measured namely Menstrual Phase, Follicular phase, Ovulation phase, Luteal phase using Clue App and the Peak take-off Ground Reaction Force (GRF) during the Counter Movement Jump (CMJ), Standing Broad Jump (SBJ) GRF and Plyometric Pushup (PP) were measured through Kistler Force plate model 9287CA with dimension 1200x600x100 and analysed using MARS software. Subjects were asked to perform 3 trials with 1min rest between them. Best of the 3 trials was chosen for the research. Since only the anaerobic power of the athlete was studied, the take-off force was chosen as the variable of study [2].

RESULTS AND DISCUSSION

The athletes were categorised into group 1 and group 2 based on the bleeding phase of the individual. 63.2% athlete's mensural phase length was between 1-4 days, 21.1% was between 1-6 days, and 15.8% was 7 days or more.78.9% athletes prefer moderate intensity workout during the menstrual phase.26.3% athletes agreed that they feel strong during menstrual phase. 52.6% athletes prefer to train or compete during follicular phase of the menstrual cycle. Among twenty athletes 84.2% were comfortable competing during bleeding phase. The results from the table I shows that the obtained 't' values of 3.277, 2.269 and 2.879 were smaller than the table 't' value of 2.101. It is obviously shown that there was a significant difference between Counter Movement Jump (CMJ) GRF, Standing Broad Jump (SBJ) GRF and Plyometric Push-up (PP) GRF among bleeding and non-bleeding group of young female athletes.

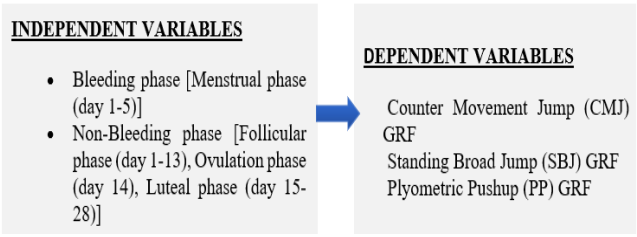

Figure 1 Research Design- Two Group Comparative study.

CONCLUSIONS

These results show that there is difference in the peak force generation between bleeding [Menstrual phase (day 1-7)] group and non-bleeding [Follicular phase (day 1-13), Ovulation phase (day 14), and Luteal phase (day 15-28)] group of female athletes. Further studies in the same area with static group comparation by repeated design to study the anaerobic power during different phases of MC might provide more insights.

INTRODUCTION

Gravel biking is a recent trend in cycling. The profiled and wider tires of gravel bikes allow for a more variable use than traditional road bikes and also allow riding off paved roads. For the design of the bikes, the loads that occur during typical riding maneuvers, such as hitting a small obstacle, are of interest.Noteworthy, data on ground reaction forces in cycling is rare.
Therefore, this pilot study aims to provide metrics on the bike-ground interaction for biking over a small obstacle.

METHODS

Ground reaction forces (GRF) when riding over a 40 mm x 40 mm obstacle were recorded by three riders (BM: 75.3 ± 9.5 kg, BH: 1.83 ± 0.04 m). Each participant completed three attempts at 6 m/s approach speed in a seated position. The Gravel-Bike (Addict Gravel 10 2022, Scott, CH) included carbon rims (Capital 1.0 X40, Syncross, CH) and 700x45c tires (G-One Bite performance, Schwalbe, GER) at 1.5 bar tire pressure. GRF (Kistler, Winterthur, CH) were recorded at 1000 Hz and lowpass filtered (Butterworth, 2nd order, recursive, 300 Hz).
The front wheel and rear wheel impacts on the obstacle were detected via the anterior-posterior GRF. Extracted discrete variables are the vertical and longitudinal peak forces and the momentum of force along the driving direction to quantify the amount of braking. Signal processing and descriptive statistics are done using Matlab (Matlab R2021B, The MathWorks, USA).

RESULTS AND DISCUSSION

Figure 1 illustrates vertical and longitudinal GRF for the front-and-rear wheel during a single impact. Vertical peaks occurred up to 904.8 ± 194.7 N at the front wheel and 1311.0 ± 349.2 N at the rear wheel. Backward-oriented peaks reached up to -293.2 ± 19.7 N (front) and 402.4 ± 50.9 N (rear). Discrete variables are summarized in table 1.

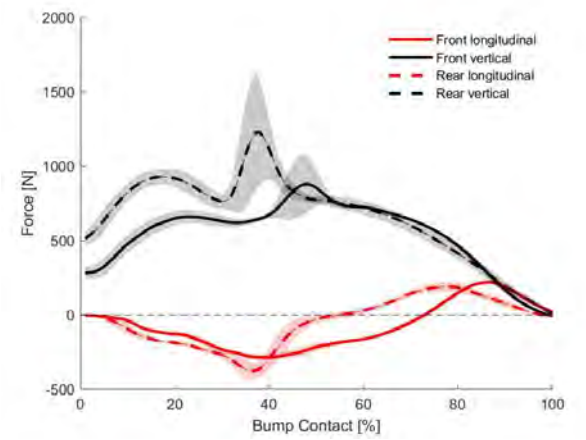

Figure 1: Vertical (black) and driving direction (red) GRF for front and rear wheel impact. Negative longitudinal GRF is orientated against the driving direction (backward).

CONCLUSIONS

The results suggest, following previous research, that rear-wheel loading is higher than front-wheel loading [1]. Horizontal peak forces at 30% of the vertical peak force demonstrate, that the loading scenario is not purely vertical but a 2D phenomenon. To the best of our knowledge, this study is the first to provide GRF time histories for typical loading scenarios as single impacts in (gravel) biking. The methodological approach might help future research to understand the systematic effects of e.g., speed, obstacle size, or technical interventions such as damping systems on bicycle loading.

Performing both resisted and non-resisted trunk extension in prone are recommended to elicit maximum voluntary contraction of the spinal extensors in adolescents with idiopathic scoliosis and controls

INTRODUCTION

Adolescent idiopathic scoliosis (AIS) is a three-dimensional deformity of the spine, diagnosed between the ages 10-18 years. It is associated with morphological and physiological differences in paraspinal muscles. Paraspinal muscle activation, recorded using electromyography (EMG), may also differ between convex and concave sides of the spine in those with AIS. The greatest evidence for asymmetrical paraspinal muscle activity is in those with progressive, right-thoracic curves, recorded during static postural tasks [1]. However, inconsistent EMG electrode placement, data processing, reporting of methods, and normalisation methods prevents clear interpretation of current evidence. Normalisation of EMG is important when comparing amplitude of activation during submaximal tasks between individuals, groups and/or muscles [2]. The development of standardised EMG recording and normalisation procedures will assist comparison of paraspinal muscle activation amplitude between sides and participants with and without AIS.

The aim of this study was to identify the spinal extension task that achieves peak amplitude of activation above, at and below the primary scoliosis curve in adolescents with AIS, and the same spinal levels in controls. We first compared five tasks during pilot testing: maximal trunk extension in i) prone and ii) sitting, both resisted with multiple straps; iii) a modified biering-sorenson test; iv) manually *resisted* trunk extension in prone (Fig 1A), and v) the *superwoman* with no resistance (Fig 1B). From these, the *resisted* and *superwoman* tasks consistently provided the greatest activation amplitude of paraspinal muscles, and were chosen for further study.

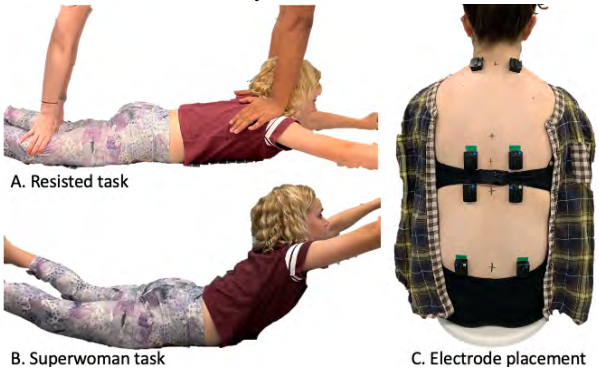

Figure 1 The (A) resisted and (B) superwoman tasks performed to obtain maximal activation of paraspinal muscles, measured using bilaterally placed surface electromyography electrodes (C).

METHODS

Adolescent females with primary right thoracic AIS (n=11, mean[SD] age: 13.8[1.3] years) and without AIS (n=11, 13.8[1.9] years) were recruited through a Spine outpatient clinic at the Queensland Childrens' Hospital, and community. Bipolar surface electrodes were placed bilaterally at vertebral levels: C7,T9,T12, & L5 (Fig 1C).

Participants were provided with training of the maximal voluntary activation tasks, during which they were provided with visual feedback of their muscle activation. Once familiar with the tasks, participants were verbally encouraged to increase their contraction over 3 seconds, then *contract as hard as possible* for ~ 3 seconds before returning to rest. Both tasks were repeated 3 times, with at least 1 minute rest between contractions. Data were sampled at 2000sps, then filtered (50-500Hz, 4th order Butterworth band pass), and rectified and low pass filtered at 2Hz. The maximum amplitude obtained for each contraction was obtained, and all data were then normalised to the maximum obtained across all contractions for each muscle independently.

RESULTS AND DISCUSSION

On a group level, there was neither a difference in the normalised EMG amplitude between tasks (*superwoman* and *resisted;* main effect task: p=0.71), nor group (AIS and control; main effect group: p=0.22). Peak activation was achieved with the *superwoman* task in 45%, and in the *resisted* task in 55%, of the activation measurements [considering activation was measured on 2 sides x4 muscles x2 tasks x22 participants]. For individual participants, the difference in maximum amplitude between tasks was up to 46% (mean [SD]: 20 [15]%). This means that if only one of these tests were performed the maximum amplitude could be underestimated by up to 46%, which severely impacts the ability to interpret normalised activation data.

CONCLUSIONS

We recommend using resisted and non-resisted trunk extension in prone as an optimal approach to determine peak voluntary activation.

INTRODUCTION

Adolescent idiopathic scoliosis (AIS) is a three-dimensional deformity of the spine, diagnosed between the ages 10-18 years. Curve progression is associated with three-dimensional wedging of spinal vertebrae and discs. It is well known that muscle activity and morphology influence muscle force generation, and that the forces applied to bones and discs are substantial moderators of growth and adaptation [1]. To date, the greatest evidence for asymmetrical paraspinal muscle activity is in those with progressive, right-thoracic curves, recorded during static postural tasks [2]. However, data varies greatly between studies, and previous outcomes are highly dependent on the methodological approaches taken [2].

The aim of this study was to determine if the symmetry of paraspinal muscle activation amplitude differs in adolescents with AIS compared to controls, during a voluntarily driven, symmetrical, submaximal task.

METHODS

Adolescent females with AIS (primary right thoracic curves, n=11, mean[SD] age: 13.8[1.3] years) and without AIS (n=11, 13.8[1.9] years) were recruited through a Spine outpatient clinic at the Queensland Children's Hospital and the local community.

Participants first performed a series of six maximal back extensions. Three of these were conducted in an unresisted *superwoman* pose, and three were manually *resisted* at the shoulders and thighs. The maximum activation recorded in any trial, for each muscle separately, was used for normalisation. Participants then performed a series of five (20-40s) submaximal *superwoman* contractions (Fig 1A). Visual and verbal feedback was provided to encourage participants to maintain a level of activation at T9, which was between 10-30% of their maximal activation (i.e. 10-30% MVC, from T9 left + right).

Muscle activity was recorded using bipolar surface electrodes placed bilaterally at vertebral levels: C7, T9, T12 & L5 (Fig 1B). Data were sampled at 2000sps, then filtered (50-500Hz, 4th order Butterworth band pass), and rectified and further low pass filtered at 10Hz. The *symmetry index of muscle activity was determined using* Ln (Right/Left), which equates to Ln (Convex/Concave) in the AIS cohort. The symmetry index, for each muscle separately, was compared using independent t-tests.

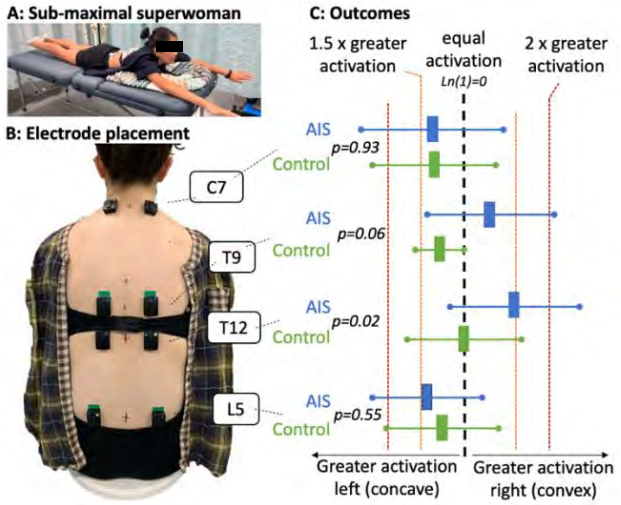

Figure 1A) Submaximal superwoman pose; B) electrode placement, C) symmetry index of muscle activation in adolescent idiopathic scoliosis (AIS) and controls. Data right of the line of equality = greater activation on the right (convex in AIS) side.

RESULTS AND DISCUSSION

The symmetry index was different between groups at T12 (p=0.02; Fig 1C). Greater activity was observed on the convex side of the curve at T12 in all but one participant with AIS. Individual variability in this measure will be further explored. The difference in asymmetry between AIS and controls was also close to significant at T9 (p=0.06). Our work supports previous studies, that use a variety of tasks and normalisation methods, and demonstrate the greatest evidence for convex>concave paraspinal muscle activation asymetry at the level of the apex and lower end vertebral level of the curve (~T9 and T12 respectively for our study) [5].

CONCLUSIONS

Compared to control participants, adolescents with AIS display greater asymmetry in paraspinal muscle activation at T12 during submaximal trunk extensions. This asymmetry was not observed in the cervical or lumbar spine regions. The origins and consequences of this asymmetry are important to consider further.

Ankle power in gait is more relevant to the maximum instance firing rate of soleus than gastrocnemius

Hayase Funakoshi[1], Takanori Kokubun[1]
[1] Department of Health and Social Services, Graduate School of Saitama Prefectural University / Saitama, Japan.
Email: Funakoshi-hayase@spu.ac.jp

INTRODUCTION

Gait speed is a crucial health indicator that is closely associated with mortality and a primary focus of rehabilitation interventions. Ankle plantar flexion plays a significant role in generating the propulsive force required for faster gait, accomplished by pushing off with the toes. This movement is driven by the triceps surae muscles, which comprise the Soleus and Gastrocnemius. The force generated by these muscles is determined by structural and neural factors, including the firing patterns of motor units. Previous study has established that the Impulse is closely linked to the maximum instance discharge rate (IDRmax) of motor units during isometric contraction tasks[1)]. And ankle power has been shown to be related to gait speed[2)]. So we hypothesizesd that ankle peak power in gait is also contributed by IDRmax of triceps surae. We used decomposition algorithms capable of tracking the firing behavior of individual MUs during dynamic tasks to investigate the relationship between MU firing and ankle power (NeuroMap software; Delsys Inc.; De Luca et al., 2015).

METHODS

Subject was 12 healthy young adult (6 male and 6 female). They are provided written informed consent, following a detailed explanation of the study's purpose and risks according to the Declaration of Helsinki. The 4 channel Electromyography (EMG) (Delsys.inc) was putted on soleus (SOL), medial (MG) and lateral (LG) gastrocnemius. Task was 3-minute gait at 6 different speed including the maximum and minimum speed on the treadmill with force plate surrounded by the 3-dimensional motion capture system. Each speed was determined with self-awareness. MU firing times were extracted from the EMG signals from each sensor separately using decomposition algorithms. Only MUs with accuracy estimates of 85% or higher were included into further analysis. The correlation coefficient was calculated between IDRmax (maximum value of reciprocal of inter spike interval in a 150 msec interval before the ankle moment peak) of MU and ankle power, and maximum gait speed.

RESULTS AND DISCUSSION

High MU maximum firing rate contributes generating ballistic force. So, we expected that ankle plantar flexion that is related to the gait speed in faster gait is related to the higher IDRmax. Consistent with previous research, there was a significant positive correlation between ankle peak power and maximum walking speed (r=0.72, p>0.00). The correlation coefficient between IDRmax of SOL and ankle power was 0.71 (p>0.00), IDRmax of MG was -0.19 (p=0.10), IDRmax of LG was 0.17 (p=0.16). In addition, IDRmax of SOL has significant positive correlation with the maximum gait speed (r=0.61, p>0.00). Only SOL had significant positive correlation, but because previous study indicates that triceps surae doesn't completely receive the same neural drive, this study supports this phenomenon. And the factor for difference between SOL and MG, LG can be related to the MU twitch properties and size principle. MUs of soleus are recruited early for 90% slow-twitch fibers, so the firing rate is related to the subsequent increase in force. On the other hands, gastrocnemius has a 1:1 ratio of slow-twitch and fast-twitch fibers. Since recruitment and firing were mixed in gastrocnemius, IDRmax of MG and LG didn't have significant correlation with ankle peak power.

CONCLUSIONS

We conclude that instance firing rate of SOL can contribute to the gait speed via ankle peak power. But further studies are needed to completely confirm this hypothesis.

Supraspinal integration of proprioception is crucial for locomotor robustness

Alessandro Santuz[1,2], Olivier Laflamme[2] and Turgay Akay[2]

[1] Development and function of neural circuits, Max Delbrück Center for Molecular Medicine, Berlin, Germany.

INTRODUCTION

Animals constantly move in complex environments. In vertebrates, locomotor activity is generated in part by central pattern generators in the spinal cord [1]. When somatosensory feedback is removed and supraspinal pathways are left intact, central pattern generators alone are not sufficient to ensure robust locomotion in the presence of external perturbations [2]. In mammals, information about the position of the body in space and relative to the body itself (i.e. proprioception) is conveyed to the central nervous system by mechanosensory neurons that carry signals from muscle spindles, Golgi tendon organs and joint receptors. Feedback from muscle spindles and Golgi tendon organs plays a central role in locomotion [2], [3]. Part of the proprioceptive information is processed in the spinal cord and three main pathways convey the rest to brain structures: the dorsal and ventral spinocerebellar tracts and the dorsal column-medial lemniscus (DCML) pathway. While the sensory circuitry in the dorsal column is relatively well investigated, the role of higher centres in integrating proprioceptive information during locomotion is still unclear. Here, we set out to explore the relevance of supraspinal integration of proprioceptive feedback via the DCML pathway during mouse locomotion. We hypothesised that not only spinal but also supraspinal processing of proprioception must be involved in the tuning of locomotor output in challenging environments. We show that supraspinal processing of proprioceptive feedback becomes critical when locomotion is challenged by external perturbations.

METHODS

Recordings were conducted on 18 adult (age 89 ± 20 days; mass 25.9 ± 3.9 g) male mice with C57BL/6 background: 5 wild-type for DCML lesion, 5 muscle spindle-deficient *Egr3*$^{-/-}$ [4], 5 *PV*^{Cre}*::Avil*^{iDTR} for acute ablation of muscle spindles and Golgi tendon organs triggered by diphtheria toxin injection [5] and 3 *PV*^{Cre}*::Rosa*^{EGFP} for the sham experiments. Eight bipolar EMG electrodes were surgically implanted in as many muscles of the right hind limb. Muscle synergies were extracted from EMG activity using the R package "musclesyneRgies" [6] v0.7.1-alpha. The DCML pathway was surgically lesioned using micro scissors. Animals walked on a custom-built perturbation treadmill (University of Cologne, Germany), capable of administering sudden mediolateral displacements or accelerations of the belt at random time intervals. For markerless body part tracking we processed high-speed videos of the sagittal plane in DeepLabCut [7] v2.1.10.

RESULTS AND DISCUSSION

The effects of perturbations on kinematics were visible only in the wild type, as an increased variability of the hip joint angle at touchdown. In *Egr3*$^{-/-}$ and *PV*^{Cre}*::Avil*^{iDTR} mice, the lack of proprioceptors made the kinematic variability increase, independently on the presence of perturbations. After lesion, wild-type mice showed overall low kinematic variability, comparable to that observed before surgery in unperturbed locomotion. Similar to kinematics, the complexity or "accuracy" of muscle activation patterns was lowered in response to perturbations only in wld-type animals. Proprioceptive-deficient mutants always showed low complexity of activation patterns, a sign of constant internal perturbation. Lesioned wild-type mice often halted locomotion in the presence of perturbations, showing no modulations of complexity, which remained high.

CONCLUSIONS

We showed that animals lacking proprioceptors locomoted in a constantly perturbed state, irrespective of the administration of mechanical perturbations. This was not the case in wild-type mice, in which we surgically interrupted the flow of proprioceptive feedback to the brain through the dorsal column. After the lesion, the lesioned animals behaved similarly to pre-lesion unperturbed walking, both in the absence and presence of external perturbations. This translates into two main conclusions: i) the removal of proprioceptors in mice impairs locomotion proportionally to the level of ablation and ii) supraspinal integration of proprioceptive information is crucial to ensure robust locomotion. Taken together, our results show a clear involvement of supraspinal proprioceptive structures in the production of robust, continuous locomotion.

INTRODUCTION

Gene Fragile X Messenger Ribonucleoprotein 1 (FMR1) encodes an RNA binding protein that is implicated in a multitude of crucial neurodevelopmental processes, including early embryonic motor circuits [1]; transcriptional silencing of the FMR1 is the main cause of inherited intellectual disability and autism spectrum disorder called Fragile X Syndrome (FXS). "Premutation" and "full mutation" are the two main categories of FMR1 mutations associated with different clinical phenotypes; somatic mosaicism can represent a strong FXS phenotype modulator [2]. Mosaicism in FXS refers to two different FMR1 allele variations: size mosaicism (i.e. different numbers of CGG repeats between the two alleles), methylation mosaicism (i.e. full-mutation allele is fully or partially methylated) [3]. The present study explored the differences between healthy subjects, full mutation and both methylation and size mosaicism in terms of musculoskeletal alterations during gait.

METHODS

After appropriate informed consent by the parents, the gait of 36 FXS children ((FX) mean(±SD) age of 10 (±3.6) years, BMI of 19.4 (±3.6) Kg/m2) and 10 controls ((CS), mean(±SD) age of 10 (±3.07) years, BMI of 20.4 (±4.5) Kg/m2) was assessed at the BiomovLab (CS) and at the Paediatric Department of the University of Padua. Within the FXS group of 28 children with full mutation ((FX-FM), 3 children with methylation mosaicism (FX-MET) and 5 with size mosaicism (FX-DYM) were detected . Kinematics in terms of joint angles and surface electromyographic data (sEMG) were simultaneously acquired through four synchronized cameras (GoPro Hero3, 30fps) and an sEMG system (FreeEmg, BTS, 1000Hz) that collected the activity of Tibialis Anterior, Gastrocnemius Lateralis, Rectus Femoris and Biceps Femoris. At least three left and right gait trials per subject were processed. From sEMG parameters, envelope peak and its occurrence within the gait cycle were computed, sagittal plane kinematics was assessed from video recordings [2].

RESULTS AND DISCUSSION

In terms of joint angles both FM-MET and FM-DYM showed a statistically significant reduction of the knee flexion and an increase of the ankle extension; meanwhile only FX-MET showed an increase in hip flexion angle during the whole gait cycle. Concerning with sEMG, FX-MET showed a decrease in Tibialis Anterior activity during midstance and terminal swing, accompanied by an increase in terminal stance; a decrease in Gastrocnemius Lateralis activity during midstance, and finally an increase in Biceps Femoris activity during terminal stance. In the comparison between both FX-MET and FX-DYM with CS, even though no statistically significant differences were detected, the envelope shapes of all muscles showed an altered pattern.

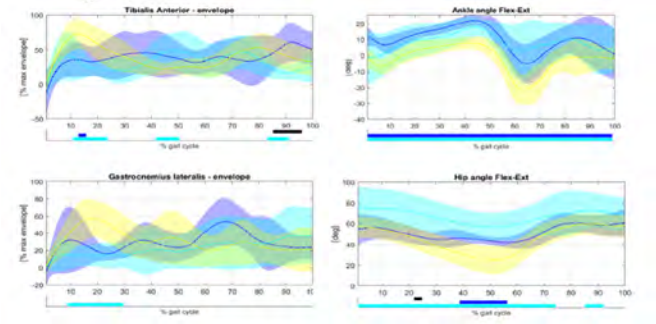

Figure 1 On the right column Tibialis Anterior and Gastrocnemius Lateralis envelope shaper, on the left column knee and hi angles in degree. Mean and standard deviations are represented as bands according to the colour reported in the legend.

CONCLUSIONS

These results seem to suggest that FX-DYM and FX-FM presented similar differences in the sEMG pattern when compared with CS, while FX-MET displayed a pattern more similar to CS. -M eanwhile, in terms of kinematics, the data showed similar alterations in FX-MET and FX-DYM with respect to CS.

INTRODUCTION

Ankle sprains have been reported as the most common injuries during sport games. They may occur during landing or fast cutting movements either with or without interference of an object or opponent. Often considered to be a minor injury an unrecognized high proportion of complications and associated costs were reported by Larsen et al. [1]. In a recent review [2], it has been stressed that the underlying injury mechanism may vary between cases while many studies assessed the general benefits of interventions, such as bracing or training, The goal of this study was to assess the effect of bracing on muscle activity of lower extremity muscles during side cuting on normal and simulated slippery surfaces.

METHODS

Sixteen team sports athletes volunteered in this study (28.2 +/- 3.7 y, 72.9 +/- 7.0 kg, 175 +/- 7 cm). Full-body kinematics (Qualisys, 240 Hz) and ground reaction forces (AMTI, 1000 Hz) were recorded. The force plate rested on a 4-DoF robotic actuator [3] which moved horizontally in approach direction by 0, 4 or 8 cm in a randomized order, 25 ms after touch-down. Cutting was performed in two sets with eight trials per condition, when wearing a semi-rigid ankle brace (AirCast) or no brace. Electromyographic (EMG) signals were recorded from nine leg and thigh muscles of the cutting leg and rectus femoris and gluteus maximus of the contralateral side (1200 Hz, Biovision). Kinematic data were analysed in Visual3D (C-motion) and EMG data using a customized script in MatLab (The Mathworks).
Joint angles, moments and corrected GRF values were determined at touch-down and during the stance phase. From the EMG data, average rectified values (ARV) were calculated in three time-intervals, i.e., the last 50 ms prior to touch-down (PRE), the first 70 ms after initial ground contact (EARLY) and 70-120 ms after touch-down (LATE). A two-factor repeated measures ANOVA on the factors BRACE and SLIP condition was employed for statistical analysis using a Bonferroni post-hoc test. Significance was attested if $p<0.05$.

RESULTS AND DISCUSSION

The kinematics showed marginal differences between slip conditions while the main effect for BRACE was a more dorsiflexed ankle at touch-down and a slightly increased range of knee flexion during ground contact, confirming [4]. Different SLIP conditions did not alter the muscle activity in the PRE and EARLY intervals but a reduced activity for VM during LATE (not shown). There was a significantly increased RF_C activity during LATE for the BRACE condition (shown for 0 cm slip in Fig. 1) indicating that the use of a brace affects muscle action of the contralateral hip.

CONCLUSIONS

Wearing a brace affects not only the ankle and knee kinematics of during cutting but also the muscle activity of the muscle of the contralateral hip during a cutting task. This may have implications for long term use of ankle braces.

INTRODUCTION

The hamstring muscles are biarticular; that is they span two joints. Biarticular muscles in the thigh control the distribution of force and torque around the hip and knee joints. They are often considered to have well-defined actions and function based on their anatomy. However, recent evidence suggests that some biarticular muscles have region-specific activations that can be interpreted as regional differences in function within the muscle [1]. For instance, in the medial gastrocnemius, motor units (MU) can show different behaviour across distinct muscle regions, suggesting that a single muscle could have areas that are controlled selectively by the nervous system. Surprisingly, little is known about the representation of this phenomenon in the hamstring muscles. The aim of this study was to determine regional variation in hamstring muscle MU firing properties during voluntary contractions performed at different muscle lengths (hip and knee joint configurations).

METHODS

Twelve recreationally active male volunteers, aged between 18-30 years, participated in the study. With the participants laying in the prone position, four different joint configurations were used to manipulate hamstrings muscle length (Hip 0° – Knee 0°; Hip 0° – Knee 90°; Hip 70° – Knee 0°; Hip 70° – Knee 90°). At each position, participants performed isometric contractions at 40% of a previously determined maximal voluntary isometric contraction. High-density electromyography (HD-EMG) signals were recorded from the biceps femoris long head (BFlh) using two 2-D adhesive grids of 32 channels (8 rows x 4 columns, 10 mm inter electrode distance). Electrodes were placed in the mid and distal regions of the muscle. Signals were sampled using a wireless analogue to digital converter (Sessantaquattro, OT Bioelettronica, Torino, Italy). Knee flexion torque was quantified using an isokinetic dynamometer (Humac Norm, Stoughton, USA). HD-EMG signals were decomposed [2] to identify the following MU properties: mean discharge rate, recruitment threshold and coefficient of variation of the inter-spike interval (CoVisi). A mixed-effects model was used to evaluate the effect of 'joint configuration' (four levels) and 'region' (two levels) on motor unit properties ($p \leq 0.05$).

RESULTS AND DISCUSSION

The mixed-effects analysis revealed no main effects or interactions (joint configuration x region) for any of the variables analysed (Figure 1).

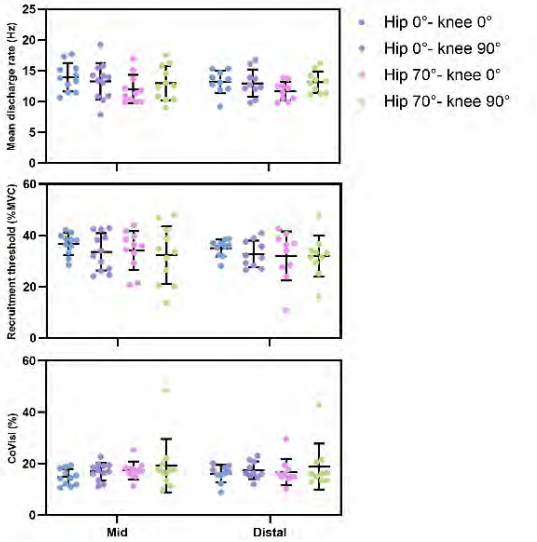

Figure 1 MU properties at different joint configurations and BFlh regions.

These results show no regional variation in BFlh muscle neural control during isometric contractions performed at different joint configurations. This may suggest that MUs are uniformly recruited througout the BFlh when the muscle activates at maintained muscle lengths. However, since previous evidence suggests regional changes in BFlh EMG amplitude during concentric/eccentric tasks [3], it may be plausible that the change in muscle length rather than the muscle length itself is a key factor leading to regional changes in neural control. Further, it is still possible that regional differences in MU firings are more evident in the proximal end of the muscle (closer to the hip).

CONCLUSIONS

The BFlh muscle does present regional variation in neural control during voluntary isometric contractions performed at different muscle lengths. Further studies are needed to elucidate if the same treand is maintained during shortening/lengthening contractions.

New approach for calculating a functional subtalar joint axis

Anja Seeger[1], Sascha Schlechtweg[2] Wilfried Alt[1]
[1] Institute of Sport and Movement Science, University of Stuttgart, Stuttgart, Germany.
[2] Stryker Leibinger GmbH & Co. KG, Freiburg im Breisgau, Germany.

INTRODUCTION

The orientation of the subtalar axis (STA) might be associated with various overload and injury mechanisms of ankle and knee joints [1]. Methods of axis determination mostly concentrate on a anatomical STA and are often expensive and time-consuming (e.g. imaging methods) and therefore an obstacle to large-scale studies. Antother possibility is the analysis of a ***functional axis*** of eversion and inversion movement (fSTA). Schlechtweg [2] describes an approach to calculate the the deviation and inclination angle of the fSTA using two Intertial Meausurment Units (IMU) and a kinematic model based on Seel and Schauer 2012 [3] in reference to an anatomic coordinate system defined by Manter in 1941 [4]. In this study a measurement procedure was used that only needs a single IMU for estimation of the orientation of a fSTA.

METHODS

The IMU is attached dorsal to the calcaneus, using a fixing clamp with the yaw axis of the IMU (aktos-mini, myon AG, Schwarzenberg, Switzerland) in line with the longitudinal axis of the foot (Figure 1a). To indentify the sensors pitch and roll orientation a static acceleration measurement was conducted while the subjects' foot stood flat on the ground. By calculating the angles between the acceleration vector and the frontal and transverse planes the orientation of the IMU in the anatomical coordinate system could be fully defined. The gyroscope signals from eversion and inversion movement were captured with the foot in max. dorsiflexion to lock the talocrural joint within the mortise. The algorithm calculates the rotation axis of the IMU by using a principal component analysis (PCA) of the gyroscope signals based on the assumption that the IMUs connection to the heel bone is quasi-rigid and on the definition of the fSTA as an finite non helical axis.

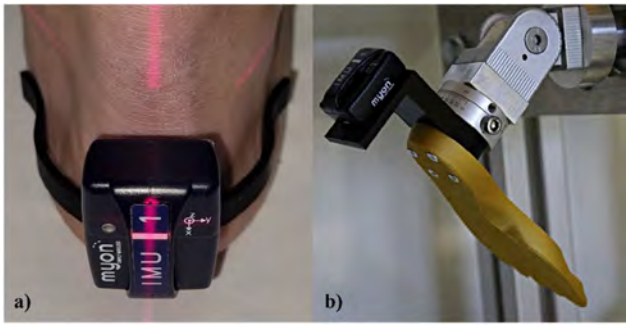

Figure 1: a) Fixing clamp with IMU, b) Testing machine with IMU.

Validity was tested with a mechanical testing machine (Figure 1b), simulating the movement of the subtalar joint for different predefined deviation and inclination angles. The measurement settings included a range from 10° lateral to 40° medial deviation and an inclination range from 15° to 60°. The mean difference between the values pre-set on the testing machine and the measured IMU values and the RSME are shown in Table 1.
In order to test the reliability of the system, the procedure was repeated 10 times with one male subjects right foot. The average of inclination and deviation and the CV (coefficient of variation) are shown in Table 1.

RESULTS AND DISCUSSION

In this study we tested a new method to determine a functional axis of rotation of the subtalar joint. With a CV of 0.07 for the deviation and 0.01 for the inclination angle, the subject measurements show acceptable reliability of the method. The validity of the method has been proved within a mechanical testing machine. The results show a small RSME for the deviation (0.5) as well as for the inclination angle (0.6). Thus the angles calculated by the algorithm describe the orientation of a fSTA.

Table 1: Results for testing machine and subject measurements.

	Testing machine		Subject	
	Difference	RSME	Angles	CV
Deviation °	0.25 ± 0.4	0.5	14 ± 0.1	0.07
Inclination °	0.4 ± 0.6	0.6	39 ± 0.5	0.01

CONCLUSIONS

The algorithm is valid for calculation an axis of rotation between inversion and eversion movements of the foot. This functional axis might be highly determined by the anatomical STA. The position is assumed based on the paper from Piazza et al. [5]. Therefore, this described procedure could be a huge benefit especially for large-scale studies.

Acute Effects of High-Definition Transcranial Direct Current Stimulation on Ankle Force Sense and Cortical Activation

Chuyi Zhang[1], Bin Shen[1], Songlin Xiao[1] and Weijie Fu[1,*]

[1] Key Laboratory of Exercise and Health Sciences of Ministry of Education, Shanghai University of Sport, Shanghai, China.

Email: fuweijie315@163.com

INTRODUCTION

Force sense is a conscious proprioception that assesses an individual's ability to detect muscle tension [1]. The ankle is positioned close to the body's base of support, and its force sense plays an important role in maintaining human balance and motor control [2]. Transcranial direct current stimulation (tDCS), a neuro-biomechanical ergogenic technology that can effectively modulate cortical excitability and enhance physical performance, has recently been introduced into the field of sports science [3]. However, little is known regarding the central modulation mechanism of tDCS in terms of foot and ankle sensorimotor function. Therefore, the purpose of this study was to explore the acute effects of high-definition tDCS (HD-tDCS) on the ankle force sense and activation of the sensorimotor cortex in healthy adults, in order to provide new ideas for improving ankle proprioception at the level of the central nervous system.

METHODS

Sixteen healthy adults (8 males and 8 females; age: 25.5 ± 1.8 yrs; height: 170.8 ± 10.9 cm; weight: 63.9 ± 11.9 kg) were recruited. Participants were randomized to receive 2 mA HD-tDCS or sham stimulation over the primary motor cortex (M1) for 20 minutes in two sessions (3-7 days apart). Both before and after the intervention, the plantarflexion force sense of the right ankle was obtained by the Contrex Isokinetic dynamometer, and the activation of the sensorimotor cortex was monitored by the functional near-infrared spectroscopy (fNIRS) in 23 channels during the plantarflexion force control task. A two-way repeated measures ANOVA (tDCS condition × time) was performed on all test variables.

RESULTS AND DISCUSSION

The root mean square error (RMSE) of the ankle force sense test had a main effect of time ($F_{(1,30)} = 5.880$, $p = 0.022$, and $\eta_p^2 = 0.164$, Figure 1). Specifically, RMSE decreased by 19.97% after real stimulation and by 10.23% after sham stimulation. This suggested that HD-tDCS has the potential to enhance ankle force sense, which may contribute to improving ankle stability. The maximum voluntary isometric contraction (MVIC) of ankle plantarflexion had no significant interaction or main effect. The cortical activation of channel 2, which is located in the supplementary motor area, had a significant interaction between tDCS condition and time ($F_{(1,30)} = 9.899$, $p = 0.004$, and $\eta_p^2 = 0.248$, Figure 1). Post-hoc analysis showed that the activation of this channel was significantly greater after real stimulation than before ($p = 0.02$, Cohen's $d = 0.91$), while there was no significant difference in the activation of the channel after sham stimulation. It indicated that the modulation of cortical excitability by HD-tDCS may have an impact on ankle force sense. No significant interaction or main effects were found for other channel activations.

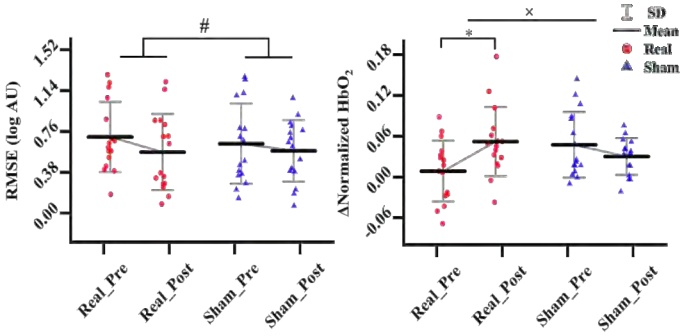

Figure 1 Effects of tDCS on the right ankle force sense and the cortical activation of channel 2.
Notes: # indicates a significant time main effect; × indicates a significant interaction; * indicates a significant difference before and after the intervention.

CONCLUSIONS

This study found that anodal HD-tDCS over M1 can increase the activation of the sensorimotor cortex during the ankle force sense test in healthy adults, suggesting that HD-tDCS is a potential intervention to improve the ankle force sense at the level of the central nervous system.

How do bones of the sub-talar joint complex cope with size?

Paige Treherne[1], Dr Michael Rainbow[2], Dr Luke Kelly[1]
[1]Human Movement and Nutrition Sciences, The University of Queensland, Brisbane, Australia
[2]Department of Engineering, Queen's University, Kingston, Canada

INTRODUCTION

Despite the wide variation in the size and shape of humans and their feet, less is known about how our feet change shape with increasing size. This may have important consequences for how we contend with increased body weight associated with size and the large muscular forces that are applied across the joints. The square-cube law states that if a bone grows isometrically, the surface area (SA) will grow at a slower rate than the volume ($SA = volume^{2/3}$). Under isometric scaling conditions, as bone and body mass increase in volume joint contact stress increases more rapidly, since stress = force/SA. Some terrestrial taxa scale allometrically across a range of interspecific sizes - meaning the shape of their skeleton changes as they get larger such that joint contact stress remains relatively constant across a wide range of sizes [1]. Within humans, the calcaneus and talus are the largest bones in the foot and form the sub-talar joint, which experiences high forces during locomotion. This study aimed to determine if the calcaneus, talus and the sub-talar joint surface areas (JSA) scale isometrically or allometrically across individuals.

METHODS

3D bone models of the talus and calcaneus were generated from computed tomography scans of the right foot in 36 individuals (mass: 73.4 ± 13.9 kg; height: 171.2 ± 8.1 cm; 21M, 15F) using Mimics. Calcaneus and talus bone models were centred then aligned using their inertial coordinate systems and an iterative closest point approach. Correspondence was obtained using a non-rigid coherent point drift (CPD) algorithm to a reference bone. The bones were scaled with a Procrustes analysis, and final correspondence was found using non-rigid CPD to the mean bone of the sample. For sub-talar joint complex analysis (calcaneus and talus combined) the bones were aligned to their respective inertial coordinate systems. Two different analyses were completed: principal component (PC) analysis of the individual bones and PC analysis of the sub-talar joint complex. Each principal component is a quantitative measure of shape variation, with each individual bone, or joint in the sample given a PC score (dependent on individual bone or joint complex PC analysis). To evaluate allometry, log-log plots were calculated for the bone volume and surface area of the talus and calcaneus, and surface area of their articular surfaces (Figure 1, A and B). A slope of 0.67 means the surface scales isometrically, with values either side of this termed allometry. To determine the relationship between size and shape, the PC scores for each mode of variation at a bone level were plotted against bone volume, and at a joint level against the combined bone volume.

RESULTS AND DISCUSSION

The calcaneus scales with negative allometry (slope = 0.62) meaning the surface area grows even slower than would be expected for isometric scaling. Similarly, the calcaneus' anterior medial facet scales with negative allometry (slope = 0.65), while the posterior facet scales with strong positive allometry (slope = 0.72) where the surface area grows faster than the isometric function. The talus scales isometrically (slope = 0.67). The talar dome and sub-talar surface scales with positive allometry (slope = 0.71 and 0.71). The first PC of calcaneus shape variation (15.6% of variation, $p<0.05$) was associated with bone volume. Here, the tuberosity becomes larger, the cuboid facet gets longer, and the bone grows taller relative to its length as the bone gets larger (Figure 1 C, top). No PCs of the talus showed any relationship with size. At a joint complex level, the second mode of variation (12.5% of variation, $p<0.05$) was linked to total bone volume. The calcaneus showed similar shape variations as the single bone analysis (larger tuberosity, longer cuboid facet, taller). On the talus, the talar head widened and the posterior process shortened as the sub-talar joint complex volume increased (Figure 1 C, bottom).

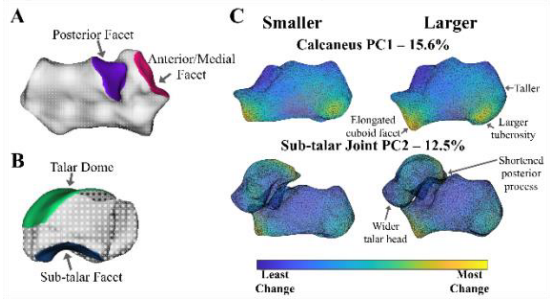

Figure 1 (A) Joint surface areas (JSA) on the right calcaneus. **(B)** JSAs on the right talus. **(C)** Anatomical shape variations at ±2SD from mean shape of calcaneus PC1 and sub-talar joint PC2 modes of variation. Heatmap shows where the most change is occurring.

CONCLUSIONS

We have shown the presence of distinct patterns of shape and scaling variance in the two largest bones of the foot. Interestingly, at a bone level the calcaneus scales allometrically and appears to become more robust (cube-like) as it gets larger. Additionally, the joint surfaces areas on both bones (except for the anterior/medial facet on the calcaneus) scale with positive allometry, potentially assisting with offsetting joint contact stresses as humans become larger. Whether these changes are present at birth or are the result of plasticity is an open question. Further analysis is required to determine if these scaling and shape variances are related to function.

The mechanism of leg stiffness adjustment during hopping with different hop frequencies

Kazuki Kuriyama[1], Daisuke Takeshita[1]
[1] Department of Life Sciences, The University of Tokyo, Tokyo, Japan
Email: k-kuriyama@g.ecc.u-tokyo.ac.jp

INTRODUCTION

The spring-like property of muscle-tendon complexes (MTC) plays an important role in movements with stretch-shortening cycle. A simple spring-mass model can express the characteristics of hopping and running [1]. In this model, the leg stiffness can be determined by the center of mass (CoM) movement and ground reaction force. Nagano et al. determined the leg stiffness for hopping with different hop frequencies based on the spring-mass model [2]. They found that the leg stiffness is higher for a higher hop frequency and speculated that the leg stiffness was adjusted by the contraction of triceps surae muscle fibers. However, the details of the mechanism for the adjustment of leg stiffness remain ambiguous. Therefore, we aimed to clarify the mechanism of the leg stiffness adjustment during hopping with different hop frequencies, from the viewpoint of the behavior of triceps surae MTC.

METHODS

Nine healthy adult men who exercise regularly participated as subjects. They conducted hopping at seven different frequencies (from 2.0 Hz to 3.5 Hz) controlled by a metronome. They were instructed to place their hands on the opposite shoulders and keep their knees as extended as possible. The coordinates of anatomical landmarks of the whole body were recorded with a motion capture system. The ground reaction force was recorded with force plates embedded in the ground. In addition, longitudinal images of the medial gastrocnemius muscle (MG) of the right leg were obtained by a real-time B-mode ultrasound apparatus. The MTC length of MG was calculated from the ankle and knee joint angles [3]. The fascicle length of MG was determined by manually digitizing the ultrasound images. The leg stiffness (k_{leg}) was determined by the vertical displacement of the CoM of the subject and the ground reaction force. The stiffness of MTC (k_{MTC}) was determined by the MTC length change and the load on the Achilles tendon, which was calculated from the ankle joint torque and the moment arm of the Achilles tendon.

RESULTS AND DISCUSSION

k_{leg} increased with increasing hop frequencies. This result is consistent with the previous study [2]. k_{MTC} also increased with increasing hop frequencies, and there was a strong correlation (r=0.88, p<0.001) between these two stiffness values. At hop frequencies used in the present study, ankle joint stiffness is the major determinant of k_{leg} rather than knee or hip [4]. Therefore, k_{MTC} appeared to mainly determine k_{leg}.

While the MTC length change showed similar patterns for all the hop frequencies, the fascicle length change showed different patterns for different hop frequencies (Figure 1). The fascicle almost kept its length at low hop frequencies. On the other hand, the fascicle shortened throughout the entire ground contact phase at high hop frequencies.

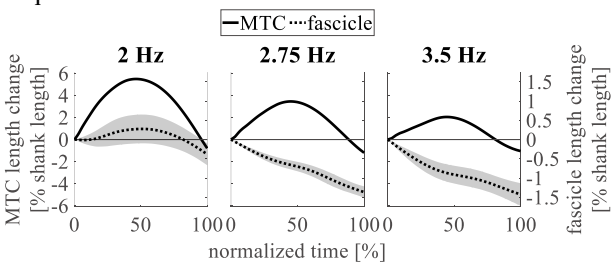

Figure 1: the length changes of the MTC and the fascicle of MG during the ground contact phase

To understand how the length change of the MG fascicle affected k_{MTC}, a simulation with a model consisting of contractile component (CC) and series elastic component (SEC) was performed. The result showed that the shortening and lengthening of CC increases and decreases k_{MTC}, respectively. This can be interpreted from the viewpoint of the equivalent spring of CC and SEC connected in series. Using the stiffness of CC (k_{CC}) and that of SEC (k_{SEC}), k_{MTC} can be determined based on the formula for two springs in series:

$$1/k_{MTC} = 1/k_{CC} + 1/k_{SEC}.$$

When CC lengthens under increasing load, CC is considered to have positive stiffness, making k_{MTC} smaller than k_{SEC}. In contrast, when CC shortens against load, CC is considered to have "negative stiffness", making k_{MTC} larger than k_{SEC}. MG fascicle shortening appeared to contribute to the large leg stiffness, which is required to realize high hop frequencies, by increasing k_{MTC}.

CONCLUSIONS

Large k_{leg} at a high hop frequency was associated with large k_{MTC}. The large k_{MTC} was presumably caused by the MG fascicle shortening during the ground contact phase. The fascicle shortening can be interpreted as negative stiffness, increasing k_{MTC}. It was suggested that humans can adjust their leg stiffness to realize a certain hop frequency during hopping, by changing the dynamics of triceps surae muscle fibers.

EFFECTS OF COMPRESSION GARMENTS ON LOWER LIMB BIOMECHANICS DURING RUNNING UNDER FATIGUE

Jichao Wang, Yang Yang, Yongxin Xu, Weijie Fu*
Key Laboratory of Exercise and Health Sciences of Ministry of Education, Shanghai University of Sport, Shanghai 200438, China
Email: fuweijie@sus.edu.cn

INTRODUCTION

Compression garments are widely used in sports, and it has a certain promotion effect on athletes' abilities such as endurance, strength, speed and fatigue recovery. Exercise fatigue increases the risk of injury and is one of the applications for compression garments. Earlier research found that the efficacy of compression garments could be more effectively tested through fatigue intervention. This study aimed to investigate the role of compression garments in running and to provide a theoretical basis for improving performance.

METHODS

Twelve healthy male subjects (age: 23.3±2.1, height: 177.2±6.6, weight: 73.3±5.7) were randomly selected to wear compression garments and control shorts for two running fatigue sessions. Each test was conducted before and after the fatigue induction program, and data were collected for 15 s after the subjects' movements were stabilized. The kinematic and kinetic data of the hip, knee and ankle joints during exercise were collected synchronously using a Vicon motion capture system and a Bertec three-dimensional treadmill. One-way ANOVA was used to analyze joint angle, moment, vertical work and other parameters.

RESULTS AND DISCUSSION

After fatigue, during the stance phase, the maximum flexion angle of the knee was significantly increased (p=0.029), the minimum flexion angle of the knee (p=0.013) and the maximum flexion angle of the hip (p<0.001) was significantly decreased in the compression garments condition. The peak value of the pedal-extension moment of the knee was significantly increased (p=0.035) in the compression garments condition (Table 1); in addition, after fatigue, the subjects had greater vertical work (p=0.016) in the compression garments condition. Compression garments can significantly increase the peak moment of the knee (Figure 1), Duffield et al. [1] showed that there was no change in peak contraction force or force production rate in fatigued muscles when wearing compression garments, thus compression garments do not directly increase muscle power, but rather improve mechanical efficiency. Therefore, we believe that the increased moment of the knee in this study may be an increase in the overall mechanical efficiency of the muscle movement. Therefore, we believe that compression garments can have some anti-fatigue effects through their mechanical advantages.

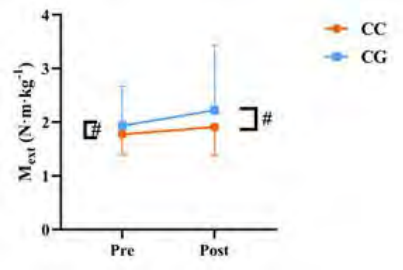

Figure 1 Pedal-extension moment of the knee joint.

CONCLUSIONS

When wearing compression garments, knee and hip flexion angles decreased, knee moments increased, and lower limb work capacity improved. These changes are the opposite of the effects caused by exercise fatigue, thus suggesting that compression garments may help to delay fatigue, and improve muscle control.

Effects of HD-tDCS on the Changes of EEG-sEMG Coherence after Running-Induced Fatigue

Jianglong Zhan[1], Changxiao Yu[1], Weijie Fu[1]
[1] School of Exercise and Health, Shanghai University of Sport, Shanghai, China.
Email: fuweijie@sus.edu.cn

INTRODUCTION

High-definition transcranial direct current stimulation (HD-tDCS) can cause changes in the local excitability of cerebral cortex and has been used to explore the effect on fatigue. However, most studies evaluating the effects of HD-tDCS have focused on changes in extrinsic exercise performance (e.g., exercise duration, muscle strength)[1,2], while ignoring to some extent the intrinsic connection between the central nervous system and peripheral muscles. The purpose of this study was to investigate the effect of HD-tDCS on corticalmuscular coherence (CMC) between central electroencephalography (EEG) signals and peripheral muscle surface electromyography (sEMG) signals in beta (16-30 Hz) and gamma (31-50 Hz) bands after running-induced fatigue.

METHODS

A total of 24 healthy male college students were enrolled in this study. Subjects were randomly assigned to real and sham HD-tDCS groups and received real (2 mA stimulation for 20 minutes on M1) and sham stimulation (30 seconds of active stimulation only at the beginning) for five consecutive days, respectively. After the subjects wore EEG caps and wireless sEMG electrodes and warmed up sufficiently, the running-induced fatigue test was performed. Immediately after the fatigue test, continuous maximum force is performed in an ankle plantar flexion-dorsiflexion exercise (this process simultaneously acquires EEG signals and sEMG signals). After the first trial, HD-tDCS intervention was performed. On the first day after the end of the intervention, a second trial was conducted: the procedure and duration of the run were the same as above.

EEG data selection: Based on previous related study[3], 5 regions of interest (FC1, FCz, C1, Cz, CP1) related to lower limb movement were selected in this study.

sEMG data selection: The tibial anterior muscle (TA), lateral head of gastrocnemius (LG), medial head of gastrocnemius (MG), and soleus muscle (SOL) of the subject's right lower limb were selected as test muscles. A two-way ANOVA (Stimulus condition×Time) was performed on all tested variables (21.0, SPSS Inc., USA).

RESULTS AND DISCUSSION

In the beta band: After the intervention of the real stimulation group, the coherence coefficients between EEG of C1 Cz and TA were increased significantly during the ankle joint dorsiflexion phase as compared to the sham group (Table 1).

In the gamma band: After the intervention of the real stimulation group, the coherence coefficients between EEG of C1 CP1 Cz FC1 and TA were increased significantly during the ankle joint dorsiflexion phase as compared to the sham group (Table 1).

CONCLUSIONS

HD-tDCS can increase the synchronization of bio-electric activity between peripheral muscles and contralateral motor cortex in beta and gamma bands after running-induced fatigue, and the central nervous system regulated motor cortex and peripheral muscle activity, resulting in increased coupling between contralateral motor cortex and peripheral muscle activity.

ACKNOWLEDGEMENTS

Tibial-tuberosity trochlear-groove distance in healthy subjects and patients with patellofemoral pain syndrome: a weight-bearing 4DCT study

L. Buzzatti[1,3], B. Keelson[1,2], T. Scheerlinck[2], S. Héréus[1], G. Van Gompel[2], T. Verstraten[1,4], J. Vandemeulebroucke[1], J. De Mey[2], N. Buls[2], E. Cattrysse[1]

INTRODUCTION

In medical imaging, weight-bearing dynamic analysis could provide more valuable information on the kinematics of the lower limb than unloaded static images. Dynamic CT (4DCT) is an image acquisition method that allows capturing motion with good temporal resolution and excellent morphological details. However, the performed movements have always been investigated in non-weight-bearing conditions due to the supine position required by the CT scanner design. TTTG is an orthopaedic metric that is used to estimate whether there is an indication for surgical correction (i.e. distal realignment procedures). This study aims to provide reference data on normal tibial tuberosity-trochlear groove distance (TTTG) values observed in healthy subjects during weight-bearing dynamic CT acquisition. In addition, we compared data from patients with patellofemoral pain syndrome (PFPS) to their contralateral asymptomatic side and the reference values of healthy subjects.

METHODS

21 healthy adults and 3 patients with PFPS volunteered for this study. The study was approved by the local Ethics Committee. In order to simulate constant gravitational force during horizontal dynamic CT acquisition, a novel weight-bearing device compatible with a 256-slice wide beam CT was used. The device had a platform to position the feet, a moving component to support the subject, and a loading system that provides constant resistance. Each subject performed consecutive cycles from full knee extension to flexion and back to full extension. A dynamic CT scan protocol (16x50cm FOV, 80kvp, 50mA, 6.7s) was used to acquire images of both knees at the same time, while the subject was performing the task. Using automatic multi-atlas segmentation and rigid registration, a transformation matrix was computed for each time point representing the movement of each bone (Tibia, Femur). TTTG was calculated, and its change during 0° and 30° of knee flexion was evaluated. TTTG values of the PFPS knees were compared to their contralateral asymptomatic side and healthy subjects.

RESULTS AND DISCUSSION

Going from full extension to 30° of knee flexion, the TTTG decreased gradually by 6.8 mm from 12.2 mm of full extension in healthy subjects (Figure 1a). A similar decreasing pattern was seen in patients. However, the symptomatic side (S-red) presented higher values than both the asymptomatic side (AS-blue) and knees of healthy controls (green). TTTG of the asymptomatic side aligned with the values from the healthy control group after the first 10-15 degrees of flexion (Figure 1b).

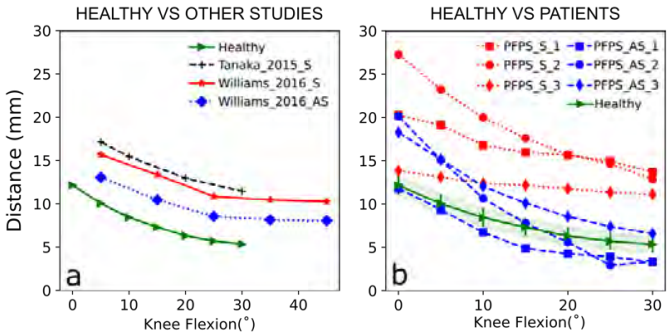

Figure 1 a: TTTG comparison between healthy subjects and published studies [1,2] on patients with patella dislocation; b: TTTG comparison between healthy subjects and patients with PFPS; S: symptomatic; AS: asymptomatic

Overall, TTTG distances in healthy subjects were lower compared to those measured in other studies [1,2] on symptomatic knees but these studies did not have a weight-bearing condition and included patients with patella dislocation (Figure 1a).

CONCLUSIONS

Our study shows the possibility to describe orthopaedic metrics, such as TTTG, in a dynamic weight-bearing mode in healthy subjects and patients using dynamic CT images.
Compared to both healthy subjects and the contralateral asymptomatic side, patients suffering from PFPS show more lateralized tibial tuberosity in the first 30° of knee flexion during a weight-bearing dynamic flexion-extension movement. This was observed during the whole motion trajectory.
The results from healthy participants can be used as preliminary normative values when comparing patients suffering from patella motion related conditions.

INTRODUCTION

The calf raise test (CRT) is used in rehabilitation and sports medicine to evaluate calf muscle function [1]. The novel Calf Raise application (CR_{app}) for iOS uses computer-vision algorithms to objectively measure CRT outcomes (i.e., repetitions, positive work, total height, peak height, fatigue index, and peak power) and replicate laboratory-based metrics that are difficult to measure clinically [2]. We aimed to validate the CR_{app} by examining its concurrent validity and agreement levels against laboratory-based equipment. We also assessed its intra-rater and inter-rater reliability.

METHODS

CRT outcomes (i.e., repetitions, positive work, total height, peak height, fatigue index, and peak power) were assessed in thirteen individuals (6 males,7 females) on three occasions on both legs using the CR_{app}, 3D motion capture, and force plate simultaneously. Data were extracted from two markers: below the w lateral malleolus (n=77) and on the heel (n=77). Concurrent validity and agreement were determined from 154 data files using intraclass correlation coefficients ($ICC_{3,k}$), typical errors expressed as coefficient variations (CV), and Bland-Altman plots to assess biases and precision. Reliability was assessed using $ICC_{3,1}$ and CV values. (See Figure 1 for the test experiment set-up).

Figure 1 Marker placement below the lateral malleolus (left image) and on the heel (middle image). The back round sticker of 24 mm in diameter and retroreflective marker of 12.5 mm in diameter enabled tracking within the Calf Raise application and Qualisys SD motion capture system, respectively. The placement of two-iPad devices positioned 30 cm from the markers is also shown (right image).

RESULTS AND DISCUSSION

The validity of CR_{app} outcomes was good to excellent across measures for both markers (mean ICC ≥0.878), with precision plots showing good agreement and precision. CV ranged from 0% (repetitions) to 33.3% (fatigue index) and were on average better for the lateral malleolus marker. Inter and intra-rater reliability were excellent (ICC≥0.949, CV≤5.6%). Due to the lack of tools to objectively quantify CRT performance, repetition is the primary outcome used in clinics. Lab-based equipment is not suitable for clinical use due to its expensive price, time commitment, expertise requirements, and portability. Furthermore, studies suggest that measuring calf raise height and total work alongside the repetitions are crucial in measuring plantar flexion endurance using CRT in both healthy and clinical populations [3, 4].

CONCLUSIONS

CR_{app} is valid and reliable within and between users for measuring CRT outcomes in research and practice, aligning with recent advances in mobile technologies and their increased use in healthcare.

EFFECTS OF TASK DIFFICULTIES ON FIRST-GRADE CHILDREN'S HANDWRITING PERFORMANCE IN COPY ACTIVITIES

Yu-An Tsai[1], Pin-Chen Hung[1], Po-Ya Chuang[1], Wen-Feng Huang[1], Tien-Ni Wang[1] and Hao-Ling Chen[1]
[1] Department of Occupational Therapy, National Taiwan University, Taipei, Taiwan.
Email: r11429010@ntu.edu.tw

INTRODUCTION

Handwriting is a fundamental academic skill for children. In general, children start learning handwriting skills in the first grade by copying characters. The structure of Chinese characters is varied, some of them with complicated geometric features and strokes [1], which causes different difficulty levels in copying, and may affect handwriting performance. A previous study suggested that the number of strokes may affect handwriting fluency in first-grade children [2], however, the effects on handwriting legibility remained unclear. In addition, the materials used in the study were alphabetic letters. Given the uniqueness of spatial arrangement in Chinese characters, the generalizability of the above result was constrained. Hence, this study aims to investigate the influence of copy task complexity on handwriting performance in first-grade children using Chinese characters.

METHODS

17 typically developing children in first grade were recruited in the study. Subjects were required to complete 2 copy tasks on a Wacom tablet: (1) easy task characterized by fewer strokes; (2) difficult task characterized by more strokes. All tasks used high-frequency Chinese characters selected from the mainstream textbooks in Taiwan. In addition, the kinetic and kinematic data would be collected by the tablet to record the writing process. A computerized program was implied to evaluate the legibility of writing products in 4 aspects: Size, Position, Orientation, and Deformation [3]. The larger value of each aspect indicated poor legibility. Pair t-test was examined for the differences between two copy tasks from the same subjects.

RESULTS AND DISCUSSIONS

All the kinematic and kinetic variables demonstrated significant differences (Table.1). Subjects showed greater tip force and writing speed, along with less length and time ratio (in-air/ on-paper) in the easy task, representing higher efficiency. In addition, less coefficient of variation (CV) of tip force and stroke velocity was found in the easy task, representing higher consistency and fluency. Regarding legibility, significant differences were only found in orientation and deformation (Table.1). The results suggested orientation and deformation were the main reasons caused the decline of legibility in the difficult task, not size or position.

CONCLUSIONS

The present study suggests the number of strokes is one of the critical reasons affecting the handwriting performance (especially in orientation and deformation aspects) of first-grade children. The findings may support clinicians and educators to modify the content of handwriting tasks and develop intervention principles.

INTRODUCTION

Mirror neurons (MN) are activated in action observation and execution, which are involved in motor learning [1]. Mirror therapy (MT) is one typical strategy for dealing with upper limb motor impairment in stroke rehabilitation. Patients perform simple tasks with the unaffected arm, and the mirror reflects movements like the affected arm. When they focus on mirror reflection, MN activities are observed to facilitate neuroplasticity in the brain [2]. In this study, we instructed healthy adults to execute three tasks via augmented reality mirror therapy (ARMT). Simultaneously, surface electromyographic signals (sEMG) were recorded from the abductor pollicis brevis (APB), extensor digitorum communis (EDC) and flexor digitorum superficialis (FDS) in the upper extremities. The study aims to investigate muscle activities in the non-dominant hand, which keeps static during the ARMT. We hypothesize that muscle activation in the non-dominant hand will be detected during tasks.

METHODS

We developed a mobile application which is deployable on iOS operating systems. Subjects were asked to sit in front of a table with a virtual reality headset (https://apps.apple.com/tw/app/armt/id1637540862). The software captured image data and mirrored these movements when they performed tasks with the dominant hand. Thus, bilateral hand movements would be shown through the ARMT headset to the real world. Because we recorded muscle activities in healthy subjects to examine whether MN was activated during ARMT, we considered the non-dominant hand to be affected [3,4]. We used Trigno Wireless EMG System, (Delsys Inc., Natick, USA), EMGworks® Analysis 4.7.3.0 (Delsys Inc.), and MATLAB® (The MathWorks, Natick, Massachusetts, USA) to collect then analyze muscle activation in APB, EDC and FDS in both hands during the ARMT. There were three tasks in the study. Task 1: Sequential finger touching. Task 2: Wrist extension. Task 3: Wrist flexion. APB was detected in task 1. Both EDC and FDS were detected in task 2 and task 3. During ARMT, subjects followed instructions to do tasks 30 times respectively with their dominant hand and kept their non-dominant hand static. The descriptive analysis would be used to inspect the muscle activation in the non-dominant hand during ARMT in different tasks.

RESULTS AND DISCUSSION

We recruited five healthy adults for this study by convenience sampling. The participants (3 females and two males) ranged from 22 to 25 years old (mean age of 23.8 years; 0.98 standard deviations). All of them were right-handed. From the results, the muscle activation in EDC of the non-dominant hand (Figure 1) in task 2 in subject No.4 was activated remarkably. The other trials could not find similar muscle activities. There were two possible explanations: (1) The motor control ability of subject No.4 was worse than other subjects, so muscle activation in the non-dominant hand was not inhibited completely only in task 2; and (2) MN were activated successfully during task 2.

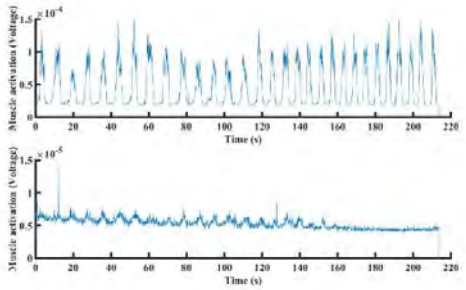

Figure 1 Muscle activation in EDC of task 2 in subject No.4 (Upper: Dominant hand; lower: Non-dominant hand).

CONCLUSIONS

This study provides preliminary outcomes about MN activities via sEMG. Additional research is needed to support the MN activation during ARMT. Future work should recruit a larger sample of subjects and collect brain activity during ARMT to clarify the MN activation in the brain and muscles.

INTRODUCTION

Upper limb dysfunction is a typical impairment in children with unilateral cerebral palsy (UCP), which causes difficulties in their daily lives. To deal with these deficits, bilateral intensive training (BIT), one of the most promising evidence-based neurorehabilitation programs, has been frequently applicated to children with UCP. This approach is based on the neuroplasticity and motor learning theories that emphasizing on the use of bimanual hands in daily participation. BIT was reported to be benefited for children's motor function in affected hand, and further transfer these motor skills to daily activities [1]. Owing to the repetitive practice, the intensive protocol often challenges the participants' motivation [2]. Thus, a child-friendly and group-formed camp, with relatively low dosage as 36 intervention hours within one week, was proposed to fit their busy schedules. The aim of this study is to estimate the efficacy of the low-dose camp-based BIT for UCP children on the motor function including upper limb movements of the affected hand and the performance of daily bimanual activities.

METHODS

Sixteen children with UCP were recruited. Participants received the BIT intervention program for 36 hours during a one-week summer camp. Outcome measures included the Melbourne Assessment-2 (MA-2), the ABILHAND-Kids, and the Observation Test of Capacity, Performance, and Developmental Disregard Questionnaire (OTCPDDQ), which were conducted at pre-intervention and post-intervention. The MA-2 was used to examine movement quality of unilateral upper limb including 4 subtests: active range of motion (AROM), accuracy, dexterity, and fluency. Moreover, the ABILHAND-Kids and the OTCPDDQ were used to represent a child's daily bimanual motor performance. Paired t-test was used to examine the difference between pre- and post-intervention.

RESULTS AND DISCUSSION

Table 1 reveals the scores of each outcome measure. The upper limb movements measured by the MA-2 showed significant improvement in AROM (t=3.873, p=0.002), dexterity (t=2.711, p=0.016), and fluency (t=4.069, p=0.001) after the intervention, while accuracy (t=-1.472, p=0.162) was no evidence for increase. Regarding bimanual performance, there was a significant increase in the quality of OTCPDDQ (t=3.419, p=0.004), but not in the frequency of OTCPDDQ (t=1.602, p=0.130) or ABILHAND-Kids (t=1.7466, p=0.101). Additionally, the effect size of this intervention (d=0.11-0.46, small to moderate effect) was lower than a previous program (η^2=0.21-0.58, large effect), which was a 60-hours BIT treatment for the hand function of UCP children [3]. The results demonstrated that the intesive intervention with the total of 36 hours, which was near half of 60 hours, could obtain small to moderate effectiveness.

CONCLUSIONS

This study indicates that the camp-based BIT intervention with low dosage has the potential to be a feasible and effective approach for children with UCP. It benefits the affected hand function and the quality of daily bimanual motor performance. Future research for different measurement domains, such as kinematic or psychosocial outcomes, is recommended to vairified our study findings.

MOTOR PLANNING IN CHILDREN WITH UNILATERAL CEREBRAL PALSY

Cherng-I Chou[1], Chiao-Yu Yang[1], Kai-Jie Liang[1], Hao-Ling Chen[1] and Tien-Ni Wang [1]
[1] Department of Occupational Therapy, National Taiwan University, Taipei, Taiwan.
Email: caflys8697@gmail.com

INTRODUCTION

Motor planning is the process of managing a sequence of movement to perform a task [1]. The end-state-comfort (ESC), which describes the tendency to reach comfortable position at the end of motion, has often been used to represent motor planning skills. Moreover, as Surkar et al (2018) suggested, reaction time (RT), the time interval between presentation of task stimuli with onset of motor execution, is aslo an important parameter in motor planning [2]. Previous study indicated that individuals with unilateral cerebral palsy (UCP) may have problems in motor planning skills, leading to daily living dysfunctions [3]. Given the motor planning in children with UCP remains unclear, this study aims to compare motor planning skills for children with UCP. Besides, predictors of motor planning skills in children with UCP were also investgiated.

METHODS

Fifteen children with UCP and eighteen TD children aged 5 to 13 years old were recruited in this study. The motor planning skills were assessed with a cup-grasping task, in which the ESC and RT (modified to the time lag between presentation of task stimuli with the onset of manipulating the target object) were collected. The motor quality and the motor proficiency were assessed by the Melbourne Assessment-2 (MA2) and subtests of the Bruininks-Oseretsky Test of Motor Proficiency-2 (BOT-2), respectively. Independent t-test was examined for the group differences, and stepwise regression was performed for exploring the predictors of motor planning skills.

RESULTS AND DISCUSSIONS

The result showed that children with UCP demonstrate significantly less ESC ($t = 3.258$, $p = 0.004$) and more RT ($p = -5.555$, $p < 0.001$) while using their nondominant hand compared to TD children. The MA2 is a significant predictor for the ESC ($F = 7.550$, $R^2_{adj} = 0.319$, $p = 0.017$, Table 1), and MA2 and BOT-2 are important factors for the RT ($F = 8.442$, $R^2_{adj} = 0.515$, $p = 0.005$). The results inferred that the motor quality may affect the motor planning accuracy, and the poor motor quality and proficiency may lead to increased RT in UCP children. Different predictors were identified for various motor planning parameters (ESC and RT) which highlights the importance to include both aspects into measurement.

CONCLUSIONS

In summary, impaired motor planning skills were observed in children with UCP. Motor planning accuracy could be predicted by their motor quality, while motor planning RT could be predicted by both motor quality and proficiency. These results would benefit for the clinicians to provide adequate activities while targeting on the specific outcome.

PREDICTING FACTORS OF HANDWRITING LEGIBILITY IN CHILDREN AT PRESCHOOL AND FIRST GRADE

Pin-Chen Hung[1], Wen-Feng Huang[1], Po-Ya Chuang[1], Tien-Ni Wang[1], Hao-Ling Chen [1]
[1]School of Occupational Therapy, National Taiwan University, Taipei, Taiwan, R.O.C
Email: hlchen@ntu.edu.tw

INTRODUCTION

Handwriting is considered a critical functional skill for children. Poor handwriting might affect their academic achievement and learning motivation, especially for handwriting beginners. Understanding factors that influence beginners' handwriting is essential in formulating effective strategies and interventions. Various factors related to handwriting legibility have been demonstrated in some research[1], such as visual perception, motor coordination, and visual motor integration. Previous studies have revealed that lower-grade and middle, upper-grade children respond to handwriting demands via different related skills. However, few studies explored which related skills contributed to beginners' handwriting legibility. Therefore, this study aimed to investigate which visual perceptual motor skills had potential contributions to handwriting legibility for children in the beginning stage, that is, kindergarten and first grade.

METHODS

20 children were recruited respectively in preschool (5-6 years old) and first grade in Taipei, Taiwan. Children were instructed to copy Chinese characters which were high-frequency characters they often contacted with. In addition, a computerized program developed by our research team was adopted to analyze written legibility in four aspects: *Size, Position, Orientation,* and *Deformation.* The larger the value of each aspect, the worse the performance of legibility[2]. The visual perceptual motor skills were assessed by the following evaluation tools: (1) Test of Visual Perceptual Skills, 4th Edition (TVPS-4) for understanding visual perception (VP) ability of children; (2) Beery-Buktenica Developmental Test of Visual-Motor Integration (Beery VMI) for assessing visual motor integration (VMI) of children, and (3) Computerized Perceptual Motor Skills Assessment developed by our team for exploring motor coordination ability in which the higher score represents poorer motor coordination (MC) performance[3]. Pearson correlation coefficients and step-wise regression were completed to investigate the significant predictors of each handwriting legibility aspect.

RESULTS AND DISCUSSION

The results showed a medium level of correlation between MC ability and handwriting deformation in preschoolers (r=.539, p=.017). Regression analysis indicated that MC was the only significant contributor to deformation for preschoolers accounting for 29.1% of the variance. Preschoolers with satisfactory MC seemed to have efficient pen control, which would in turn influence their handwriting legibility. On the other hand, a medium negative relationship was found between VMI and handwriting deformation in the first grade (r=-.478, p=.039). Regression analysis demonstrated that VMI was the only significant predictor of deformation for first graders contributing 22.9%. First graders with acceptable VMI seemed to have fine copy skills, which was regarded as a fundamental function in writing.

CONCLUSIONS

This study identified the predicting factors associated with legible handwriting in kindergarten and first grade. The handwriting legibility of the preschoolers seemed to heavily depend on motor coordination, whereas that of the first graders was visual-motor based. The findings may assist clinicians and educators in developing intervention guidelines, preventing children from handwriting deficiency.

The static method of computing leg stiffness in running measures a smaller value than the dynamic method.

INTRODUCTION

Elastic energy stored momentarily during running is closely related to energy consumption and serves as a key indicator of energy stored in muscle fibers and tendons. Leg stiffness(k_{leg}) is used when estimating elastic energy. Thus, when k_{leg} varies by the computing methods, it can potentially affect the analysis of energy storage characteristics in muscle fibers and tendons. In general, k_{leg} is computed by calculating the ratio of the maximum vertical ground reaction force(F_{peak}) to the maximum contraction length of the leg(ΔL_{peak}) based on the spring loaded inverted pendulum(SLIP) model [1,2] (Figure 1A). Alternatively, it can be computed as a parameter of the SLIP model that best predicts the entire ground reaction force(GRF) data [3,4]. Therefore, this study will compare the differences in k_{leg}, ΔL, and elastic energy values resulting from the two different methods of computing k_{leg}.

METHODS

In this study, we computed the k_{leg} value in two ways base on SLIP model: a static method based on peak values and a dynamic method based on generated GRF value. The static method uses the $-F_{peak}/\Delta L_{peak}$ formula, with ΔL_{peak} calculated by the method of Farley et al. [1]. The dynamic method computes k_{leg} as a parameter of the SLIP model that minimizes the sum of the mean square error between the vertical and horizontal GRF data and the model's GRF. The value of k_{leg} was determined using fmincon function of MATLAB®, with k_{leg}, touchdown angle, and touchdown velocity as input parameters. For the model's GRF, we used the GRF value from the 30th step of the model that guaranteed at least 50 steps. The vertical displacement of the center of mass (CoM) was calculated by double integration of the vertical acceleration. The length of the subject's leg was modelled as 0.53 times the subject's height [5]. The elastic energy was calculated as half of k_{leg} times ΔL_{peak} squared, according to the formula for elastic energy.

Ten male participants (age: 24.80 ± 2.10 years, mass: 72.60 ± 4.50 kg, height: 1.75 ± 0.05 m) were recruited for the study. The participants performed running on a treadmill at a fixed speed of 3.1 m/s. The GRF data for 29 consecutive steps were collected for each participant.

RESULTS AND DISCUSSION

Both k_{leg} and ΔL_{peak}, and elastic energy, showed statistically significant differences between the static and dynamic methods (Figure 1C). For k_{leg}, the static method produced a lower value. For the magnitude of ΔL_{peak} and elastic energy, the dynamic method produced a smaller value.

When calculating leg length change(ΔL) using the calculation method employed in the static method and examining the GRF values according to ΔL, the values do not follow linearity throughout the entire phase (Figure 1B). Therefore, the difference in k_{leg} values between the two methods can be explained by the point that the static method relies solely on information from the moment of maximum contraction, whereas the dynamic method includes and represents information of the entire contact phase.

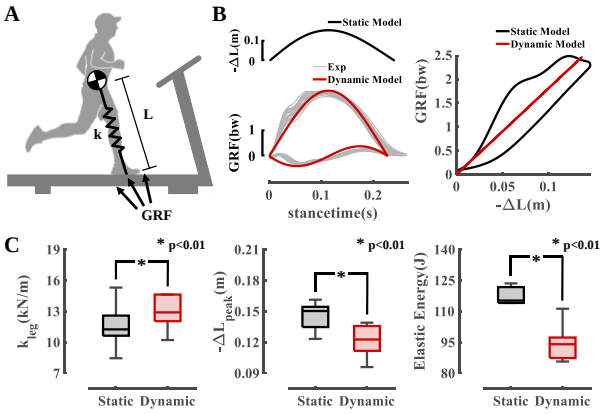

Figure 1 (A) SLIP model in running (B) GRF and $-\Delta L$ during contact phase. (C) k_{leg}, $-\Delta L_{peak}$, and stored elastic energy values obtained by two methods.

CONCLUSIONS

In this study, we confirmed that the k_{leg} value varies significantly depending on the computing method used in running, leading to a difference in the estimated elastic energy. This indicates that the computing method of k_{leg} affects the analysis of energy consumption, as well as the energy storage characteristics of muscle fibers and tendons in running. Furthermore, it is necessary to determine a more appropriate method for estimating elastic energy in future studies.

SIDESTEP CUTTING MANOEUVRES DURING HUMAN RUNNING EXHIBIT SPRING-MASS BEHAVIOUR

Kat Daniels [1,2] and J F Burn [2]

Email: k.daniels@mmu.ac.uk

INTRODUCTION

Sidestep cutting manoeuvres are used by running bipeds for rapid changes of direction [1]. In humans, these manoeuvres are commonly studied in the context of athletic performance and injury. The spring-mass model is a simple mathematical model of bouncing gait that has been used to gain insight into the mechanics and control of locomotion in 2D and, more recently, in 3D [2-3]. Here, we show that many features of human sidestep cutting dynamics can be captured by a simple 3D spring-mass model. We then use the model to explain previous empirical observations relating cutting dynamics to running speed and angle.

METHODS

Whole-body optical motion capture and ground reaction force data were collected from 63 human participants (male; aged 18-35; no self-reported musculoskeletal or neurological impairments) during the change-of-direction stance phase of a running cut manoeuvre. Participants performed three maximum-effort 90° sidestep cuts from each leg. The location of the centre of mass (CoM) was estimated from segment positions and published inertial data. Individual spring-mass model simulations for each trial were generated using input parameters initial velocity (v_x, v_y, v_z,), leg stiffness (k; estimated as average leg stiffness from initial contact to the instant of maximum leg shortening), body mass (m), initial leg length (L_0) and leg angle from the vertical (θ_{xy}, θ_{xz}) (Figure 1A). The equations of motion for the model were solved numerically (MATLAB 2020a, The MathWorks, Inc., USA) and simulations were compared to measured kinematics and ground reaction forces.

RESULTS

Average model prediction errors were <10% for stance time, mediolateral impulse, braking impulse and CoM-foot displacements (stance time results presented as an example in Figure 1B). The model also predicted leg angle at foot-off to within 5° of the measured angles. Model simulations explained (a) the relationship between running speed and key kinematic and kinetic variables during the change-of-direction stance phase; and (b) the non-linear relationships with cutting angle that have previously been reported (e.g. [4]) for horizontal plane ground reaction forces and CoM stance phase kinematics.

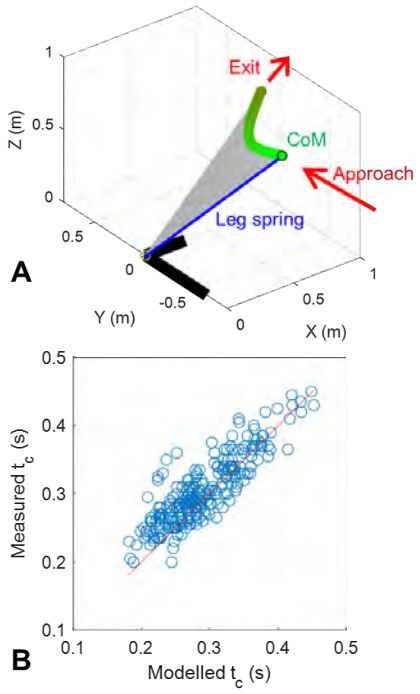

Figure 1. 3D spring-mass model schematic (A) and relationship between modelled and measured sidestep cut stance time (t_c) for all participants (B; r = 0.84; p<0.001).

CONCLUSIONS

Our findings suggest that several key aspects of sidestep cutting dynamics are governed by a relatively small number of parameters and can be explained by a simple 3D spring-mass model. Further exploration and development of this model may provide insight into performance limits and optimisation of turning manoeuvres in humans and other bipedal species.

INTRODUCTION

Connecting the legs with a spring attached to the shoelaces reduces energy expenditure during steady-state running [1]. While experiments have shown that this spring can reduce the joint moments generated by muscles, it is unknown which muscles are able to save energy. We used muscle-driven simulations to discern which muscles were saving energy and how.

METHODS

We collected experimental data of 7 subjects running on a treadmill at 2.67ms^{-1}, with and without the spring connecting their legs [1]. We scaled a full-body musculoskeletal model to each subject and used direct collocation to create muscle-driven simulations that tracked kinematics and solved for the muscle activity required to generate the movement [2,3]. We simulated four gait cycles per subject-condition and computed the rate of energy expenditure for each muscle, ensuring the summed full-body rates were similar to those measured experimentally [4].

RESULTS AND DISCUSSION

Simulations showed savings in both stance (1.5±0.2 W/kg, P<3x10-4) and swing (0.3±0.1 W/kg, P<0.05), though savings in stance were larger, with savings occurring in the gluteal muscles (-0.14±0.03 W/kg, P<0.004), quadriceps (-0.14±0.04 W/kg, P<0.03), hip flexors (-0.11±0.02 W/kg, P<0.003), hamstrings (-0.09±0.03 W/kg, P<0.04), and hip adductors (-0.06±0.01 W/kg, P<0.002) in each leg. Interestingly, the muscles that saved the most energy, did so during stance when the spring does not have any tension. The savings were facilitated by participants adopting a higher stride frequency with less hip, knee and ankle flexion. With this gait, supporting and redirecting the body center of mass became less costly, as seen in muscles such as the gluteus medius and the vastus lateralis. The gluteus medius saved the greatest amount of energy of the muscles in the model, and did so by reducing its muscle fiber velocity, force, and activation (Figure 1). Similar changes occurred in the quadriceps, which led to a reduction in heat production by the muscle, as well as the mechanical work that it performed. These results show that the simple spring device reduced the energy cost of running at the same speed by supplying an external force to users, allowing them to take advantage of a more efficient gait pattern.

CONCLUSIONS

Musculoskeletal simulations revealed that the gluteal, quadriceps, hip flexor, hamstrings, and hip adductor muscle groups saved energy while running with a spring connecting the legs. We dissected the muscle state changes that contributed to the reductions in energy expenditure. Further, this understanding could be used to aid the design of devices that can assist runners at different speeds or that provide alternative benefits to users such as offloading a tendon or joint.

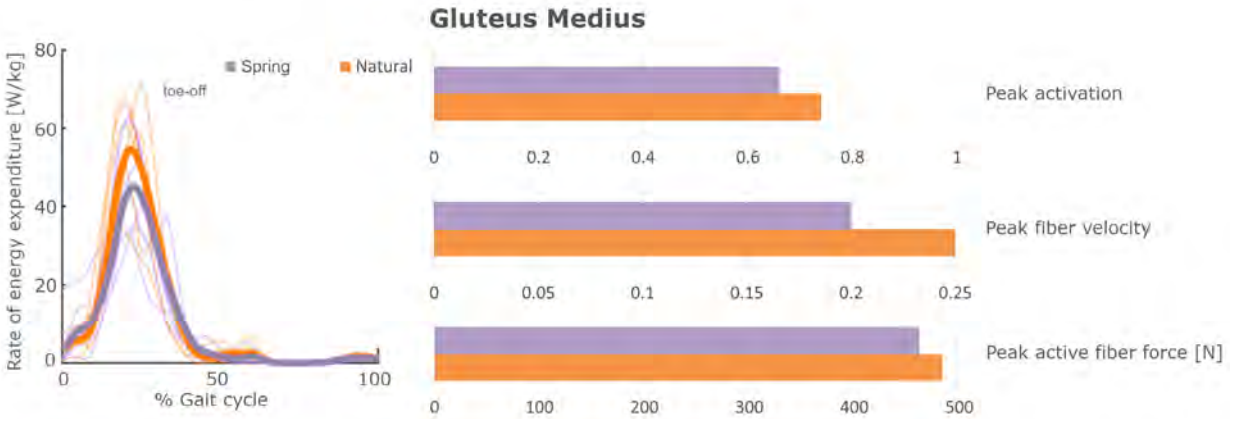

Figure 1: Gluteus medius changes in rate of energy expenditure throughout the gait cycle and the corresponding muscle state changes that contribute to the reduction. On the left, the average of all subjects (thick line) and individual subject averages (thin dotted line) for the gluteus medius muscle rate of energy expenditure are plotted throughout the gait cycle. Orange lines represent the natural runs and purple shows the runs with the spring. The bar plots on the right show the peak muscle activation (range from 0-1), fiber velocity (in normalized units of number of optimal fiber lengths per second), and active fiber force averaged across all subjects at the time of highest energy expenditure for both natural (orange) and spring (purple) running.

Changes in Leg Stiffness as a Result of Differences in Leg BMD in Various Age Groups During Running

INTRODUCTION

One of the biological characteristics that often decreases with aging is bone mineral density(BMD), which indicates the strength of the bones. Meanwhile osteoporosis and other bone-related disorders, as well as decreased physical performance, are mostly brought on by a decline in BMD. A decrease in BMD has been linked to cases of decreased physical performance[1]. The fact that kinematic characteristics during running change according to differences in BMD, while kinetic characteristics do not, has been reported[2]. And kinematics and kinetics are not independent but together determine the dynamics of running. Therefore, in this study, through a correlation analysis between BMD and leg stiffness during running, we set out to investigate and quantify the relationship between BMD and running biomechanics.

METHODS

We measured leg BMD, and by applying ground reaction force(GRF) and kinematic data from running experiments to a model from a prior study, we were able to obtain leg stiffness. 19 male subjects, ranging in age from 20 to 70, participated in the experiment (43.7±16.9yrs, 171.5±5.1cm, 70.2±8.1kg). Dual Energy X-ray Absorptiometry(Hologic, USA) was used to measure the subjects' leg joints' BMD. After that, the subjects ran on a treadmill with a force plate embedded in it for 5 minutes at a self-selected speed while the GRF and motion capture data were collected(Bertec, USA; Qualisys, Sweden) (Fig.1 A). The running SLIP model by Geyer et al. was used for data analysis[3]. The leg stiffness(k) and strike angle (α_0) were determined through a non-linear optimization process that minimizes the objective function defined by the RMSE between the measured GRF and the simulation values. The model's numerical solution was calculated using the ode45 function in MATLAB® (Fig.1 B). We ran enough optimization processes with random initial conditions to prevent local minima of the variables, and k was normalized by initial leg length(l_0) and mass.

RESULTS AND DISCUSSION

The correlation between the subjects' characteristics and their leg BMD revealed that there were significant variables that displayed noteworthy relationships. With regard to leg BMD, we looked at age, GRF peak, running speed, and normalized leg stiffness K (Fig.1 C). These variables indicated R^2 of 0.206, 0.010, 0.045, 0.376, respectively, and *p-values* of 0.051, 0.684, 0.385, and 0.005. Particularly, a strong correlation between leg stiffness and leg BMD is indicated by the comparatively high R^2 and low *p-value* of K. The running SLIP model assumes that the leg behaves as a single spring. So the range of motion (ROM) of the leg joint influences the displacement of the spring. The kinematic characteristics such as the ROM of knee during running are known to considerably decline with age[2], and from the data of this study, there are no relationship between the leg BMD and GRF. As a result, it could be inferred that the GRF, which is unrelated to leg BMD, causes the leg stiffness to increase if the leg joint's ROM decrease as a result of older age and low leg BMD.

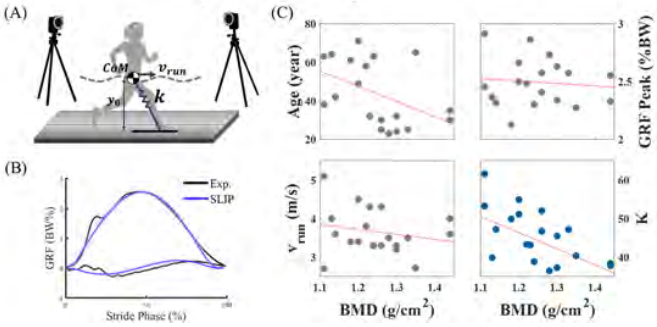

Figure 1 (A) Experimental setup and SLIP model for finding leg stiffness (B) Measured results of vertical and horizontal GRF and simulation results of the SLIP model (C) The correlation between BMD and age, GRF peak, running speed, normalized leg stiffness

CONCLUSIONS

This study identified a link between leg stiffness and leg BMD during running. This is assumed to be the outcome of changes in leg BMD and leg joint movement, as reported in previous study. These findings relating leg stiffness, which is an indicator of physical condition and the capacity to store and release energy during running, may help future studies understand the characteristics of running in the elderly.

INFLUENCE OF SYNERGY CONTROL ASSUMPTIONS ON PREDICTED WALKING FUNCTION FOLLOWING PELVIC SARCOMA SURGERY

INTRODUCTION

A recent study predicted the impact of operated side psoas muscle retention on walking function following pelvic sarcoma surgery [1]. While the predicted post-surgery walking motions were generally consistent with clinical observations, an unrealistically large lateral trunk lean to the operated side was observed. These walking predictions were generated using a synergy control structure to define lower body muscle activations, where time-invariant synergy vectors (minus muscles removed during surgery) were assumed to remain unchanged post-surgery while time-varying synergy activations were allowed to change to achieve a periodic walking motion. In this study, we investigate whether allowing the time-invariant synergy vectors to change while keeping the time-varying synergy activations constant would produce post-surgery walking predictions more consistent with clinical observations.

METHODS

Video motion capture, ground reaction, and EMG data collected previously from a healthy male subject walking at his self-selected speed were used for this study [1]. A neuromusculoskeletal model of the subject was created in OpenSim [2] by personalizing four model elements: joint models, muscle-tendon models, foot-ground contact models, and a neural control model using muscle synergies (see [1] for details). The most common surgical scenario encountered at MD Anderson Cancer Center in Houston, which involves removing multiple hip (including gluteus medius) and lower back muscles on the operated side, was applied to the model assuming the simulated patient received a custom pelvic prosthesis with artificial hip joint.

The modified model was used in two direct collocation optimal control problems formulated in GPOPS-II [3] to investigate the influence of lower body synergy control assumptions on predicted post-surgery walking function. The first problem allowed synergy activations to change freely while the corresponding synergy vectors (minus muscles removed during surgery) remained unchanged, while the second problem allowed synergy vectors to change freely while the corresponding synergy activations remained unchanged. Both problems included light tracking of the original joint motions. Pre- and post-surgery walking data collected from an actual pelvic sarcoma patient whose surgical decisions were similar to the most common scenario were visualized for comparison.

RESULTS AND DISCUSSION

Both optimization problems produced physically realistic walking motions. However, the formulation that allowed synergy vectors to chage freely (Fig. 1c) produced a lateral trunk lean that was the most consistent with clinical observations (Fig. 1b). Thus, individuals who receive pelvic sarcoma surgery may change their coordination strategy (as indicated by synergy vectors) more than their coordination timing (as indicated by synergy activations) to achieve a post-surgery walking motion with minimal lateral trunk lean.

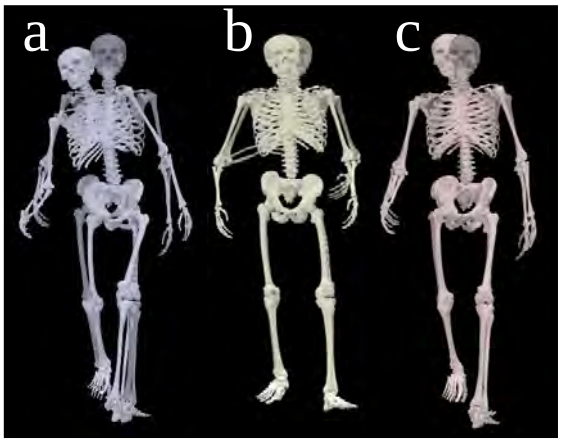

Figure 1: Comparison of pre-surgery (translucent skeleton) and post-surgery (opaque skeleton) walking motions. a) Experimental vs. predicted post-surgery with changeable synergy activations for healthy subject. b) Experimental pre-surgery vs. experimental post-surgery for pelvic sarcoma patient. c) Experimental vs. predicted post-surgery with changeable synergy vectors for healthy subject.

CONCLUSIONS

The goal of this research is to predict post-surgery walking function given a pre-surgery personalized walking model and the implemented surgical decisions. Once such predictions can be generated reliably, this computational approach may help inform surgical, rehabilitation, and custom pelvic implant design decisions for this unique patient population.

PREDICTING KNEE ADDUCTION MOMENT DURING WALKING BY LOWER LIMB ALIGNMENT USING FORWARD DYNAMICS SIMULATION

JongHyeon Park[1], Seungbum Koo[1]
[1] Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea.
Email: skoo@kaist.ac.kr

INTRODUCTION

Varus and valgus lower limb alignments affect knee adduction moment [1], which is closely associated with symptoms in the knee [2]. It has been reported that medial knee osteoarthritis is associated with higher knee adduction moment [3]. The quantitative relationship between lower limb alignment angle and knee adduction moment could be calculated using a simple statics calculation for a standing pose, but it has yet to be well investigated during dynamic walking. Recently, gait controllers for forward dynamics simulation could be made of artificial neural networks and trained using deep reinforcement learning. The study's objective was to quantify the association between the knee alignment angles and knee adduction moment during walking using the forward dynamics simulation.

METHODS

The RaiSim dynamics solver [4] and a custom skeletal model with 27 degrees-of-freedom were used for forward dynamics simulation (Figure 1). A two-layer perceptron was trained for the skeletal model to track a measured normal walking motion of a healthy subject using deep reinforcement learning [5]. Reference gait motions with varus and valgus lower limb alignments were generated by adjusting the knee angle in the normal walking data. A total of five gait controllers were trained, including two valgus (-5° and -10°), two varus (5° and 10°), and a normal lower limb alignment (0°). The knee adduction moment (KAM) was measured through the torque applied to the knee of the skeletal model for the five lower limb alignment cases. The moment arm of the ground reaction force for the knee joint was calculated using the center of pressure of the sole and the center of mass of the skeletal model in each frame.

RESULTS AND DISCUSSION

The KAMs were affected by the lower limb alignment. KAM and moment arm increased as the lower limb alignment angle increased toward the varus. In the varus lower limb alignment (10°), the average and peak value of the KAMs were 43.5 Nm and 122 Nm. In the valgus lower limb alignment (-10°), the average and peak value of the KAMs were -7.69 Nm and 54.9 Nm (Table 1). The knee adduction moment (y, Nm) and lower limb alignment angle (x, degree) were associated with $y = 2.449 x + 18.20$, $p<0.001$.

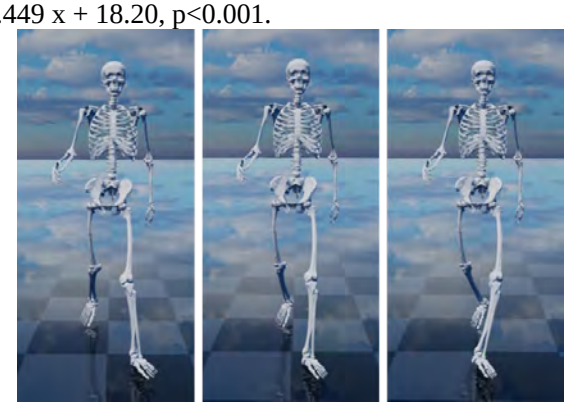

Figure 1 The valgus (left), normal (middle), and varus (right) lower limb alignment for forward dynamic simulation

CONCLUSIONS

Our forward dynamics simulation could generate walking motions with arbitrary lower limb alignments and be used to calculate knee adduction moment. The knee adduction moment angle increased by about 2.5 Nm with the increase of lower limb alignment toward the varus by 1°. Larger varus lower limb alignment causes higher KAM during walking.

THE FOOT'S MIDTARSAL JOINT ALTERS THE METABOLIC COST OF WALKING

Daniel J. Davis and John H. Challis
The Biomechanics Laboratory, The Pennsylvania State University, University Park, PA, USA.
Email: DanielJDavis@psu.edu

INTRODUCTION

Researchers have used computational musculoskeletal models to investigate the mechanisms underlying changes in the metabolic cost of locomotion. However, the midtarsal joint (i.e., the arch) is frequently ignored. The function of the foot's arch is thought to influence the energetics of locomotion [1], but most current musculoskeletal models are unable to capture this influence.

The aim of the present study was therefore to examine the differences in the metabolic cost of the stance phase of walking due to modelling the midtarsal joint. To do so, a whole-body musculoskeletal model with a three-segment foot that could produce stance phase midtarsal joint angles, moments, and powers similar to those estimated *in vivo* was developed.

METHODS

A two-dimensional musculoskeletal model was developed in OpenSim [v4.4; 2]. The model comprised two three-segment feet along with shanks, thighs, and a pelvis, head, arms, and trunk segment. Twenty-six muscles actuated the model's joints. The plantar aponeurosis was modelled using a path spring along the plantar surface of the foot, and a torsional spring at the midtarsal joint represented other passive structures.

Walking data from 14 participants was collected [3], and the generic model was scaled to a representative subset of three participants (2M/1F, 65.8 ± 10.6 kg, 1.72 ± 0.11 m) for which bilateral marker data was available. Simulations which minimized the sum of muscle excitations squared, and the discrepancies with experimental joint angles, joint angular velocities, and ground reaction forces during the stance phase of walking gait were then performed using OpenSim Moco [4]. The torsional spring stiffness at the midtarsal joint was treated as a parameter which was varied between simulations. The metabolic cost of the stance phase was estimated used modelled muscle behavior [5].

To explore the influence of modelling the foot without the arch, the midtarsal joint was converted to a weld joint which permitted no angular displacement. The stance phase of walking gait was then simulated again.

RESULTS AND DISCUSSION

The inclusion of the midtarsal joint reduced the metabolic cost of the stance phase of gait by 0.3%, 3.0%, and 1.4% for each participant, respectively. The largest difference in the net metabolic rate between the two conditions occurred near the time of push-off, when the ankle joint angles were also the most different (Figure 1). Both the gastrocnemius and soleus muscles consumed more energy at this time as well (Figure 1), indicating that ignoring the mechanics of the midtarsal joint alters the extent to which the triceps surae function in a metabolically favorable manner.

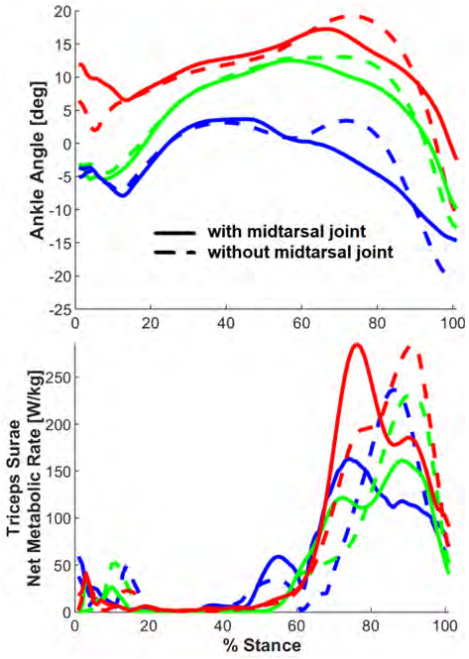

Figure 1 Ankle joint angle and triceps surae net metabolic rate differences between simulations with and without a midtarsal joint.

CONCLUSIONS

Including the midtarsal joint (i.e., the arch) in a whole-body musculoskeletal model decreased the metabolic cost of the stance phase of walking. This was primarily due to a reduction in metabolic energy required for push-off. More appropriately modelling the foot therefore allows for an enhanced understanding of locomotor propulsive energetics, which has important implications for studies of human performance, disease, and/or aging.

INTRODUCTION

Cerebral palsy (CP) is neurodevelopmental disorder arising from a brain lesion during the neonatal period and is a common cause of disability in children and adolescents [1], [2]. Although the brain lesion is single-stage, non-progressive neural damage, CP musculoskeletal movement impairments worsen progressively with age [1]. In this research, we investigate the shape, fibre architecture, and growth of the soleus muscle which is an important muscle for gait and has been shown to be commonly affected by CP [3]. Conventional structural and architectural properties of the soleus muscle have been extensively investigated previously. However, quantitative shape descriptions of the soleus muscle have only recently been reported by our group in children and adolescents with CP [4]. Here, we conduct a 4-dimentional (longitudinal) statistical shape model and fibre architecture assessment of the soleus muscle to investigate the shape progression and growth in a cohort of children and adolescents with CP and a typically developing (TD) cohort. This *de novo* approach utilizes recent advancements in anatomical and diffusion MRI (aMRI and dMRI) to offer an *in vivo* assessment of the spatial and temporal variations of the soleus in children and adolescents with CP to better understand growth, shape change, and associated altered biomechanics.

METHODS

We acquired aMRI and dMRI at three discrete time points over a period of 15 months for a cohort of children and adolescents with CP and a TD cohort. We generated 3-dimensional volumetric meshes and vector fields of fibre orientation (input data) of the data representing the 3-dimentional architecture of the soleus muscle of both cohorts. The input data was normalized and size was removed. Then, the 3-dimensional volumetric meshes were registered against a reference mesh and vector fields were registered accordingly. Vector field data were interpolated to reduce computational cost using a nearest neighbour algorithm. Principal component analysis was applied and dominant shape and fibre tracts arrangements (i.e., principal components) were extracted. The means and variations of model output were quantified and compared between the two cohorts.

RESULTS

The 4-dimensional models of the children and adolescents with CP cohort and TD cohort can extract the dominant features and their variance in each cohort with a few principal components depending on the discrete time points of data collection. In our research, we were able to capture a maximum of two dominant features that distinguish each cohort given that we conducted three discrete time points of this longitudinal study.

CONCLUSIONS

We generated 4-dimentional shape and vector field models of the soleus muscle in cohorts of children with CP and TD children. The 4-dimentional shape and vector field models can describe shape progression and growth variations within and between the two cohorts. Future studies will include more longitudinal and cross-sectional data to extract more distinguishable dominant features of the soleus muscle between both cohorts and use finite element modelling to interpret the functional impairment of the soleus muscle in children and adolescents with CP.

INTRODUCTION

The estimation of neuromusculotendon parameter values can be highly influenced by the type of movements used during the estimation process [1]. Moreover, the choice of human movements to accurately reproduce the kinematics and dynamics is not obvious. Tests in animals allow measuring data that in humans would be more difficult. In this study, we estimated neuromusculotendon parameter values of a rat hindlimb, such that they are able to reproduce the kinematics of trajectories produced from stimulation of a single muscle.

METHODS

The experimental data used for the estimation contained marker trajectories (Vicon, Oxford, UK) of six trials in which a single muscle of a rat hindlimb was stimulated at a time. The rat was anesthetized with the pelvis fixed, and at each trial one muscle was stimulated through intramuscular electrodes while the others remained passive. The six muscles stimulated were iliopsoas, gluteus superficialis, semitendinosus, vastus lateralis, biceps femoris posterior, and biceps femoris anterior. Each stimulation consisted of a step function with a duration of 0.5 seconds. A rat hindlimb model with 13 degrees of freedom was used [2] to obtain joint angles in OpenSim and represent the skeletal dynamics. Absolute degrees of freedom of the pelvis with respect to the ground and secondary degrees of freedom of the ankle were prescribed. The other degrees of freedom of the model (three at hip, one at knee and one at ankle) were driven by 38 muscles, represented with compliant muscle-tendon Hill-type actuators [3]. The system included fibre and tendon damping properties to analyse their impact on the prediction results. A tracking optimal control problem (OCP) was formulated [4] to optimize optimal fibre and tendon slack lengths of all muscles, and fibre and tendon damping parameters, such that the predicted kinematics during muscle stimulation replicated the experimental kinematics. Time activation and deactivation constants, and the maximum activation value were also calibrated for the stimulated muscle. The state variables included joint coordinates and their velocities, and normalized tendon forces, while joint accelerations, and the derivative of normalized tendon force served as control variables. The OCP was formulated using a direct collocation method, imposing Hill-equilibrium equations for all muscles, muscle activation dynamics equations for the muscle activated, and equations of motion for all degrees of freedom in an implicit form. Deviations of optimal fibre length values from the reference [2] were penalized.

RESULTS AND DISCUSSION

The calibrated set of optimal fibre and tendon slack lengths led to overall accurate results for all five degrees of freedom (Table 1), as illustrated by the example of stimulating gluteus superficialis shown in Figure 1. Once muscle parameters are optimized, this framework can also be used to predict other movements.

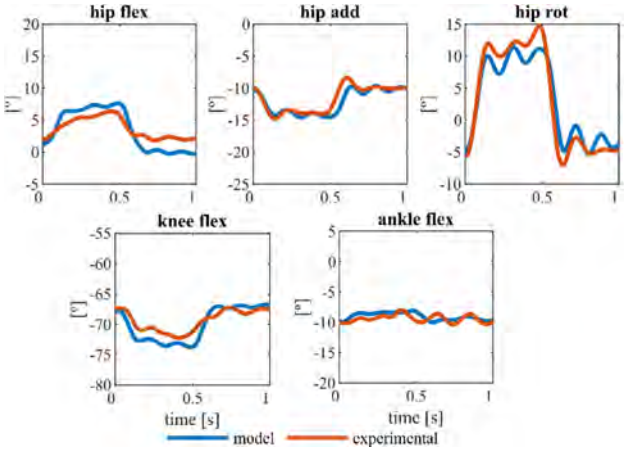

Figure 1 Example of kinematics tracking, stimulating gluteus superficialis.

CONCLUSIONS

The presented model can reproduce experimental data accurately. This framework allows the study of the influence of damping parameter values and level of stimulation on the estimated musculotendon parameter values.

Musculoskeletal simulations integrating a smooth knee pressure contact model

Mohanad Harba[1], Joan Badia[1], Gil Serrancolí[1]
[1] Department of Mechanical Engineering, Universitat Politècnica de Catalunya, Barcelona, Spain
Email: mohanad.harba@upc.edu, joan.badia.torres@estudiantat.upc.edu, gil.serrancoli@upc.edu

INTRODUCTION

One of the benefits of biomechanics modelling is that we can compute variables that are usually not directly measurable, like joint contact forces or pressures. Computational efficiency and level of personalization are two terms that could seem contradictory. While we would need to know the contact pressure values to study joint degeneration, the computation of these variables within a musculoskeletal simulation, which is already computing muscle and contact forces and kinematics, might be quite time consuming. Moreover, collision detection algorithms are typically not continuous. Gradient-based optimizations using automatic differentiation tools have been shown to be the most efficient when formulating musculoskeletal simulations [1]. However, the cost function and constraints need to be continuous to avoid issues with the convergence.

METHODS

In this study, we developed a smooth collision-detection algorithm to compute joint pressures within musculoskeletal simulations, and this was applied to a knee joint wearing a prosthesis [2]. An optimal control problem (OCP) was formulated to track experimental data while satisfying dynamic, path, boundary, and continuity constraints. The OCP was solved using CasADi, calling the equations of motion (from OpenSim/Simbody). We formulated a smoothed pressure contact model based on elastic foundation theory in a C++ code, which was embedded into a .dll file. As indirect validation, we ensured that knee contact forces were reasonably well tracked with respect to experimental ones using data from the Knee Grand Challenge to Predict In Vivo Knee Contact Loads [3], while joint kinematics and ground-reaction forces can be tracked closely. Skeletal dynamics were represented using an OpenSim model with 34 degrees of freedom driven by 94 muscles. A visualization framework developed in Blender was created to visualize the results.

RESULTS AND DISCUSSION

An optimal solution is obtained tracking knee contact forces with RMSE = 56.0 N (r = 0.99) for the medial side and RMSE = 45.2 N (r = 0.98) for the lateral (Figure 1), and joint angles with RMSE = 1.62 ± 3.24º (r = 0.94 ± 0.20). Simultaneously, muscle forces and foot-ground contact forces were estimated. The computational time was 8.16 hours without parallelization in an Intel Xeon W2123 CPU at 3.6 Hz. This model provides the pressure values in each mesh face for both the tibial and femoral components of the prosthesis. One of the main advantages of this model is that pressure values could be minimized during predictive simulations to obtain patterns which avoid joint degeneration. So far, the pressure contact model is based on an elastic-foundation contact model. The integration of tangential contact forces is assessed to model the interaction more closely.

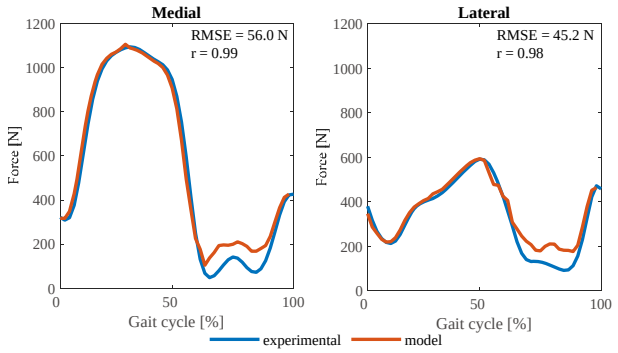

Figure 1 Experimental and model knee contact forces (medial – left, and lateral – right), with root mean square errors (RMSE) and correlation coefficients (r).

CONCLUSIONS

The validation in natural knees (without instrumented prosthesis) is challenging, though the possibility to simultaneously predict kinematics and dynamics data is promising to validate the results indirectly. This will allow studying how joint pressure distribution and muscle activation change after an orthopaedic injury or a neuromuscular disorder. This model could also be applied in other applications, such as in human-device interactions, and open the door to perform simulations of musculoskeletal simulations at the level of pressure data.

Quadriceps Adaptation in Response to Split-Belt Asymmetric Walking in Long-Term Post-ACLR Patients

Yannis K. Halkiadakis[1], Noah A. Davidson[1], Kristin D. Morgan[1]
[1]Department of Biomedical Engineering, University of Connecticut, Storrs, CT 06269, USA
Email: yannis.halkiadakis@uconn.edu

INTRODUCTION

Lingering neuromuscular dysfunction often continue to plague post anterior cruciate ligament reconstruction (ACLR) individuals long after rehabilitation and their return-to-sport. These deficits commonly present as quadriceps inhibition resulting in decreased muscle activation and strength [1,2]. This quadriceps inhibition can have detrimental consequences including the initiation and progression of knee osteoarthritis and increased secondary ACL injury risks. Thus, post-ACLR rehabilitation protocols that increase quadricep muscle strength and engagement are needed to combat these harmful consequences.

Purposely induced asymmetric walking is a promising rehabilitation protocol that can override inhibitory muscle activation to restore healthy gait dynamics in pathological populations. Here, purposely induced asymmetric walking perturbations was used to increase quadriceps function and promote positive gait adaptations in post-ACLR individuals. We hypothesize that asymmetric walking trial will result in increased quadriceps activation that will be maintained after the asymmetric walking trial.

METHODS

Fifteen post-ACLR individuals (>1 year from surgery) participated in an asymmetric walking protocol. The protocol was performed on a Bertec split-belt instrumented treadmill, with marker data collected using a 12-camera Vicon motion capture system. Participants completed an asymmetric walking protocol that consisted of three trials: baseline symmetric 1.0 m/s trial, an asymmetric walking trial with the reconstructed limb at 1.0 m/s and contralateral limb at 1.5 m/s, and a de-adaptation symmetric trial at 1.0 m/s.

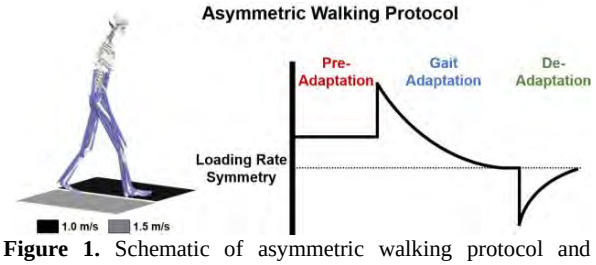

Figure 1. Schematic of asymmetric walking protocol and the reduction in between-limb loading rate asymmetry.

OpenSim musculoskeletal software was used to generate patient-specific simulations of the participants to evaluate changes in muscle function in response to the asymmetric walking protocol (Fig. 1). First, participants anthropometrics were scaled to OpenSims' 23 degree-of-freedom, 92 musculotendon actuator model. Next inverse kinematics was performed to compute the joint angles. Residual reduction algorithm tool was run to ensure that the gait simulations were dynamically consistent. Lastly, computed muscle control (CMC) was used to estimate individuals' lower extremity muscle forces during the loading phase of each gait cycle for each trial. The muscle groups of interest include the quadriceps, hamstrings, gastrocnemius, and gluteal groups. Peak lower extremity muscle force was during the loading phase was extracted from the CMC results. A repeated measures ANOVA was run to determine if there was a significant difference (p = 0.05) in muscle force production between trials for any muscle group.

RESULTS AND DISCUSSION

The percent change in muscle activity was calculated for each muscle group using the baseline 1.0 m/s results as the initial condition (Fig. 2). The results demonstrated that there was a significant increase in force production in the quadriceps, hamstrings, and gluteal muscles during the asymmetric walking trial (Fig. 2). Moreover, it was shown that the quadriceps, hamstrings, and gluteal muscles all maintained elevated muscle force production, compared to the baseline trial, during the symmetric de-adaptation walking session. These results are significant because it indicates that the asymmetric walking trial not only can induce positive muscle force production, but lead to short-term sustained elevated muscle force production. Between-limb loading rate asymmetry also decreased in response to the protocol (Fig. 2).

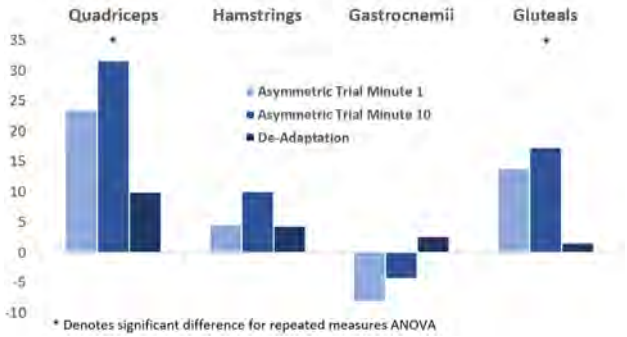

Figure 2. The percent change in muscle output for each of the muscle groups of interest when compared to the baseline symmetric trial at 1.0 m/s.

CONCLUSIONS

This study demonstrated that a purposely induced asymmetric walking protocol has the potential to promote healthy quadriceps function in post-ACLR individuals.

INTRODUCTION

Achilles tendon (AT) adaptation can be modulated by strain, a mechanical variable modifiable via biofeedback [1]. Achilles tendon force, predicted using neuromusculoskeletal (NMSK) modelling [2], can be used to estimate AT strain. However, NMSK methods require high-quality data from specialised laboratory equipment and extensive data processing. Combining computer vision with deep learning is an alternative solution for obtaining AT force in ecologically valid settings. Pose estimation methods (e.g., OpenPose) enable automatic detection of human keypoints (e.g., joint centres and anatomical landmarks) from videos, facilitating real-world application. Deep learning models (e.g., long short-term neural network (LSTM)) have shown promise in predicting biomechanical variables (e.g., joint angles and moments) and may be trained to map the complex relationship between human motion and AT force. Therefore, this study aimed to develop a LSTM model to predict AT force from keypoints synthesised from laboratory based NMSK data and test the developed model using new videos recorded by two smartphones.

METHODS

The training dataset of LSTM model consisted of 3D motion capture (MOCAP), ground reaction forces, electromyography (EMG) of 16 participants (male:10; female:6) performing over-ground walking tasks. A calibrated EMG-informed NMSK model (CEINMS) estimated AT force time-series during the stance phase [3]. For the LSTM model training ten pose-estimated keypoints were synthesised (bilateral hip, knee, ankle, toe; midpoints hip joint centres, and midpoint of acromia) from 3D MOCAP marker trajectories. Synthesised keypoints data were augmented using a per-trial [4] and per-frame Gaussian noise. The final training data comprised 910 trials including the ten 3D keypoints position data, and the height and mass of each participant, used as LSTM model inputs to predict the AT force. Model hyperparameters were optimised using hyperband tuning with a train-test split of 7:1. Leave-one-out cross validation was used to evaluate model performance using coefficient of determination (r^2) and root mean square error (RMSE) between the NMSK and LSTM estimates of AT force. A final LSTM model was then retrained using the fully available training dataset. The final LSTM model was then verified using new outdoor video data of three participants (two males) not previously included in the training dataset. The slow-motion videos (sample rate: 240Hz; resolution: 1080×1920) were recorded from two smartphones (iPhone 8 and iPhone 13, Apple) and cropped to the right leg's stance phase, using OpenPose (v1.7.0) to automatically obtain pose keypoints [5]. Keypoints were triangulated and transformed to the world coordinates, consistent with the training data, and used as input to the final LSTM model to predict AT force.

RESULTS AND DISCUSSION

Leave-one-out cross validation showed that AT force could be predicted using the LSTM model with low error compared to NMSK modelling (RMSE = 200.44±69.86N; r^2 = 0.92±0.05). When using the pose estimation data of new participants extracted from the smartphone videos, the model estimated AT forces comparable to ground truth data (Figure 1).

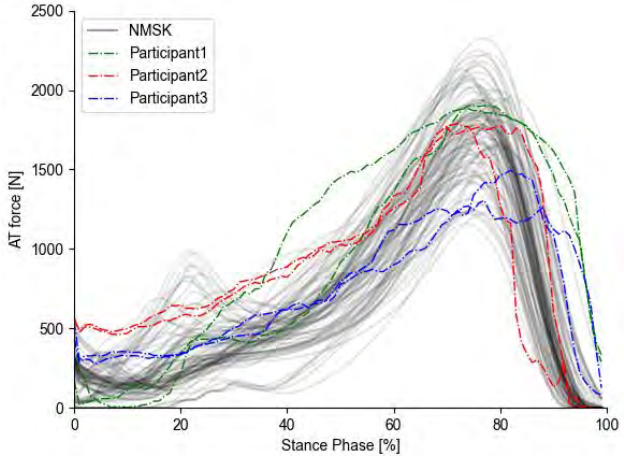

Figure 1 The comparison of ground-truth AT force from NMSK modelling pipeline and predicted AT force using real pose estimation data as input for the LSTM model.

CONCLUSIONS

Achilles tendon force during walking can be well predicted by LSTM model using videos recorded from two smartphones. These predictions are within the expected range of AT force established via NMSK modelling of the training dataset. Future refinement and application of this technology may see biofeedback approaches being developed to inform AT training and rehabilitation programs.

Explaining Deep Learning Models for Age-related Gait Classification Based on Time-series Acceleration

Xiaoping Zheng[1], Michiel Reneman[2], Bert Otten[1] and Claudine Lamoth[1]
[1] Department of Human Movement Sciences, University of Groningen, Groningen, The Netherlands.
[2] Department of Rehabilitation Medicine, University of Groningen, Groningen, The Netherlands.
Email: X.Zheng@umcg.nl

INTRODUCTION

Gait pattern classification is important in healthcare for age and pathology related gait changes monitoring and classification [1]. To improved the gait classification performance, conventional machine learning (CML) has been widely used, which is based on handcrafted gait features extracted from accelerometer data. However, the extraction of handcrafted features is laborious, requires expert knowledge, and may lead to suboptimal classification performance. In contrast, end-to-end deep learning approaches such as convolutional neural networks (CNN) integrate feature extraction and classification within the neural network model, eliminating the need for handcrafted features and potentially leading to improved performance. While DL approaches may provide promising classification performance, their black-box character limits their use in healthcare decision-making [2].

Therefore, this study aims: 1) to compare the classification performance of 4 CML approaches (based on handcrafted gait features) with a CNN to classify age groups (adult vs. older adult) based on raw accelerometer data. 2) to increase the transparency in gait classification process for CNN by using Explainable Artificial Intelligence approach (XAI, e.g. layer-wise relevance propagation (LRP)).

METHODS

A total of 267 healthy adults were involved and divided into two groups: adult (18-65, n=130) and older adults (>65, n=137). Participants completed a 3-minute walking with a 3D-accelerometer (100 Hz) attached near the L3 lumbar segment. 36 gait features were extracted and used to train CML (Support Vector Machine (SVM), Naive Bayes, K-Nearest Neighbourhood, and Random Forest). The raw signal data were fed to CNN with 256-sample window size. The classification performance comparison of CNN and CML was evaluated by commonly used evaluation metrics (e.g. the area under the receiver operating characteristic curves (AUC)). The CNN classifier model was explained by LRP. Higher absolute LRP values mean more relevant to the classification.

RESULTS AND DISCUSSION

Table 1 Classification performance comparison.

	Accuracy	AUC	Precision	Recall	F-score
CNN	0.88	0.93	0.83	0.96	0.89
SVM	0.74	0.83	0.74	0.74	0.74

Table 1 shows the classification performance of CNN and SVM (the best performing CML). CNN outperformed SVM in all accuracy metrics by a significant margin. This supports that CNN is more effective than CML and eliminates the need for handcrafted features. In Figure 1, the absolute LRP values visualized the key signal regions for classification. The figure shows that the signals during heel-strike play a significant role in distinguishing between the adult and older adult groups. Higher LRP values in these regions may indicate distinct movement patterns and aid in age group differentiation.

CONCLUSIONS

DL such as CNN outperformed CML in gait pattern classification and does not need handcrafted features. The use of XAI techniques, such as LRP, increases the transparency of DL and holds great potential for applicating in clinical gait analysis to support medical decision-making in the future.

INTRODUCTION

Machine learning is a powerful tool for modeling complex human movements. However, the high cost of acquiring biomechanical data often limits observations and therefore the generalizability of these models. Meanwhile, there is untapped utility in musculoskeletal models for informing machine learning predictions. Transfer learning, the process of training a machine learning model on one task (e.g. simulated data) and re-purposing this knowledge for another task (e.g. measured data), has therefore emerged as a potential tool for predicting human movement [1,2].

Our objective was to create and validate transfer learning frameworks that use artificial neural networks to model complex upper extremity movements. Specifically, we modeled lateral pinch, a task involving the combined, redundant effort of muscles acting about the wrist and thumb. Our results elucidate the impact of transfer learning on machine learning model accuracy and exemplify how this technique may be used to improve predictive models of human movement.

METHODS

We developed feedforward (FF) and long short-term memory (LSTM) neural networks to regress three-component lateral pinch thumb-tip forces from eight muscle activations. We trained and tested two versions of each neural network. The first was trained solely on recorded data. The second was a transfer-learning model that was pre-trained with simulated data and fine-tuned on recorded data (Fig. 1, left).

To provide observations to the transfer learning models, we generated 6,594 lateral pinch simulations using a thumb model [3] and OpenSim v. 4.1. Each simulation included a unique combination of scaling (young adults [4]) and target force (40 to 80 N). Simulation-derived muscle activations were neural network inputs and thumb-tip forces were outputs.

To train and test the neural networks, we recorded experimental data. These data were recorded from five female and three male, right-handed, young adults (IRB#202202263). Muscle activity was recorded using fine-wire electromyography (EMG) collected at 3000 Hz from eight muscles. Simultaneously, lateral pinch force was collected using a 6-axis force sensor. During data collections, subjects performed three 5-second maximum voluntary contractions of lateral pinch with 30 seconds of rest between each. Each neural network was trained on the same seven subjects' data, with one subject's data used for testing.

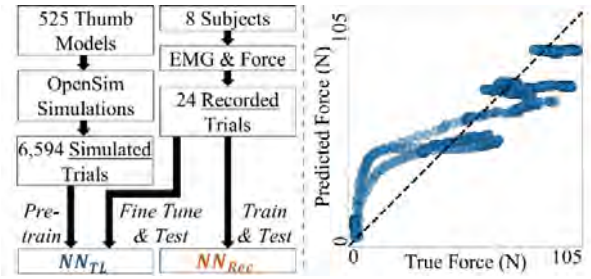

Figure 1: Framework used to develop neural networks informed via recorded data and transfer learning, denoted NN_{Rec} and NN_{TL}, respectively (left). Parity plot for LSTM developed via transfer learning when predicting on the test subject's data (right). The forces displayed represent thumb-tip force magnitude.

RESULTS AND DISCUSSION

Neural networks trained on recorded data alone underperformed relative to their transfer learning counterparts. Test predictions of FF and LSTM models trained only on recorded data had mean absolute errors (MAEs) of 6.9 N and 5.9 N, respectively. By comparison, FF and LSTM models developed via transfer learning achieved MAEs of 6.0 N and 5.6 N. The LSTM developed via transfer learning (Fig. 1, right) outperformed every other model and maintained generalizability to distal and palmar thumb-tip forces. These results indicate that pre-training neural networks on simulation data enhances model generalizability. Furthermore, our approach can be easily adapted and applied to predict other movements.

CONCLUSIONS

Our work suggests that machine learning models of human movement can benefit from the knowledge contained in musculoskeletal simulations. Through continued efforts, models with greater generalizability to real-world conditions may be achieved.

INTRODUCTION

3D motion capture is widely used to evaluate human biomechanics [1]. Innovative markerless systems have emerged as an alternative to expensive and time-consuming reflexive marker-based methods using computer vision and machine learning to track motion without physical markers [2]. Here we set out to determine the validity and reliability of lower limb angular kinematics and centre of mass (CoM) displacement obtained using a markerless system using low-cost webcams compared to a gold standard system.

METHODS

Eighteen participants (26.2 ± 6.3 years) performed a countermovement akimbo protocol, consisting of 10 trials (30 seconds rest) in a test-retest design. Data were collected with a Vicon Motion System (15 cameras, Bonita B10, sampling at 100 Hz, 21 reference markers, Plug-in Gait model) and a markerless system using pre-trained artificial intelligence model and a custom-built triangulation algorithm using Python (2 cameras, Logitech C270, sampling at 30 Hz) operating simultaneously. Signals Position data were filtered (low-pass, 2nd order, Butterworth, 5 Hz cut-off). The right hip and knee sagittal plane angular movements were calculated. Validity was assessed using Statistical Parametrical Metrics (SPM) 1D and reliability was assessed using paired t-test and intraclass correlation (ICC) using take-off peak angles and the maximal jump height.

RESULTS AND DISCUSSION

SPM revealed a consistent signal pattern between both systems (Figure 1). We did not observe significant test-rest differences, and good to very good ICC values were found (Table 1). Further analysis should include the ankle joint and the analysis of bilateral asymmetries.

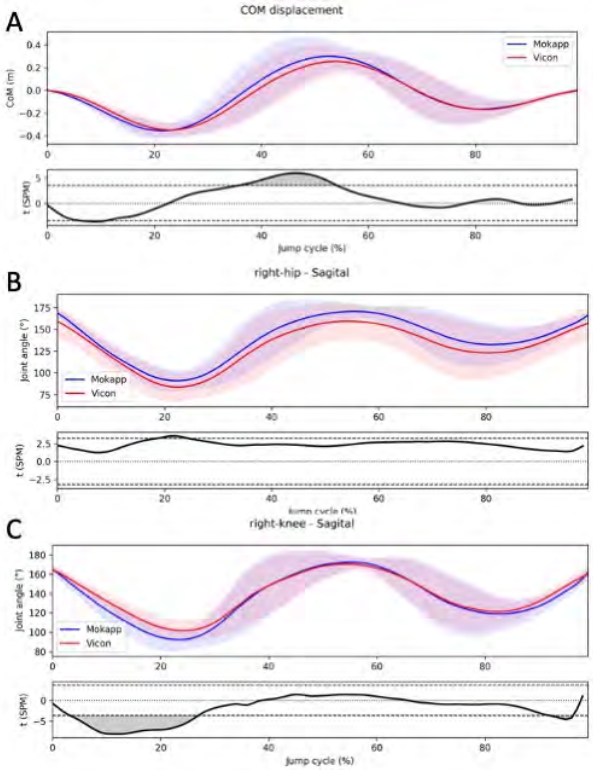

Figure 1. CoM displacement (A), hip (B), and knee (C) kinematics plotted with mean signal represented by lines and standard deviation represented by a shaded area. Markerless data are shown in blue and Vicon data are shown in red. The bottom panel showed the SPM outcomes with the grey-shaded area indicating a significant difference.

CONCLUSIONS

3D markerless motion capture using off-the-shelf, low-cost cameras accurately tracked hip, knee, and CoM kinematics during a countermovement jump.

INTRODUCTION

Radiologists find MRI interpretations of pediatric knee joints challenging, especially the ones with growth plates [1], [2]. Pediatric MRI's low-level information on thin structures such as cortical bone or growth plate create complexity. In such cases, thresholding-based methods (including binary or multilevel thresholding) are typically used to uncover the intensity profile ranges of different classes [3]. However, current automatic segmentation methods do not use any thresholding techniques. The main contribution of this study was to introduce a new multilevel thresholding-based training framework as a separate input channel to a deep learning 3D-UNet model to improve the performance of the segmentation.

METHODS

The proposed framework involved following steps: 1) The MR image dataset was passed to the Multi-level Otsu algorithm which divided it into different classes and for each class, number of thresholds were estimated. 2) For each class, optimal thresholds were identified by the multi-Otsu algorithm and threshold images were reconstructed. 3) The images were then used in the UNet training model as an input channel. 4) After training, a post-processing algorithm (removal of small objects, largely connected components etc.) was performed to enhance the quality of the segmented outputs.

Retrospectively acquired pediatric knee MRI datasets (n = 20) of girls (age 13 to 16 years) were used in this study (3.0T scanner, 3D GRE sequence). Each dataset was manually segmented for training using 3D Slicer toolbox. Labels considered for this study are Trabecular (femur proximal, fibula distal, tibia distal), cortical (femur, tibia, fibula) and others (Femur distal, fibula proximal, tibia proximal. For Multi-Otsu algorithm the number of classes assigned for each individual label were three. The proposed method was compared with existing meta-heuristic thresholding method and Baseline 3D-UNet model using metrics of DICE (similarity index), Hausdorff distance (HD), Root Mean Square Error (RMSE), and Mean Absolute Error (MAE). The AdamW optimizer was used with 600 epochs and the channel size of 16, 32, 64, 256.

RESULTS AND DISCUSSION

Histogram thresholding method performed poorly and failed to identify the homogeneity intensity issue (Table 1). Baseline 3D-UNet model performed better for labels with larger spatial size such as trabecular region, but performance declines with smaller spatial size such as cortical regions (Table 1). The proposed framework performed better than the other two algorithms in all the regions except for cortical femur (Table 1). This could be due to fuzzy intensity ranges that may have failed to fit within defined class of multi-Otsu.

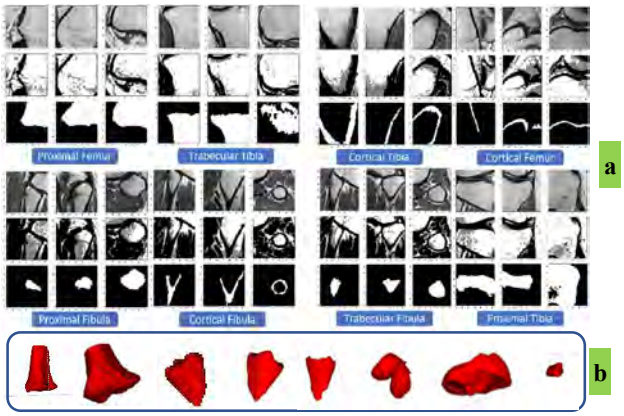

Figure 1 (a) Threshold images generated based on optimal Multi-Otsu algorithm. (b) Segmentation output using proposed model

CONCLUSIONS

This study focused on eliminating the issue of intensity homogeneity in pediatric MRI and proposed a Muti-level thresholding approach to be integrated with a deep learning model for training. This work is limited with bone segmentation application. Future research can be directed towards combining multi tissue and bone structures for pediatric knee segmentation.

INTRODUCTION

Accurate and timely movement intention prediction can facilitate exoskeleton control during transitions between different locomotion modes [1]. Detecting movement intentions in real-environments remains a challenge due to unavoidable environment uncertainties [2]. False movement intention detection may also induce risks of falling and general danger for exoskeleton users. To this end, in this study, we aimed to develop a method for detecting human movement intentions in real environments. The proposed method is capable of self-correcting by implementing decision fusion and deep Bayesian neural network [2].

METHODS

Data was collected on 2 able-bodied subjects, including environment images and 3D gaze points from a portable eye tracker (Pupil Core), and linear accelerations and angular velocities from IMU sensors (Cometa System) during level ground walking, ramp ascent, ramp descent, stair ascent, and stair descent were used to preliminarily evaluate the feasibility of the proposed method. In total seven IMU sensors were placed on lower limbs and pelvis of the participants. All data were segmented and labelled as different locomotion modes. Eighty percent of the total data were used for training: four temporal features extracted from all gaze points and IMU sensor signals within an analysis window of 150 ms were concatenated and used as inputs to train the prediction model for movement intention detection with a deep Bayesian neural network [2]. Images from the scene camera on the eye tracker were used to train the prediction model for identifying terrains with a deep convolutional neural network [3]. All neural network models were trained carefully to avoid overfitting. During the testing process, the remaining 20% of gaze points and IMU signals were used for movement intention detection and the images for terrain identifications. Decision fusions were then made based on the detected movement intentions and the identified terrains (Figure 1).

RESULTS AND DISCUSSION

Based on our preliminary test, fusing gaze points and IMU signals achieved higher prediction accuracy than only using IMUs for movement intention detections. Fusions at the decision level further improved the prediction accuracies by correcting partial false detections from the previous step (Table 1). For instance, we found that the intentions from walking to ramp ascent which were incorrectly detected as from walking to walking were corrected by the identified terrain, i.e., the next terrain was ramp instead of level ground. Data collection and method evaluation in real environments are currently. underway. More locomotion modes, participants, and complex terrains, for instance, mud, concrete, and grass will be investigated.

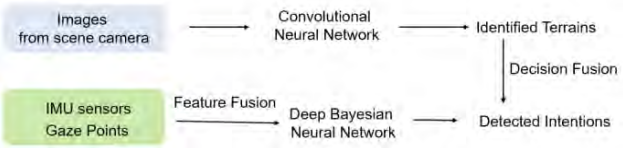

Figure 1 Framework of the proposed method

Table 1 Overall prediction accuracy (%) among locomotion modes, with and without feature fusion and decision fusion

	Without Decision Fusion	With Decision Fusion
Pure IMUs	87.7	–
IMUs+Gaze Points	90.2	96.4

CONCLUSIONS

This study proposed a new method of detecting human movement intentions using and eye tracker and IMU sensors. The overall prediction accuracy was increased by fusions at two levels: 1) at the feature level, fusing gaze points with IMU sensor signals for detecting movement intention; 2) at the decision level, fusing decisions of identifying terrains from images with the previously detected movement intentions from gaze points and IMUs. We believed that the proposed method could potentially improve the robustness of movement intention detection in real environments.

DIFFERENCES IN JOINT KINEMATICS BETWEEN SNATCH AND CLEAN LIFTS IN WEIGHTLIFTING

Ganbat Tumen-Ulzii[1], Munkhbat Tumurbaatar[1], Khosbayar Tsenkherjav[2] and Batbayar Khuyagbaatar[1]
[1]Department of Technical Mechanics, Mongolian University of Science and Technology, Ulaanbaatar, Mongolia
[2] Mongolian Weightlifting Federation, Ulaanbaatar, Mongolia
Email: batbayarkh@must.edu.mn

INTRODUCTION

The snatch and clean and jerk are the main lifting techniques involved in the competition. Both techniques start with the same movements until the second pull phase, then the body movement is differentiated during the turnover, catch, and recovery phases [1]. Few studies have studied the bilateral comparison of kinematic parameters between the snatch and clean techniques. In this study, we have investigated the kinematic difference between the two techniques using wearable inertial sensors.

METHODS

In this study, seven female Mongolian weightlifters participated. Two test sessions were carried out to record body movements using the wearable inertial sensors (Wearnotch, Notch Interface Inc), which were attached to the chest, waist, arm, forearm, thigh, and shank using the straps. The first tests were snatch followed by clean. Each participant performed three snatch and clean lifts at 70 % of the one-repetition maximum. The shoulder, elbow, hip, knee, and trunk joint angles were calculated, normalized, and averaged for two different techniques using Matlab® [2]. The lifting phases were defined for the snatch and clean [1,3]. The barbell velocity at the 2nd pull phase was estimated using the sensor on the forearm. An independent sample t-test was used to compare the mean values of joint angles during the snatch and clean with a significant level of 0.05.

RESULTS AND DISCUSSION

The maximum shoulder abduction, shoulder flexion, elbow extension, knee extension, hip extension, and trunk extension were 82°/56°, 164°/87°, 185°/172°, 127°/154°, 137°/166°, 161°/164° in the snatch/clean, respectively (Figure 1). The joint movements were significantly different except for the hip and knee joints ($p<0.05$). Arm movements are different in two techniques; such as lifters moving the barbell from the floor to overhead in the snatch and the shoulder in the clean. Similar hip and knee angles were observed which is known to elicit the greatest amount of power output during the pulling phases. The barbell velocity was higher in the snatch (1.14 ± 0.51 m/sec) than in clean (1.07 ± 0.66 m/sec) ($p=0.68$), which was similar to the previous studies, where they reported that 1.65–2.28 m/sec during the snatch and 0.88–1.78 m/sec during the clean [1,3].

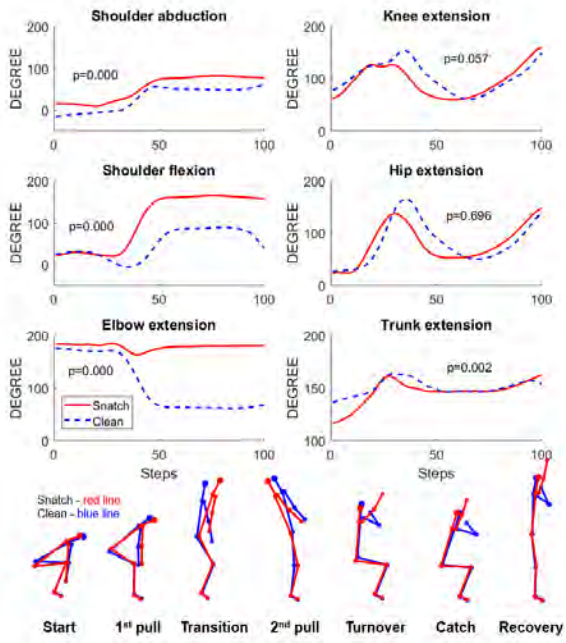

Figure 1 Joint angles during the snatch and clean with p-value

CONCLUSIONS

We investigated the joint angles and barbell velocity to find the difference between the snatch and clean technique using wearable inertial sensors. Although some of the information is known to coaches and athletes, it is better to be aware of the detailed body segment movements. This study provides a kinematic comparison between the snatch and clean lifts, which may help to understand the similarities between the two techniques and enable us to best prescribe the appropriate exercises.

INTRODUCTION

Ballistic training (BT) allows the athlete to accelerate a light load as fast as possible with no deceleration phase, which improves neural factors, including motor-unit recruitment, and to develop explosive strength. Complex training (CT) is a resistance training that comprision of heavy load resistance training to induce post-activation potentiation (PAP), followed by a matched light load and higher velocity training. Both types of training have been proved to improve velocity and explosive performance, but which is the best training method to enhance velocity and explosive power has attracted the attention of coaches and athletes. Hence, this study aimed to compare the training effects between BT and CT. Secondly, this study could provide practical support and sugesstion to strength and conditioning professionals/coaches working in competitive environments to aid in strength development of their athelets.

METHODS

Twenty-four health college students were recruited and divided into a ballistic training group (BTG, n=12) and a complex training group (CTG, n=12).

Two training groups completed an 8-week resistance training program that included 3 training sessions per week. The subjects of BTG performed bench throw (figure 1) with 40% 1RM. The subjects of CTG performed bench press with 85% 1RM at first set, then completed the final two sets of bench throw training with 40% 1RM.

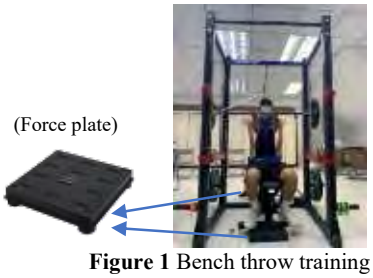

Figure 1 Bench throw training and test.

Before and after the resistance training, two force plates (force plate, PASCO, California, USA) be used to test the maximum voluntary contraction and the height of push-ups (PH), then calculate the rate of force development during the bench press. (RFD_{50ms}, RFD_{100ms}, RFD_{max}). Data of baseline and enhancement percentage of training effects between both groups were analyzed using Independent-Sample t-Test. The Paired Samples t-test was used to compare the difference between pre-test and post-test. $\alpha = .05$.

Figure 2 The height of push-up test.

RESULTS AND DISCUSSION

Both groups have significant improvements in explosive power (RFD_{50ms}, RFD_{100ms}, RFD_{max}), and height of push-up ($p<.01$). However, the enhancement percentage of RFD_{max} in CT was significantly higher than BT ($p<.01$).

Table 1: Comparison of dependent variables between pre and post test.

	G	Pre-test *M (SD)*		Post-test *M (SD)*		*t-value*
RFD_{50ms}	BT	966.37	(223.4)	1219.59	(355.4)	-5.518**
(Ns^{-1})	CT	975.44	(246.4)	1195.99	(249.6)	-7.269**
RFD_{100ms}	BT	1852.12	(438.2)	2307.97	(471.3)	-12.013**
(Ns^{-1})	CT	1846.41	(447.9)	2360.06	(513.5)	-9.945**
RFD_{max}	BT	2257.79	(550.2)	2621.78	(566.3)	-8.456**
(Ns^{-1})	CT	2243.35	(640.2)	2783.30	(735.1)	-8.196**
PH	BT	14.96	(2.53)	17.57	(3.44)	-3.558**
(cm)	CT	14.91	(2.17)	17.15	(3.59)	-4.939**

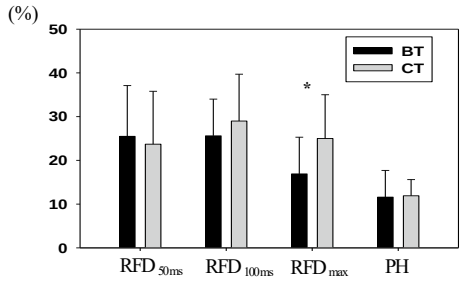

Figure 1 The percentage of enhancement of the two groups

Ballistic training could induce specific changes in the force-velocity relationship to improve the athlete's initial force rate performance [1]. However, complex training trigger post-activation potentiation and produce a better explosive power enhancement effect [2].

CONCLUSIONS

Both BT and CT are effective training methods for developing explosive strength and contraction speed. Probably because of PAP, the enhancement percentage of RFD_{max} in CT is significantly better than that of BT.

INTRODUCTION

Landing Error Scoring System (LESS) is one of the movement detection methods, that are often used on the sports sideline to predict risk of lower limbs injuries [1]. It can be used to evaluate the good or fail mechanism of jump-landing technique. Although LESS is a convenient way to manually assess the risk of lower limb injury, the agreement and validity of individual scoring items are still incomparable with the 3D motion analysis system in the laboratory[2,3]. The system of this study was using image recognition and automatic joint angle tracking method. It can track the joint range of motion (ROM) and between-limb distance on individual scoring items, so it can understand the details of jump-landing technique for individual scoring items. Therefore, the purpose of this study was to use the image recognition and automatic joint angle tracking to assessed LESS score and prospectively tracking the injury rate of lower limb of athletes for half-year as a predictor of the risk of lower limb sports injuries.

METHODS

Twenty-six collegiate athletes (10 women and 16 men, age= 20.4 ± 0.72 years, height= 169.5 ± 7.9 cm, weight= 65.4 ± 9.7 kg) performed 3 jump-landing trials that were recorded by 2 web cameras (Logitech C920 Full HD Pro web cam) in the front and lateral side of the participates (Figure 1). For the jump-landing assessment, participants jumped from a 30-cm-tall box to a designated area in front of the box. We instructed them to complete a maximal vertical jump immediately after landing in the designated area. The web cameras were controlled by a laptop computer with a self-written ROM tracking software (written with Labview VISION module). The values obtained from 3 trials were averaged to obtain a participant's LESS score. After data collection, one researcher (H.Y.C.) evaluated the recorded video data and scored the LESS. After jump-landing assessment, all participants were followed half-year by one researcher (H. C. C.) at each week by using telephone tracking to identify those who subsequently suffered any sports injury. IBM SPSS Statistics for Windows was used for data analysis. The participants according to their LESS scores divided into the Good group (LESS score ≦5) and Poor group (LESS score >5). The Chi-square test was used to compare of the differences in the manual grading LESS scores and injury rate between Good and Poor groups. The independent T-test was used to compare of the ROM differences in each item of the LESS assessment (17 items). Significance was set at $P < .05$.

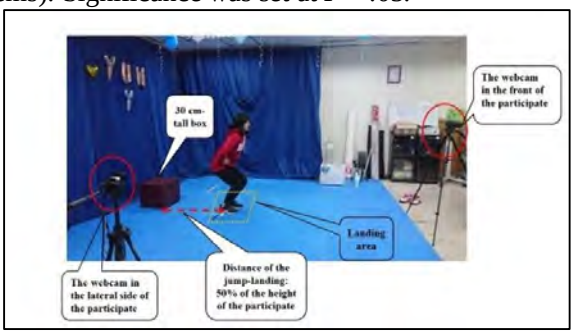

Figure 1 Experiment setup.

RESULTS AND DISCUSSION

The results indicated that significant better in LESS score for the Good group (3.92±0.9) than the Poor group (6.6±1.0) (p=.00); However, there was no significant difference between both groups for lower extremity sports injuries (Good group: injury rate=35.70%, Poor group: injury rate=40%, $\chi^2_{(df=1,\ N=24)}$=0.046, p=.831). Among the joint ROM, the mean hip ROM in maximum knee flexion (p=.011), hip joint displacement (p=.02), mean maximum knee flexion ROM (p=.025), knee joint displacement (p= .018) and the hip joint displacement greater than 45 degrees in the maximum knee flexion (p=.001) were reached a significant difference, and the rest of the items did not reach a significant difference. In total, the joint ROMs in the Good group were better than that of the Poor group; there is no significant difference between the lower limb sports injury rate and the ROM in each LESS items.

CONCLUSIONS

The Good group had better joint ROM and displacement than the Poor group; However, there was no significant difference between both groups for lower extremity sports injuries rate. It may need more tracking period and more participates to clarity the results.

INTRODUCTION

Adequate flexibility is an essential factors for athletes performance, neither for baseball players. Repeative loading in lower extremities during throwing for baseball players may lead to hip and groin injuries [1]. Limitation of hip range of motion (ROM) may alter throwing or hiting kinetmatics and affect the transfer of energy form lower to upper extremities, eventually influence the players' performance[2]. Hence, it is necessary to understand the hip ROM of the baseball players. Therefore, the purpose of this study was to examine the hip rotational ROM and to compare the difference between dominant and non-dominant hip for the healthy collegiate baseball players.

METHODS

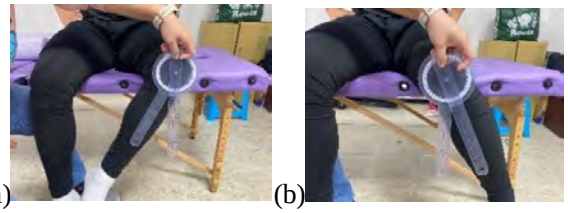
Fifteen healthy collegiate male baseball players were recruited to participate this study (Height: 178.9±7.8 cm, weight: 81.0±13.4, age: 18.1±0.4). The demography of the participates are list in Table 1. The hip rotational ROMs were taken in sitting position with using plastic goniometer, included internal and external rotation (IR and ER) (Figure 1). Total rotation ROM was obtained by summing the internal and external rotation measures from each limb. Both of limb were measured randomly. All of the hip ROM measurement were tested by one researcher (C. W. C.). The hip IR or ER ROM deficit were calculated by the following formula:

*Hip IR or ER deficit (%) = [(dominant hip ROM-nondominant hip ROM)/nondominant hip total rotation]*100*

IBM SPSS Statistics for Windows (version 20.0; Armonk, NY: IBM Corp.) was used for analysis the results. The Paired t-test was used to analyse and compare the difference of hip IR, ER, and total rotation between dominant and non-dominant side. An α-value set at .05.

RESULTS AND DISCUSSION

Tables 1 show the descriptive values for hip IR, ER, and total rotation from the collegiate baseball players. No significant side-to-side differences ($p > .05$) were found in hip IR or ER in the collegiate baseball players. Additionally, total rotation ROM did not differ between extremities in the collegiate baseball players. The result of the hip IR deficit was presented with 3.04±7.86% and the hip ER deficit was 0.77±8.05%. The hip IR deficit was more than the hip ER deficit. It was indicated that we need to pay attention to hip IR deficit.



(a) (b)

Figure 1 The hip rotational ROM assessment. (a) external rotation (ER), (b) internal rotation (IR).

RESULTS

Tables 1 show the descriptive values for hip IR, ER, and total rotation from the collegiate baseball players. No significant side-to-side differences ($p > .05$) were found between the dominant and non-dominant hip in IR or ER in the collegiate baseball players. Additionally, total rotation ROM did not differ between extremities in the collegiate baseball players. The result of the hip IR deficit was presented with 3.04±7.86% and the hip ER deficit was 0.77±8.05%. The hip IR deficit was more than the hip ER deficit. It was indicated that we need to pay attention to hip IR deficit.

CONCLUSIONS

In summarize, the healthy collegiate baseball players were no side-to-side differences in hip IR, ER, and total rotation ROM. But, the hip IR deficit was more than the hip ER deficit. It was indicated that we need to pay attention to hip IR deficit for healthy baseball players.

INTRODUCTION

Anterior cruciate ligament (ACL) is the most common knee ligament injury. Its incidence is 3 times higher in female soccer players than males, and usually it is caused by a non-contact mechanism[1]. This is due to a failure in biomechanical pattern. Studies showed a compilation of the main biomechanical risk factors thresholds which explain the "perfect loading storm" that defines the ACL injury mechanism, being the valgus collapse the main biomechanical risk factor related to ACL injury [1,2]. Latest researches have studied the incidence ratio by limb dominance condition, because in futsal the ball determinates the biomechanics pattern. The primary aim of this study was to identify kinematic differences at initial contact between female futsal players with and without previous knee injury, in a functional motor pattern test. The secondary aim was to determine kinematic differences between dominant limb (DL) and non-dominant limb (NDL) in the hole group, in the same test.

METHODS

Sixteen futsal female players volunteered to participate in the study, aged 23.4 + 5.03 years. Allocation depended on clinical history: previous knee injury (KI), by valgus collapse mechanism without surgical intervention, or no injury, that conformed the control group. The evaluation protocol included the functional test change of direction an acceler-ation test (CODAT) which was recorded ones with DL and NDL. A 3D motion capture system (Qualisys AB, Göteborg, Sweden) was used to analyze the kinematics of change of direction. Twenty-six reflective markers were placed. Visual3D software (C-Motion Inc., Germantown, USA) was used to analyze the change of direction task. Mean and standard deviation (in degrees) of the flexion/extension, adduction/abduction and internal/external rotation of the trunk, pelvis, hip and knee were computed, for the DL and the NDL.

RESULTS AND DISCUSSION

Knee valgus was significantly higher in the DL (9.02 ± 7.31 degrees) than in the NDL (1.27 ± 9.05 degrees) (p= 0.049), in the hole group. Our results showed a higher ACL injury risk motor pattern in DL than in NDL. "Valgus collapse" defined was the combination of hip adduction, hip internal rotation and knee abduction. In this study, in the DL, the limb which had a quantity of knee valgus near to injury risk threshold, KI players had more hip adduction than control players at the change of direction task (Cohen's d: 0.82). Therefore, KI group performing a kinematic pattern like the ACL injury pattern. Hip and knee internal rotation are involved in knee valgus definition [1,3]. In this study, both groups had knee internal rotation at the evaluation moment, but KI players had hip internal rotation in contrast to control players who developed hip external rotation (*Cohen's d:* 0.88). Nobody has studied the influence of the pelvic rotation yet. In our study, KI players made a contralateral pelvic rotation, following trunk motion direction. In contrast to control group, in which contralateral trunk rotation existed, combined with ipsilateral pelvic rotation to the DL (*Cohen's d:* 1.06). This might be a balance mechanism to counteract the opposite trunk rotation, and to decelerate medial velocities suffered by the knee because of the trunk rotation movement[4].

CONCLUSIONS

Our study found kinematic differences at initial contact between female futsal players with and without previous knee injury, in a motor pattern test. The players with no previous history of knee injury had more kinematic patterns to avoid the valgus collapse mechanism in the hip adduction and internal rotation and in the pelvis rotation in the DL. All the players showed more knee valgus in DL, which is the limb with more risk of injury, revealing the clinical relevance of the neuromuscular stabilization training for this limb.

Reducing variability may not increase the success rate of motor task: Toward a proper interpretation of function

INTRODUCTION

In darts or ball throwing, the release positions and velocities of the darts or ball (release parameters) may be systematically related so that deviations in one parameter are canceled out by compensatory changes in the other parameters [1,2]. The systematic relationship between release parameters reduces the variability of the ball or darts arrival position. However, it should be noted that such a systematic relationship between parameters does not always increase the success rate of the motor tasks (e.g. hitting rate to the target during the darts or ball throwing). Without recognizing this point, we might incorrectly conclude that the systematic relationship between parameters always has the function of increasing the success rate of motor tasks. Here our study will experimentally illustrate that the systematic relationship between release parameters may not increase the hitting rate to the target during ball throwing. Given the results of this experiment, our study attempts to discuss the proper interpretation of function.

METHODS

Twelve right-handed college baseball players participated in the study. Each participant threw 30 baseballs at two different-sized targets (small and large targets) aiming at a target 10 m away from the participants, for a total of 60 balls. Furthermore, the participants threw alternately with an overhand and a sidearm throwing. Therefore, the participants threw 15 balls with overhead throwing and 15 balls with sidearm throwing to a large target out of the 30 balls and did the same to a small target.

We identified the systematic relationship between the release parameters to reduce the variability of the ball arrival position and to increase the hitting rate to the target by using the method of the previous study [3]. The method identifies a systematic relationship by comparing the variability of the ball arrival position between measured and decorrelated surrogate data. The surrogate data can be produced by randomly reordering all release parameters across trials to remove all possible correlations among them. Then, the surrogate data are substituted into a forward dynamics model to determine the variability of the ball arrival position. A systematic relationship is present when the variability of the ball arrival position with surrogate data is higher than with measured data. Whether the systematic relationship increases the hitting rate to the target was examined by comparing the hitting rate of the surrogate and measured data.

RESULTS AND DISCUSSION

The variability of the ball arrival position with surrogate data was higher than with measured data in the small target (Figures 1A and 1B). It showed that the release parameters were systematically related to reducing the variability of the ball arrival position (Figures 1A and 1B). In other words, the release parameters had the function of reducing the variability of the ball arrival position. Furthermore, the systematic relationship between release parameters increased the hitting rate to the target (Figures 1A and 1B), indicating that the release parameters also had the function of increasing the hitting rate to the target. For the large target, the variability of the ball arrival position with surrogate data is higher than with measured data (Figures 1C and 1D). The result indicated that the release parameters had the function of reducing the variability of the ball arrival position. On the other hand, in contrast to the small target condition, the release parameters did not have the function of increasing the hitting rate to the target (Figure 1C and 1D). Our study revealed that the function of the release parameters may be altered depending on the target size, task constraints in abstract terms.

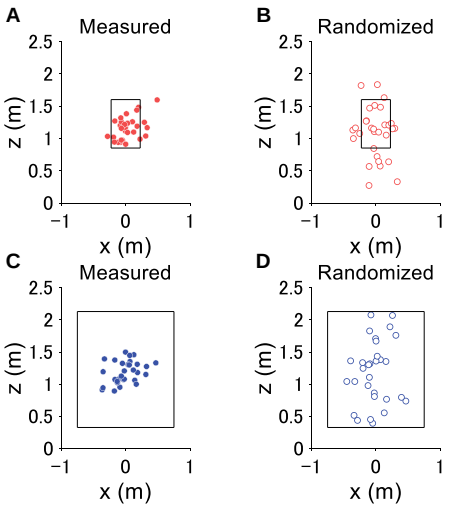

Figure 1 The ball arrival position with the measured and surrogate data in small and large target sizes.

CONCLUSIONS

Our study concluded that the proper interpretation of the function requires the consideration of the task constraints.

INTRODUCTION

Patellar tendinopathy has an incidence of 49.2% among knee injuries (1) This incidence could be conditioned by the neuromuscular deficit in single-leg stabilization actions (2). Being potentially preventable through intervention on modifiable risk factors such as neuromuscular control deficit and muscular imbalances between quadriceps and hamstrings in sagittal plane, and between vastus medialis (VM) and vastus lateralis (VL) in frontal plane.

The objective is to determine whether the use of a dynamic physiotherapy active program focused on improving muscle control of the knee stabilizers is effective in the reversal of neuromuscular risk factors in knee tendinopathies in amateur female soccer players.

METHODS

A sample of 20 amateur female soccer players from C.D. Fuensport (EG) and C.D. Valdefierro (CG) was selected, with an allocation ratio of [1:1]. Initially, muscle activation in the dominant leg (DL) and non-dominant leg (NDL) was assessed by surface electromyography (Trigno Avanty Delsys, Natick, USA). Peak activation of the rectus femoris (RF), vastus medialis, vastus lateralis and biceps femoris (BF) was recorded in two functional tests, Single leg CMJ and the Go-Back test. Gait muscular activation was used for data normalization. After the initial evaluation a physiotherapeutic intervention of specific dynamic exercises was performed on GE for 6 weeks followed by a final re-evaluation. For the statistical analysis, a contrast of variables between independent samples (T-student) and related variables (independent samples t-test) was performed. Finally, the effect size was analyzed using Cohen's d. A confidence level of 95% was established.

RESULTS AND DISCUSSION

Nine EG and eight EC players were analyzed. Significant differences were achieved ($p<0.05$) between groups in both legs in BF activation time. EG recruited all the NDL musculature and BF muscle in DL before braking, which is considered a protective factor of knee injury (3). In contras the CG activated the RF first in DL and VM in NDL, this quadriceps activation could be a risk factor for anterior instability of the knee favoring anterior translation of the tibia (4) and increasing the tension supported by the patellar tendon. Both groups presented a H/Q risky co-contraction ratio both in PD and PND, but GC presented a higher risk ($d>0.8$).

CONCLUSION

Intervention through a physiotherapy program improves neuromuscular control in amateur soccer players. Achieving BF activation prior to braking and H/Q co-contraction close to braking, reducing the risk of patellar tendinopathy injury and knee injury.

INTRODUCTION

The scapula plays an important role in kinetic chain during overhead throwing. Because of high intensity training, bone and tissue adaptations were changed in the overhead throwers. It might change the scapular and humeral motion during shoulder abduction. The purpose of this study was to understand the scapulohumeral rhythm difference between javelin throwers and healthy university students.

METHODS

Six division 1 college javelin throwers and six healthy college students were recruited in this study. The elbow should be placed in a brace at 90° of flexion with the forearm in supination, and special stand was used to made shoulder move on the scapular plane[1]. Electromagnetic motion capture system (Fastrak, Polhemus, 100Hz) was used to capture the shoulder abduction every 10 degrees from 0° to end range. Because of muscle hypertrophy, some javelin throwers test from 10° of shoulder abdction. The trunk, scapular and humerus were defined by 9 points: C7, T8, SN (suprasternal notch), PX(xiphoid process), AA (acromial angle), IA(inferior angle of the scapula), RS (root of the spine of the scapula), EL(lateral epicondyle) 、EM(medial epicondyle)[3] . The scapulohumeral rhythm were analyzed after calculating the angle between humerus and trunk (A_{HT}), the angle between humerus and scapula (A_{HS}) and the angle between scapula and trunk (A_{ST}).

RESULTS AND DISCUSSION

The end range of dominant side was 70.6±5.7 degree in the javelin throwers, 84.8±5.2 in the healthy college students. The scapulohumeral rhythm of dominant side in javelin throwers was 1:5.7 (A_{ST}: A_{HS} =1:5.7), in healthy strudents was 1:4.6 (A_{ST}: A_{HS}= 1:4.6). The relationship between A_{HS} and A_{HT} were shown in figer 1 and figer 2.

CONCLUSIONS

The pattern of scapula and humerus might changed in javelin throwers. The scapula moved less and humerus move more of dominant side during shoulder abduction in javelin throwers. It might increase the loading of glenohumeral joint and over stretched the muscle between scapular and humerus. This change might increase the risk of shoulder injury in javelin throwers.

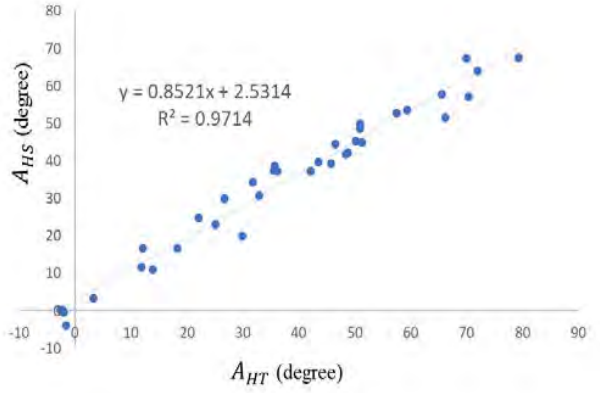

Figure 1 The relationship between A_{HS} and A_{HT} of dominant side in javelin throwers.

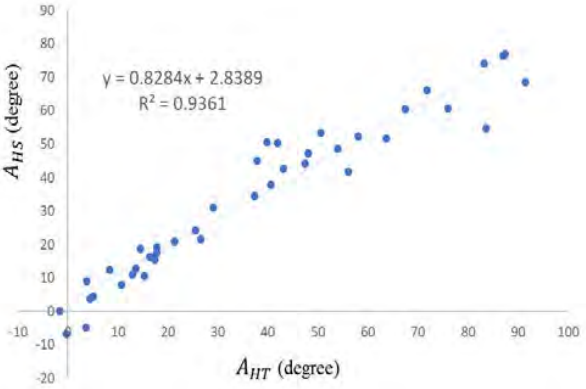

Figure 2 The relationship between A_{HS} and A_{HT} of dominant side in healthy college students.

RELATIONSHIPS BETWEEN THE LOWER EXTREMITY BIOMECHANICS AND FORWARD PROPULSION IN THE PREPARATORY MOTION FOR AN EFFECTIVE JUDO THROW

Takanori Ishii[1], Sentaro Koshida[2]
[1] Centre of Liberal Arts Education, Ryotokuji University, Urayasu, Japan
[2] Faculty of Health Sciences, Ryotokuji University, Urayasu, Japan
Email: ishii@ryotokuji-u.ac.jp

INTRODUCTION

To provide appropriate coaching of throwing skills to athletes, it is necessary to fully understand the kinematic characteristics of throwing skills. Therefore, we sought to elucidate the biomechanical characteristics that differentiate skill levels so that coaches can improve their observational skills to appropriately assess their performance. Ishii et al. (2018)[1] reported that elite athletes landed the pivot foot with a more flexed knee, whereas college athletes landed the pivot foot with a more extended and stiff knee, suggesting that the landing biomechanics of the pivot side may be important in determining the skill level of seoi-nage, one of the most frequently used judo throwing techniques. The study also showed that the elite athletes were able to maintain higher forward propulsion during the preparatory motion, resulting in larger angular momentum generation for an effective throw. Although the authors speculated that the 'soft' landing may be associated with the effective seoi-nage, there are no reports that show whether lower extremity biomechanics during the pivot foot landing are related to forward propulsion in seoi-nage. Therefore, we aimed to identify kinematic variables of the lower extremity associated with the seoi-nage skill by identifying differences in the landing kinematics of the pivot side, forward propulsion, and their relationship between the judo athletes with different seoi-nage skills.

METHODS

The participants were 19 male judo athletes including 3 medallists at the World Judo Championships. Three-dimensional coordinate data for 94 reflective markers on the participants' bodies were captured with 18 cameras of a VICON-MX system at 250 Hz for the tori (the person throwing an opponent) and the uke (the person being thrown by the tori) during seoi-nage movement[1]. The centre of mass (COM) of the tori was estimated using body segment parameters for the Japanese athletes. In addition, we calculated the predetermined kinematic parameters of the whole-body COM and knee of the tori. Finally, the uke's COM angular momentum was calculated, and the top six participants were assigned to the high-skilled group and the bottom six to the skilled group.

A Mann-Whitney U test was performed to test differences between the two groups in the COM acceleration in the anterior-posterior (A-P) and vertical directions, and in the joint angle and angular velocity of knee flexion of the tori's pivot side during the turning phase. In addition, the Pearson's correlation coefficients were calculated between the horizontal knee orientation angle of the tori's pivot side and the COM velocity in the A-P and vertical direction during the turning phase. MATLAB R2022b was used for all the calculations ($p \leqq 0.05$).

RESULTS AND DISCUSSION

In the contrast to the skilled judo athletes, the highly skilled athletes showed little forward or downward COM deceleration during the turning phase. This suggests that the highly-skilled athletes were not exposed to the braking component of the reaction force during the pivot foot landing. There was no significant difference in the knee kinematics during the pivot foot landing. However, we found significant correlations between the knee projection angle at the moment of pivot foot landing and both the A-P ($r = -0.58$, $p < 0.001$) and vertical ($r = 0.84$, $p < 0.001$) components of the whole-body COM velocity at the end of the turning phase. This suggests that the knee orientation at the pivot foot landing is related to the forward propulsion in the turning phase of seoi-nage.

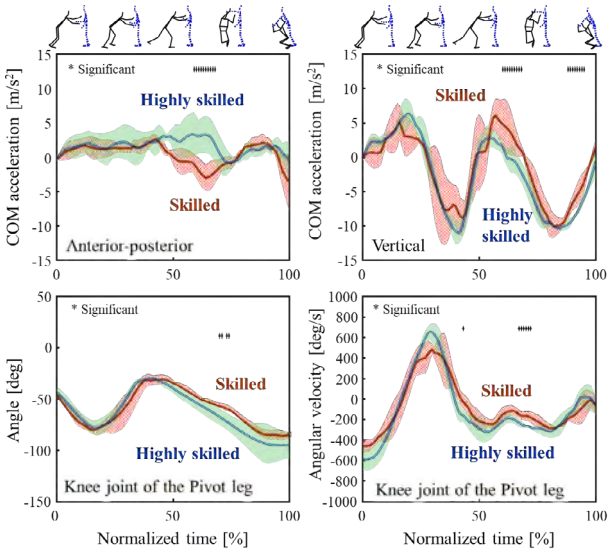

Figure 1 The kinematic variables of highly skilled and skilled judo athletes.

CONCLUSIONS

The highly skilled judo athletes were not subjected to the braking force during the pivot leg landing phase. Although there was no significant group difference in knee kinematics, we found a significant correlation between the deviation angle of hip rotation and the whole-body COM velocity. Coaches may be better to observe foot orientation rather than knee joint angle during the pivot foot landing when coaching seoi-nage.

THE EFFECT OF DECREASING COR OF BASEBALL ON BATTING STATS AND BATTING PERFORMANCE: IN A CASE OF PROFESSIONAL BASEBALL LEAGUE

Shu-Wei Chen[1,3] and Jyh-How Huang[2,3]

INTRODUCTION

The coefficient of restitution (COR) indicates the ability of an object to return to its original shape after being deformed by an outside force. The higher COR of baseball affects the greater exit velocity and flight distance of batted balls [1]. The Nippon Professional Baseball (NPB) used a "unified ball," which has been manufactured with a COR as close as possible to the lower limit for baseballs from 2011 season. It caused that the overall performance of pitchers improved, and the performance of batters dropped a lot [2]. The Chinese Professional Baseball League (CPBL) in Taiwan also reduced the COR of baseball for the unusual high batting stats and long game times. In 2020, the CPBL changed the COR requirement from 0.560 ± 0.200 to 0.550 ± 0.100 before the second half period started. The purpose of this study was to understand the effects of decreasing COR of baseball on batting stats (included hitting average, slugging percentage, and home runs), and batting performances (included exit velocity of batted balls and flight distance of batted balls) in 2 half periods of the 2020 CPBL season. To our knowledge, this is the first study of the effect of the COR of baseball on in-game performance.

METHODS

The data were produced by totally 12 batters who played in the CPBL 2020 season, and all reach on the leaderboard of hitting average, whom had 186 plate appearances per half period at least. At the moment of 2020 season ended, the mean height of these batters was 180.08 ± 3.34 cm, their mean weight was 81.17 ± 10.26 kg, and their mean age was 28.08 ± 4.74 years old. The data of batting stats were obtained from the official CPBL website. The data of batting performance were collected by TrackMan radar tracking system. The study was also approved by the Institutional Review Board (TSMH IRB No. 19-024-B). Due to minimize the ballpark factor, all data of batting performance were collected by a standard TrackMan radar tracking system at the same stadium. The paired-t test were performed to compare the difference of batting stats and batting performances between 2 different half period with different COR of baseball by using SPSS v28.0, and statistical significance was indicated by $p < 0.05$.

RESULTS AND DISCUSSION

The batting stats and batting performences of 2 half periods were presented in Table 1. The hitting avarage, slugging percentage, home runs, and exit velocity of batted ball were significantly lower in the 2nd half period of 2020 CPBL season. The result showed that the batting states and batting performances decreased followed by the decreasing of COR of baseballs. And the unchanged flight distances of batted ball might hinted that the batter adjusted their strategy to adapt the changing of COR of baseball.

CONCLUSIONS

The COR of baseball effect the batting stats and batting performance, and the batters could also adapt by the adjustment of hitting strategy.

ACKNOWLEDGEMENTS

The authors give their heartfelt thanks for the partial financial support by the Ministry of Science and Technology, Taiwan (110-2627-H-028-002). The authors also appreciate the CPBL and Wei-Chuan Dragons to provide the batting stats and batting performance data we analysed in current study.

EVALUATION OF THE MUSCLE WORK IN GYM EXERCISES WITH A "WATER BALL" COMPARED WITH A MEDICINE BALL

Alexis Herbaut[1] and Aurore Valgalier[1]
[1] Human Factors & Ergonomics, Decathlon SportsLab, Lille, France.
Email: alexis.herbaut@decathlon.com

INTRODUCTION

Medicine ball is a useful equipment for both physical conditioning and rehabilitation. Studies showed that regular training with a medicine ball during several weeks allowed to improve functional performance and to gain in muscle power [1, 2]. Also, instability resistance training with unstable surfaces or devices is popular in fitness training facilities to enhance balance, increase core activation and improve motor control [3].

The objective of this study was to evaluate the differences in terms of muscle activities when performing different gym exercises with a Water Ball compared with a Medicine Ball.

METHODS

Twenty-five women participated in the study (age: 27.1 ±4.3 years old, height: 1.68 ±0.07 m, weight: 61.5 ±7.6 kg). Inclusion criteria were to practice a gym activity at least once a week and being injury-free for 6 months.

They tested 2 conditions: control condition was a 3-kg Medicine Ball (MB) and experimental condition was a 3-kg Water Ball (WB). WB was a plastic ball half-filled with water. They performed 3 different exercises during 30 seconds: squat shaking (SS), abdo twist (AT) and backward lunge-vertical raise with dominant hand (LR).

Muscle activities of 14 muscles were recorded with EMG (®DelSys Inc, Boston, Massachusetts, 2000 Hz): Biceps Brachii, Triceps Brachii, Flexor Carpi Radialis, Extensor Carpi Radialis, Trapezius Descendant, Deltoideus Medius, Erector Spinae Longissimus, Rectus Abdominis, Obliquus Internus Abdominis, Gluteus Medius, Biceps Femoris, Rectus Femoris, Vastus Medialis and Vastus Lateralis.

EMG data were processed using Visual 3D software (®C-Motion, Rockville, MD). First, EMG signals of each muscle were filtered with a Butterworth filter (bandpass, 4th order, zero phase lag, bandwidth 20–400 Hz). After rectifying the signal, the EMG root-mean-square value was computed. For each trial, the integrals over time during the 30 sec of exercise were computed to assess the muscle activity.

Statistical analyses were done using XLStat (©Addinsoft Inc, NY, USA). A paired Student *t*-test was used to compare WB and MB. Significant threshold was set at $p<0.05$.

RESULTS AND DISCUSSION

No significant differences were found between WB and MB for SS and AT movements. Significant larger muscle activities were observed for 11 out of 14 muscles in WB compared to MB for LR movement ($p<0.05$, Figure 1).

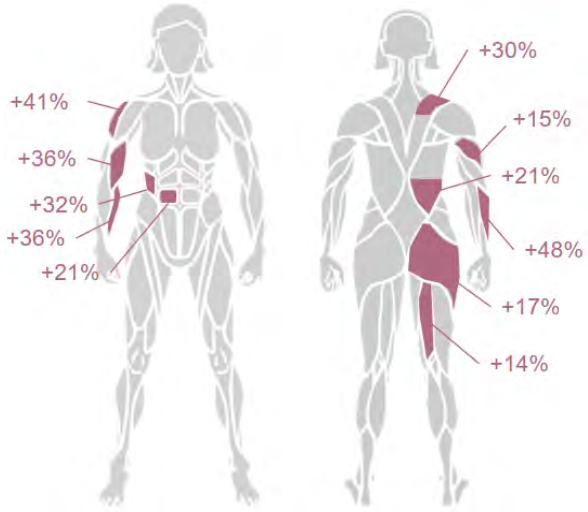

Figure 1 Differences in muscle activities (%) with Water Ball (WB) compared with Medicine Ball (MB) for the backward lunge-vertical raise exercise. Only significant differences ($p<0.05$) are presented.

The main difference between LR and the 2 other movements is that LR was performed with the ball held with only one hand while SS and AT were executed with the ball held with 2 hands. It seems that using the WB with only one hand is the necessary condition to generate the instability and as a consequence to increase the muscle work in order to compensate for it.

CONCLUSIONS

Using the Waterball allowed an increased muscle work compared with a Medicine Ball for exercise performed with one hand.

ACKNOWLEDGEMENTS

The authors would like to thank Decathlon for providing the products to test.

INTRODUCTION

Training the trunk twist muscles with stretch-shortening cycle movements is important in various sports, including throwing and hitting. Bar twist exercises are recognized as plyometrics in trunk-twisting muscles. This exercise is performed in an upright position, and trunk twist is thought to be caused by the rotation of the pelvis. However, only a few studies have examined the role of the lower limbs in exerting trunk twist kinetics. In various sports, the torque that causes the lower limb to rotate the pelvis is increased in the hip abduction position [1]. We hypothesized that changing the hip abduction angle by changing the foot width during bar twist exercises would also change the pelvic rotation and trunk twist torque. This study aimed to investigate the influence of the stance width on trunk twisting in bar twist exercises.

METHODS

The study included 13 male athletes who regularly performed strength and power training (age, 19.69 ± 0.85 years; height, 1.75 ± 0.05 m; mass, 67.91 ± 6.07 kg, mean ± SD). All participants performed the bar twist exercise in Normal (the stance width is wider than the shoulder width) and Narrow (the shoulder width is wider than the stance width) postures. Each trial was performed at least three times. The trial with the highest bar angular velocity was analyzed. The three-dimensional coordinates of the retro-reflective markers fixed on the body (47 points) and the outer ends of the bar (two points) were recorded using eight infrared cameras (200 Hz). The ground reaction force was measured using two Kistler force platforms (1000 Hz). A paired t-test was used to detect differences in the means of each variable. Effect sizes were calculated using Cohen's d and interpreted using the following scale: 0.2–0.5, small; 0.5–0.8, medium; >0.8, large. The alpha level was set at 0.05.

RESULTS AND DISCUSSION

The maximal angular velocity of the bar and trunk twist and the maximal trunk twist torque during the Narrow were significantly smaller than that during the Normal. These variables have large effect sizes. Therefore, the narrow posture may be a less trunk explosive force- and power-developing exercise in bar twist exercises than the normal posture. The pelvic rotation torque defined as the torque exerted by the hip joint torque, and the force around the superior–inferior axis of the pelvis through the left and right hip joints was not significantly different between the narrow and normal postures. Moreover, these variables have small effect sizes. Although lower limb flexion–extension movements contribute to the pelvic rotation torque [1], the lower limb joints were not restricted in this study. The results suggested that the narrow and normal postures have different lower extremity kinematics that affects the pelvic torque.

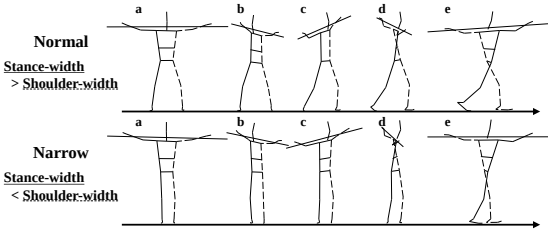

Figure 1 Difference in foot placement during the bar twist exercise. Participants rotate the bar clockwise from a to b and then rotate counter-clockwise (b to e).

CONCLUSIONS

In bar twist exercises, a narrow stance width decreases the trunk twisting torque.

ACUTE: CHRONIC WORKLOAD RATIO AND ACCUMULATED NEUROMUSCULAR FATIGUE IN COLLEGE MALE RUGBY SEVENS ATHLETES: A PILOT STUDY

Qianhui Sun [1], Heng-Ju Lee [1]

INTRODUCTION

The relationship between training load and sports injury has recently received intense attention and discussion. The acute and chronic workload ratio (ACWR) is considered an influential factor in monitoring sports injuries. Rugby league athletes with ACWR between 0.85 and 1.35 are more resistant to injury [1]. However, the relationship between ACWR and accumulated neuromuscular fatigue is not clear. At the same time, single-point variables like jumping height or peak force and power are not sensitive enough to neuromuscular fatigue [2]. The countermovement jump (CMJ) test is the gold standard for neuromuscular fatigue monitoring. Therefore, Twenty CMJ variables with ACWR in different intervals for college male rugby sevens athletes have been compared in this study.

METHODS

Data were collected from five male college rugby sevens athletes (18.6±1.2 years, 1.73±0.02m, 74.1±7.37Kg) in 4 weeks. The workload was estimated by multiplying the session rating of perceived exertion with the CR-10 scale by the session duration in minutes after every training session. One-week data (acute workload) and four-week rolling average data (chronic workload) were used to calculate ACWR. Athletes whose ACWR was either below 0.85 or over 1.35 would be classified as a non-ideal group (NIG), and the others would be the ideal group (IG). Force plate sampling at 1000Hz was used to collect data on CMJ performance for everyone at the beginning of the first week as the baseline and the end of the fourth week and the changes were examined through the differences between two weeks divided by the baseline data multiplied by 100%. Twenty CMJ variables were assessed, including velocity, power, force, and time during concentric and eccentric jump phases calculated by MATLAB. An unpaired t-test ($\alpha<0.05$) was applied to compare the CMJ performance between NIG and IG.

RESULTS AND DISCUSSION

There are two athletes in NIG whose ACWRs were 0.84 and 0.78, respectively. Three athletes in IG (ACWR: 1.12, 1.01, and 1.08). 2 variables, duration in unweighting phase and time to peak force, among 20 have shown significant differences between the two groups shown in Table 1, which may reflect the importance of variables exposing CMJ mechanics instead of single-point variables or jumping output. Time to peak force in IG has increased but decreased in NIG, which may show that different ACWR reflecting different training loads and accumulation of training stress have led to different alterations in CMJ mechanics. In a previous study, a longer time to peak force was also found after a 6-week progressively increased training load for elite female rugby sevens athletes [3]. Because of the limited sample size, further investigation into the relationship between ACWR and CMJ performance should be conducted.

CONCLUSIONS

Male rugby sevens athletes with different levels of ACWR may have different accumulated neuromuscular fatigue reflected by CMJ performance. Moreover, a thorough analytical approach to CMJ performance is advised for practitioners.

INTRODUCTION

Taekwondo Poomsae is recognized as a combination of postures, kicks, and hand techniques, but it was not scored as an official Olympic event because the scoring process was too subjective. Especially in the three-person team posture, the estimation of time consistency cannot be discerned by the eye, so how to quantify it becomes very important. In this study, a method was proposed to obtain motion signals through a wearable inertial measurement unit (IMU) to achieve the estimation of time consistency in Taekwondo Poomsae performance (Koryo-type), and then to assess the level of the group of athletes. It is expected to reduce the subjective scoring of group character judges.

METHODS

The subjects in this study were two groups of Taekwondo athletes. One group was composed of three 2022 World Championship champions (age: 20.5 ± 0.5 years, height: 175 ± 10 cm, mass: 66 ± 8 kg) and the other one was composed three sparring athletes (age: 24 ± 2 years, height: 171 ± 4 cm, mass: 65 ± 7 kg). All athletes wore inertial measurement unites (DOT, XSENS, USA) on their right wrists and left and right ankles, and performed a group exercise in a Koryo-type.

The sampling rate of IMU was 120Hz. A 40Hz low-pass filter was employed to eliminate the noise in acceleration data. The time consistency was evaluated by calculating the sum of the absolute differences in time to resultant acceleration peak between the three athletes.

RESULTS AND DISCUSSION

The world champion group has better movement consistency because of less time difference in peak acceleration occurrence (Table 1). The IMU can effectively obtain acceleration data during training and competition. It can also effectively tell the different levels of Taekwondo athletes by measuring the acceleration peak and its time of occurrence. Wearable devices are easier to implement and non-invasive, it can be placed on the athlete's body to capture their movement information [1]. IMU usually obtains the quantization criteria in motion by detecting the measured acceleration or angular velocity signals: maximum value, minimum value, or slope change [2]. With the use of IMU in Taekwondo Poomsae, the temporal and spatial characteristics of the athletes' practice of the three different postures were also effectively monitored and evaluated [3]. The IMU is easy to use and allows for effective monitoring and acquisition of athletes' time parameters in group pins, in line with previous studies.

CONCLUSIONS

IMU can evaluate athletes' time consistency in Taekwondo Poomsae, and the collection of these data can compensate for the lack of quantitative data in previous training and competitions.

INTRODUCTION

Components of artifical turf, such as infill material and fibre density, can be manipulated to alter the mechanical properities of the playing surface. Previous research has shown infill material [1,2] and fiber density [2] can influence rotational traction and athlete biomechanics. However, the influence of fibre components of an artificial surface remain unknown; therefore, the purpose of this study was to determine the influence of fibre parameters on surface traction.

METHODS

Twelve different artificial turf surfaces were mechanically tested on a robotic testing machine. The surfaces had systematic changes in fibre pile height (length of fibres), face weight (weight of the fibre pile), thatch ('root zone' of artificial turf), gauge (distance between two adjacent artificial fibre yarns), stich rate (number of stitches per 10cm), and denier (linear density of the fibre yarn).

The testing machine consisted of a six degree of freedom P2000 servo-driven parallel link robot (Mikrolar Inc., Hampton, USA) utilizing a movable platform stationed under a rigid steel frame. The turf to be tested was rigidly attached to the movable platform of the robotic testing machine and a right prosthetic foot, which was used to simulate a physiological foot, was fitted with a size 10 shoe (adidas 16.4 FXG cleat). The shoe and foot were attached to the frame of the robotic testing machine at 20° of plantarflexion in series with a triaxial load cell (AMTI, model MC5, Waterton, USA) to measure the forces and moments in all three orthogonal directions during testing.

Rotational traction testing was performed by raising the platform to apply a 650 N normal load to the shoe, after which the platform was internally rotated 20° at a speed of 75°/second. Force and moment data were recorded by the load cell at 1000 Hz throughout the duration of each test. Rotational traction between the shoe and each surface was defined as the peak moment about the vertical axis. A total of five trials were performed at different locations on each surface condition.

Linear traction testing was performed by raising the platform to apply a 650 N normal load to the shoe, after which the platform was moved linearly. It was moved forward to simulate acceleration forces and backwards to simulate braking forces for five trials of each. All trials were performed at different locations on each surface condition to account for surface wear. Linear translational traction was measured in two orientations: i) parallel to the fibre stitching and ii) perpendicular to the fibre stitching.

RESULTS AND DISCUSSION

Changes of translational and rotational traction from each fibre parameter are shown in Table 1. For both translational and rotational traction, all variables had a moderate effect on traction, with the exception of thatch. Stitch rate and gauge had the largest effect on both translational and rotational traction, with increasing stitch rate and gauge lowering traction.

Table 1. Largest percentage change in traction for each parameter.

Fibre Parameter	Translational Traction	Rotational Traction
Pile Height	10.4 %	6.5 %
Face Weight	13.6 %	6.8 %
Thatch	1.4 %	2.7 %
Gauge	22.6 %	8.9 %
Stitch Rate	22.5 %	10.5 %
Denier	17.1 %	4.3 %
Orientation	8.8 %	-

CONCLUSIONS

The results of the current study indicate that artificial turf fibres can influence traction, with stitch rate and gauge having the largest effect. Future work can create an optimal surface from combining these results with previous literature and determine its influence on athlete biomechanics and injury risk.

CLUB HEAD PARAMETER OF EFFECTING AMATEUR GOLFER'S SMASH FACTOR IN REAL GOLF COURSE SITUATIONS

Tsung-Yu Huang[1], Yu-Wei Chan[1], Chia-Yu Jih[2] and Wen-Tzu Tang[1*]
[1] Department of Athletic Training and Healthy, National Taiwan Sport University, Taoyuan, Taiwan

INTRODUCTION

Smash factor is an important indicator of golf performance (Kim & Ridgel, 2019; Lynn et al., 2013; Tilley & Macfarlane, 2012). Smash Factor is ball speed divided by club speed. For example, a smash factor of 1.3 means that when the club speed of 100 mph, the ball speed is 130 mph. The better golf swing has a smash factor of 1.50 means that when club speed of 100 mph and. ball speed is 150 mph. Improving smash factor will help increase the amount of energy transferred from the club head to the golf ball, even with the same club swing speed. From clubhead related parameters such as club speed, dynamic loft, attack angle, face angle, and club path at impact ball, there are several factors that contribute to smash factor. However, it is unclear which parameters are critical factor related to Improve smash factor. Therefore, the purpose of this study is to explore the correlation analysis between smash factor and club head parameters and find out the important factors that affect hitting efficiency. Providing coach or player related information will help improve swing performance.

METHODS

Five amateur handicap golfers participated in this study (mean handicap of 91±6.51; mean height of 175±4 cm; mean weight of 77±8.80 kg). The golfer had at least years' experience. Before performing the experiment, all participants signed an informed consent form to confirm their understanding of the experimental process. Participants were informed of the benefits and risks of the investigation prior to signing an institutionally approved informed consent document to participate in the study. This study uses the trackman instrument to measure the smash factor and other swing data of players' swings. Participants were instructed to warm up for ten minutes before entering the stand-by experimental swing position. Each golfer must swing with a 9 iron on the tee. Participants were asked to perform a exert maximum effort in performing every swing. Each participant performed 12 swings with a break of one minute between each swing. Pearson product moment correlation coefficients were calculated between the smash factor and club delivery/ ball launch. All statistical analyses were performed with SPSS version 20.0 (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

The results of this study showed that each player could observe a significant relationship between smash factor and face angle. And other parameters were not significantly correlated (table 1). When the face angle is larger, the club face is more open, and the ball will be shot to the right. The swing speed cannot transfer effectively form club to ball. Therefore, the face angle is larger, it will reduce the smash factor.

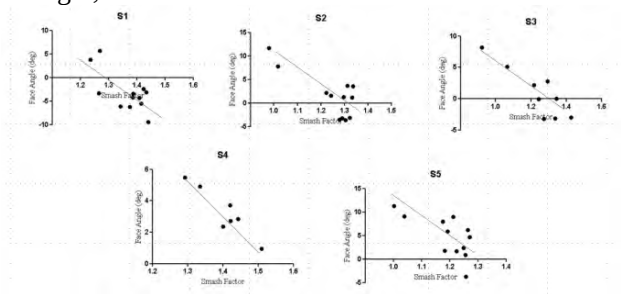

Figure 1 The correlation coefficients between the smash factor and face angle for all participants; S: Subject.

CONCLUSIONS

Our research found that the face angle error was primary factor that cause decreasing smash factor at the amateur level. This also means accuracy control the face angle is important to help improve their smash factor at the amateur level.

BIOMECHANICAL FACTORS AFFECTING LONG JUMP DISTANCE IN JAPANESE MALE UNIVERSITY ATHLETES

Yamato Takayama [1,2], Masaki Morinaga [1], Taiki Komatsu [1], Yuzo Koyama [1] and Kentaro Yamanaka [2]

[1] College of Sports Sciences, Nihon University, Tokyo, Japan.

INTRODUCTION

A number of studies have investigated the factors that affect jumping distance in the long jump. Using a multiple regression approach, Graham-Smith & Lees [1] demonstrated the regression equation for long jump distance in UK male national-level long jumpers: jump distance (m) = 1.396 + 0.485 S_{TD} (Speed of the CM at touch-down) [m/s] + 5.836 $H_{TD\text{-}TO}$ (Change in Height from touch-down to take-off) [m] – 0.655 $S_{TD\text{-}TO}$ (Change in Speed from touch-down to take-off) [m/s]. However, no study has clarified the factors that affect the long jump distance in Japanese male university athletes with different skeletal structures, muscle strength, and performance level. In this study, therefore, we investigated the factors affecting long jump distance in Japanese male university athletes using a method similar to that of Graham-Smith & Lees [1].

METHODS

Four male university athletes who signed a consent form (21 ± 1.2 years old, 174.7 ± 0.8 cm, 67.0 ± 3.39 kg) participated in this study. For a total of eight trials during Men's Long Jump in Nihon University Competition, three-dimensional (3-D) coordinates of fourteen retro-reflective spherical markers were measured by an 8-camera motion capture system (VICON) at a sample rate of 200 Hz. The markers were fixed to anatomical landmarks on the right and left side of the athlete's toe, ankle, knee, hip, shoulder, elbow and wrist. The jumping distance was measured using a measuring tape. Using by the 3-D kinematic data around the long jump take-off, we conducted a multiple regression analysis and identified factors contributing to long jump distance. Following the results of Graham-Smith & Lees [1], we chose long jump distance as the dependent variable and S_{TD}, $H_{TD\text{-}TO}$, and $S_{TD\text{-}TO}$ as explanatory variables (Figure 1).

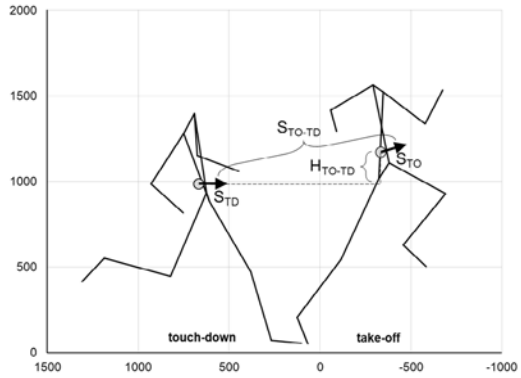

Figure 1 Stick figure representation of biomechanical parameters used as explanatory variables in multiple regression analysis.

RESULTS AND DISCUSSION

Table 1 shows the results of multiple regression analysis. The multiple regression equation of two explanatory variables in S_{TD} and $H_{TO\text{-}TD}$ significantly explained the jumping distance in Japanese male university athletes.

CONCLUSIONS

By multiple regression analysis using biomechanical parameters, we could clarify the factors that affect the long jump distance in Japanese male university athletes. It is expected that such data will be applied to sports coaching to improve performance.

ACKNOWLEDGEMENTS

The authors are grateful to all of the athletes who participated in this study.

INTRODUCTION

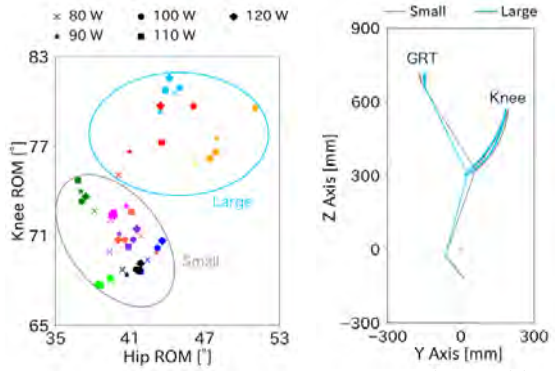
In pedaling movements, an appropriate saddle height is important to achieve efficient performance and prevent the lower limb injuries. Even though many conventional saddle height adjustments seem to assume that the pelvis does not move, recent studies have implied that the pelvis vertically moved in pedaling movements[1]. This means that the position of the hip joint also moves during pedaling motion, and then the lower extremities change based on the pelvic motion. Therefore, the purpose of this study is to clarify the relationship between the hip joint position and the joint angles of the lower extremity in pedaling movements.

METHODS

Ten healthy male volunteers (23±2 y/o, 1.70±0.05 m, 60 ±7 kg) were recruited for this study. They had no prior cycling training experience. Each subject performed pedaling motion at a comfortable saddle height. The subjects were asked to perform pedaling motion at 90 rpm and the workload of 80, 90, 100, 110 and 120 W. Three-dimensional kinematic data were recorded using an optical motion capture system (200 Hz). Using the reflective markers placed on the anatomical characteristic points of the lower limb, the joint position and the joint angles of the hip, knee and ankle were evaluated. In this study, the significance level was set to $p < 0.05$. Also, the significance level was evaluated using Mann-Whitney-U-test.

RESULTS AND DISCUSSION

Figure 1(a) shows the relationship between the ranges of motion (ROM) of the hip and knee joint angles. The subjects were divided into two groups; the Large group has the large ROM of both joints and the Small group has the small ROM. The Large group significantly shows that the length of the lower extremity is shorter than the Small group (803.2±14.7 < 842.5±20.0 mm). Figure 1(b) shows the averaged trajectories of the joint position of the greater trochanter (GRT) as the hip and knee, ankle and the 5th metatarsal joint as the toe. In the Large group, the hip and knee positions show larger trajectories than the Small group. Especially, the Large group moved the hip and knee joint positions more downward around the bottom dead center (BDC) than the Small group. On the other hand, the ankle and toe



(a) ROMs of the hip and knee joints. Each color expresses one subject. **(b)** Trajectory of the joint positions.

Figure 1 ROM and trajectory of Large and Small groups

positions show similar trajectory shapes, and the joint positions do not show a large difference around BDC. The Large group has shorter lower extremities, and then the group should had needed to make the length long from the hip to the toe around BDC. Therefore, the group should extend both of the hip and knee joints around BDC. Of course, the Large group had been potentially able to move the joints to the lower positions, because all the subjects adjusted the saddle height to pedal comfortably in this study. However, in the low position, the Large group should have required to flex more the hip and knee joint angles because the crank length is large relative to the saddle height compared with the Small group. To avoid excessive flexion, the Large groups could be prefer to a high saddle position. Thus, the Large group moved the hip and knee positions downward, and the trajectory was different from the Small group.

CONCLUSIONS

In a pedaling movement, the subjects were divided into the two groups based on the range of the hip and knee joint angles. The Large group significantly moved the positions of the hip and knee joints around BDC.

INTRODUCTION

In archery, shoulder pain is likely occur during the full draw phase. One of the factors for shoulder pain is subacromial impingement syndrome (SIS). SIS is primarily caused by collision of the humeral head and the acromion, with the acromiohumeral distance (AHD) between the humeral head and the acromion being smallest in abduction, internal rotation, and horizontal adduction positions of the glenohumeral (GH) joint. Beginners and non-experienced archers tend to have a large horizontal GH adduction angle by the string tensions at full draw [1]. However, the effect of archery experience on kinematics of the shoulder girdle and AHD at full draw is unknown. This study aimed to compare the AHD , additionally the angle of the GH and scapulothoracic (ST) joint in the frontal, sagittal, and horizontal planes during full drawing between experienced and non-experienced archers and to prevent SIS in beginner archers.

METHODS

Twenty-two healthy men participated in this study. Those with at least 1 year of archery experience were included in the archer group and those with no archery experience in the control group. Kinematic data of the ST and the GH joint were obtained using an electromagnetic tracking device (Liberty; Polhemus, Inc., USA) from all participants (archer group: 7, control group: 15) during drawing motion with and without the bow string. Full draw was as the period from 1 second before the release of the string (release) to the release. The AHD was measured under three conditions at the standing (the shoulder in 0 degrees of abduction and the humerus in a neutral position) and full draw positions (with and without the bowstring) using B-mode ultrasound (SONIMAGE MX1; Konica Minolta, Inc., Japan). The probe was fixed at the midpoint of the acromion on the bow string side in all conditions. Three images of the subacromial space were acquired for each condition, and the AHD (mm) was defined as the distance from the most lateral side of the acromion to the superior margin of the humeral head [2]. The statistical analysis used two-way ANOVA by the archery experience and the conditions ($p<0.05$).

RESULTS AND DISCUSSION

In the kinematic data, only the GH horizontal adduction angle showed an interaction effect on archery experience and the use of bow string ($\eta^2=0.074$, $p<0.05$). The main effect of archery experience was observed in ST internal rotation, posterior tilt, and GH abduction angle ($p<0.05$). There was a significant interaction effect of AHD on archery experience and conditions ($\eta^2=0.346$, $p<0.001$). No significant differences were observed between groups in the without-bow-string condition ($p=0.652$). A significant difference shows between groups in the bow string condition ($p<0.05$); the AHD was larger in the archer group than that for the control group (**Figure 1**).

Archers have greater shoulder extensor strength because they resist horizontal adduction moments in every drawing motion. In this study, the difference in shoulder extensor strength in each group may have also led to intergroup differences in the ST joint internal rotation and GH joint horizontal adduction angle. In previous studies, archers maintained a full draw position due to lower trapezius and latissimus dorsi muscle activity and string tension to reduce shoulder fatigue from the drawing motion [3]. About the archer group, contraction of the lower trapezius muscle produced higher ST joint posterior tilt and GH joint abduction, and the force of the latissimus dorsi muscle pulling the humeral head downward may have caused an increase in the AHD at full draw with the bow string.

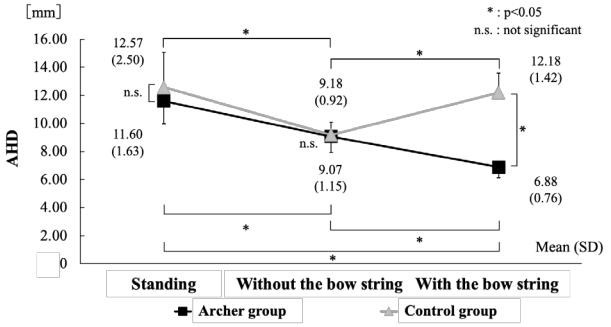

Figure 1 AHD at the standing and full draw positions.

CONCLUSIONS

This study suggested that the reducing the horizontal abduction angle at the full draw may help contain the decrease in AHD due to string tension and prevent SIS for beginner archers.

Differences of maximum inclination and center of mass accelerations between professional and amateur ballet dancers during pirouette in classical ballet

Yurina Tsubaki[1], Yui Kawano[2], and Mayumi Kuno-Mizumura[1]

INTRODUCTION

The pirouette is a fundamental turn in classical ballet and it is crucial to keep the body stable. Previous studies focus on the inclination angle between the vertical axis and the line from the center of pressure (COP) to the center of mass (COM). Previous research has indicated that less experienced dancers have greater difficulty in keeping the line straight compared to experienced dancers while performing in flat shoes [1,2]. However, pirouettes are typically performed while wearing pointe shoes on stage. Thus, it is vital to delve deeper into the movement characteristics associated with pointe shoes, which are more challenging than flat shoes. Therefore, the current study determined differences between professional and experienced amateur ballet dancers regarding the pirouette.

METHODS

A total of seven professional and nine experienced amateur ballet dancers participated in this study. Retroreflective markers were applied to 35 body sites based on the Plug-In Gait full-body model. An 8-camera motion-capture system (Vicon MX, 250 Hz) and two force plates (Kistler, 1,000 Hz) were used for data collection. The subjects wore their pointe shoes and performed the right single pirouettes from the 4th position and finished in the 5th position (Fig. 1) until they achieved three successful trials. All participants preferred to perform right pirouettes. The motion was divided into four phases (Phase 1: turn initiation, Phase 2: single leg initiation, Phase 3: single leg support, and Phase 4: ending) following a previous study (as outlined in Figure 1). The analysis items were the maximum anterior-posterior and gesture-supported leg-side inclination between the straight-line connecting COP and COM (COP-COM) and the vertical axis in each phase. Furthermore, the maximum anterior-posterior and gesture-supported leg-side COM acceleration were calculated. The average of the three trials was used for statistical analysis. Unpaired t-tests or Mann-Whitney U tests were employed to evaluate differences between the two groups, depending on the regularity of the data. Statistical significance was set at $p<0.05$.

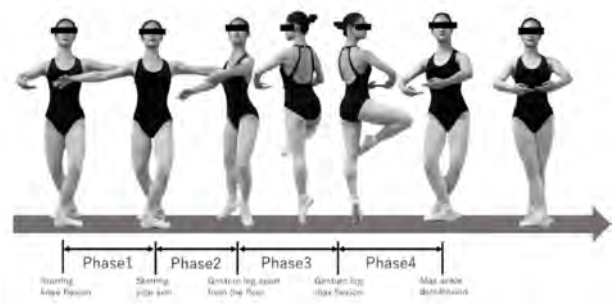

Figure 1 Task and phase division

RESULTS AND DISCUSSION

For the COP-COM inclination, there were no significant differences across Phases 1 to 3. Table1 presents the result of maximum COP-COM inclination and COM accelerations in phase 4. Professional ballet dancers exhibited significant fewer posterior inclinations than amateur dancers ($P<0.05$). Additionally, professional dancers demonstrated lower maximum accelerations for both posterior and support leg side in Phase4, when compared to amateur dancers ($p<0.05$). These findings suggested that, compared to amateur experienced dancers, professional dancers possess a greater ability to control the acceleration of their COM and maintain a less forward inclination during the ending phase.

CONCLUSIONS

In this study, we compared professionals and experienced amateurs regarding the inclination of the COP-COM and the acceleration of the COM in Pirouette. The difference between professionals and experienced amateurs was observed only in Phase4, which is the ending of the motion This fact contributes to a deeper understanding of the sophisticated movement patterns of pirouettes with pointe shoes.

INTRODUCTION

Arabesque, which is known as a basic pose in classical ballet. Several kinematic studies have reported that skilled dancers showed more pelvic motion in performing arbesque than novice dancers [1,2]. In addition, abdominal muscles have been known to play important roles for postural support before limb movements [3]. However, trunk muscle activitiy for performing arabesque has not been fully elucided.
Thus, we investigated the role of trunk muscles during arabesque.

METHODS

Five experienced contemporary dancers [age: 27 to 44 years old, 2 men and 3 women (height: 161.6±4.6 cm, weight: 50.0 ± 3.7 kg)] volunteered for this study. Participants were recruited from professional dance companies and signed written consent forms prior to participation. This study was approved by the ethical committee of Teikyo Heisei University (Approval No.2021-066). Thirty-nine reflective body markers were applied to each subject. A Three-dimensional motion analysis system (Vicon Nexus 2.5, sampling frequency: 100 Hz) and force plate (Kistler, sampling frequency: 1,000 Hz) were used to quantify the pelvis and the right leg motions. Furthermore, surface EMG (DELSYS, sampling frequency: 1,000 Hz) was used to analyse the trunk muscle activities. EMG electrodes were placed on the following muscles: rectus abdomins (RA) and lumber erector spinae (ES). The average root mean square of EMG amplitude with Butterworth filter (20 to 400 Hz passed) were using each trial. Participants practiced the movement sequence – standing position, passe, attitude, arabesque, to standing position. Each posture was held for two seconds. The right leg was the gesture leg for all participants. Medians and interquartile ranges (IQR) were calculated.

RESULTS AND DISCUSSION

During the arabesque phase, the median anterior pelvic tilt was 46.7 (IQR 39.7 to 57.2)° , the median obliquity angle toward the left leg was -1.9 (IQR -2.5 to -1.9)° , and the median transverse rotation angle toward the right leg was 33.5 (IQR 29.9 to 38.3)° (Figure 1). Furthermore, the median ES and RA activities were 19.3 (IQR 7.1 to 22.5) times and 1.4 (IQR 1.4 to 1.7) times, respectively (Figure 2).
In the current study, it is thought that the contribution of the pelvis to gesture leg motion in various ballet movements [4]. Therefore, we confirmed the pelvic rotation and anterior tilt during arabesque using Three-dimensional motion analysis system. Additionally, EMG of ES was increased during arabesque.

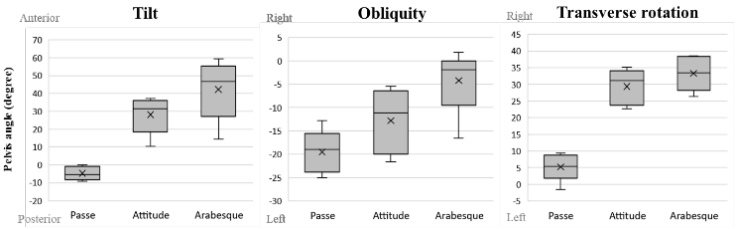

Figure 1 Angular change (pelvis).

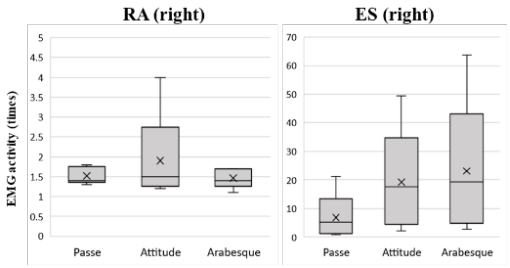

Figure 2 The activities of trunk muscles.

CONCLUSIONS

In conclusion, our study suggests that ES regulate the trunk extension during arabesque. On the other hand, the RA are not directly involved in performing arabesque.
Further investigation is required to elucidate the trunk stabilities of arabesque.

ACKNOWLEDGEMENTS

We thank the dancers who donated their time to participate in this study.

INTRODUCTION

Turnout (TO), which is the external rotation of the lower extremities mainly accomplished by the hip joint, is a major component of ballet movements. While, recent studies have pointed out the possibility that inappropriate TO, which is often called the forced TO, may be involved in the hallux valgus (HV) development of dancers [1]. The forced TO is formed with an excessed turnout angle over the possible external rotation at the hip joint, and it is an apparent turnout created with compensation by the foot hyperpronation and the floor friction. HV is a serious concern to be prevented for dancers because of its pain and deformity which affect their performance. The forced TO is pointed out as the risk factor of HV, however, the effect of forced TO on dancers' HV is unclear [1]. This study focused on the hypermobility of the first tarsometatarsal (TMT) joint which affected the HV development [2] and aimed to examine whether the first TMT mobility is different depending on the forced TO.

METHODS

In total 16 female dancers without HV deformity of pain (32 feet, average age: 18.1 ± 2.3 years old.) participated in this study. Participants performed a plié, the most fundamental ballet movement like a squat, in 3 conditions: Control, Reasonable TO (RTO), and Forced TO (FTO). Participants stood in the neutral position at hip joint internal/external rotation for Control, and The TO angle for RTO was at which each participant could create a maximum active hip joint external rotation. FTO was made as the maximum apparent TO position and it was allowed to use foot pronation or floor friction. Ultrasonography (US) was used to measure the gap of location between the first metatarsal (FM) and the medial cuneiform (MC). US system was synchronized with a 3-dimensional motion capture analysis system to detect a plié duration from the start of knee joint flexion to the end of the extension and calculated the maximum ankle joint dorsiflexion and the average foot pronation angles. The gap in the first TMT joint was represented by the vertical distance of FM minus that of MC. The comparison among 3 conditions for each parameter was performed with repeated measures ANOVA and the Bonferroni method as post-hoc test.

RESULTS AND DISCUSSION

The foot during *plié* in FTO was more pronated compared with in Control and RTO ($p<0.05$). The displacing to the plantar direction in the vertical location of MC and the changes in the gap of the first TMT joint in the FTO were greater than in the other 2 conditions (**Figure 1**).

This study showed that greater displaces to the plantar in MC and change in the gap of the first TMT joint were found with FTO. The forced TO created an apparent TO greater than the angle of external rotation possible at the hip joint is accomplished with the foot hyperpronation. Such inappropriate compensation results in the overload of the midfoot and collapsing of the medial longitudinal arch [3]. Since the lowering of the medial longitudinal arch relates to the hypermobility of the first TMT joint [3], reduction of the midfoot stability and greater valgus force on the first ray of the foot that occurred with the forced TO were considered to relate to the change in the alignment of the first TMT joint. This finding suggests that the forcing of TO may lead to compounds the hypermobility of the first TMT joint and it will be in the negative chain of increased mobility in the first TMT joint and midfoot collapse.

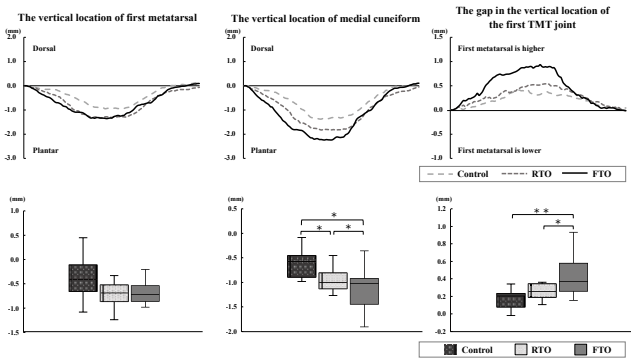

Figure 1 Comparison of the first TMT joint mobility (Upper: temporal data, Lower: moving average) during a plié in 3 conditions. *p<0.05.

CONCLUSIONS

The present study indicated that *plié* in FTO occurs the greater mobility of the first TMT joint. The results suggest that repetitive movements with the forced TO possibly compound the hypermobility of the first TMT joint and lead to HV deformity.

REGULATE VELOCITY ON COMBINED TRAINING IMPROVING THE COLLEGE BASKETBALL PLAYERS JUMPING PERFORMANCE

Chen-Fu Huang, Bo-Ying Chen
Department of Physical Education and Sports Science, National Taiwan Normal University, Taipei, Taiwan.
Email: huangchenfu@gmail.com

INTRODUCTION

Resistance training intensity could be quantified by collecting barbell mean velocity data during the concentric phase (González-Badillo et al., 2010) and using percentage velocity loss (%VL) to determine each set's repetition (Pareja-Blanco et al., 2017). Due to a lack of training time during the season, two training methods (strength and power training) combined into the same training session, Faude et al. (2013) found that combined training improved athletes' muscular strength and jumping ability. However, proper training load to avoid fatigue was critical. Thus, this study aimed to investigate the effect of velocity regulation of combined training on basketball players jumping performance.

METHODS

This study recruited eleven basketball players and divided them into velocity-based training (VBT) (n=7) and percentage-based training (PBT)(n=4). The four-week training program included session one: half squat (HS) and high pull (HP), and session two: trap-bar deadlift (TDL) and power clean (PC), which were performed on different days, three times a week. In addition to combined training, there were another three days of high-intensity technical training a week. Forty-eight hours before combined training, executed the 1 RM test and established the load-velocity relationship profile (LVRP). In the PBT training program, the first two weeks did 80%1RM HS and TDL 4 sets x 8reps and 80%1RM HP and PC 4 sets x 5 reps; the last two weeks executed 85%1RM HS and TDL 4 sets x 6reps and 85%1RM HP and PC 4sets x 3 reps. In the VBT training program, we used LVRP to determine the training load (Table 1), and we used 30%VL in the first two weeks and 20%VL in the last two weeks to regulate repetition. GymAware linear position transducer (50 Hz) was used to collect the barbell velocity, and one Kistler force plate (1000 Hz) collected CMJ parameters, including peak vertical ground reaction force (PGRF), rate of force development (RFD) and jump height (JH). Descriptive statistics were used to explain the results of the study.

RESULTS AND DISCUSSION

The main finding was that PGRF, RFD, and JH increased after four-week training in the VBT group, while the PBT group's PGRF and RFD had a slightly decreased trend (Table 2). The load was fixed for the PTB group; the intensity of the combined training might generate excessive neuromuscular fatigue that reduces the jumping performance. However, the VBT group's load was variable, and the training load would be adjusted according to the prescribed velocity. Table 1 showed that the target velocity was maintained in the first two weeks or the last two weeks, and the training load gradually increased, indicating a trend of increasing muscle strength.

Table 1: VBT group load and velocity training program

	W1	W2	W3	W4
HS	119.4±7.0	122.5±12.6	133.9±6.1	137.0±8.0
	0.54±0.07	0.52±0.04	0.50±0.03	0.49±0.01
TDL	142.1±0.6	154.0±0.6	159.6±0.6	169.5±0.5
	0.64±0.05	0.59±0.05	0.56±0.05	0.54±0.03
HP	67.1±6.7	70.3±7.3	72.2±10.5	77.6±10.8
	1.32±0.14	1.28±0.13	1.21±0.10	1.19±0.07
PC	57.7±8.1	65.1±7.5	64.8±11.7	69.8±10.9
	1.34±0.17	1.30±0.09	1.27±0.05	1.28±0.03

Note: The upper column unit was kg; the lower was m/s.

Table 2: The differences between pre-and post-training CMJ

	VBT	PBT
PGRF(BW)	0.06±0.13	-0.16±0.23
RFD (BW/s)	1.22±1.79	-0.42±0.83
JH (cm)	2.08±1.35	0.77±1.19

CONCLUSIONS

This study aimed to achieve the best training stimulation by regulating the velocity zone during combined training. The results indicated that the VBT group's jumping performance and muscle strength improved because the variable load could avoid excessive fatigue and low-stimulation training. This study recommended that coaches and strength and conditioning trainers can monitor the players' fatigue by adjusting the training velocity and %VL to avoid injuries during training and increase sports performance improvement.

ANTEROPOSTERIOR HAND POSITION AT SET POSTURE AFFECTS THE SUBSEQUENT BLOCK START PERFORMANCE

INTRODUCTION

During a sprinter's acceleration, the starting motion can be divided into reaction and pushing phases. The high performance in both phases has been investigated using the reaction time and external horizontal power [1,2]. Recently, it was found that trunk kinetics is a determinant of block performance [3]. Since skeletal muscles have an optimal length at which the muscle tension maximises [4], there would be an optimal starting posture at which both trunk and lower-limb muscle groups can generate the maximised force. Trunk muscle lengths can be simply adjusted by changing the space between the hand and foot positions. Therefore, the purpose of this study was to examine the effects of changing the anteroposterior distance from the hands to the forefoot at a set posture on various starting performances in the reaction and pushing phases.

METHODS

The participants were 16 male collegiate sprinters (age: 20.5 ± 1.2 years old; height: 174.5 ± 3.6 cm; body mass: 67.6 ± 5.6 kg; 100-m personal record: 10.64 ± 0.16 s). Participants were instructed to perform two block-start trials with five different hand-and-foot spaces (preferred distance [forefoot position from the start line: 45.5 ± 6.0 cm; rearfoot position from the start line: 74.1 ± 7.2 cm], ± 7.2 cm, and ± 14.4 cm) at the set posture. The starting blocks were fixed on two force plates (TFP-404011B, Technology Service, Nagano, Japan) using double-sided tape. The ground reaction forces (GRFs) were sampled at 1000 Hz. To familiarise the participants with the dashes from the five set postures, they performed these trials on another day. The external horizontal power was calculated by the average value of external power in an anterior direction to translate the whole-body centre of mass.

RESULTS AND DISCUSSION

Many previous studies have reported that start performances are affected by the set posture, which is especially adjusted by the block space [5]. In contrast, we first clarified the effect of changes in anteroposterior distance from the hands to the forefoot block.

It was found that the longer the hand-and-foot space, the higher the external horizontal power (Figure 1). Compared to the external horizontal power in the trial with the athlete's preferred posture, it increased by 15% in the +14.4-cm trial; in contrast, it decreased by 13% in the −14.4-cm trial. Interestingly, in the longer hand-and-foot space trials, the horizontal GRF impulses, especially the rear-foot impulses, significantly decreased. In contrast, the pushing time was significantly shorter in the longer hand-and-foot space trials. The higher external horizontal power is directly contributed by both the high horizontal GRF impulse and the short pushing time. Therefore, it was suggested that a shorter pushing time remarkably contributes to achieving higher external horizontal power when the hand-and-foot space is lengthened at the set posture.

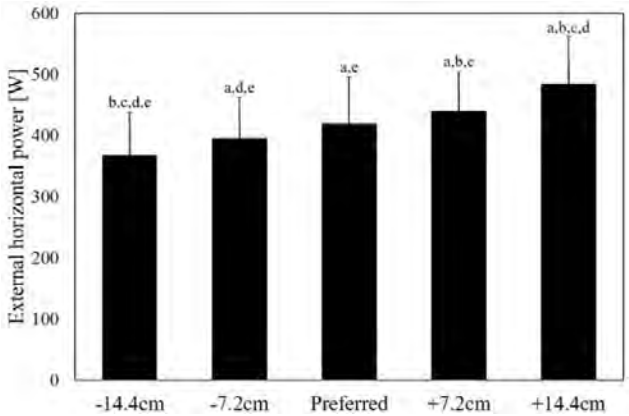

Figure 1. External horizontal power in the five trials. Significant differences between the −14.4-cm, −7.2-cm, preferred distance, +7.2-cm and +14.4-cm trials are denoted by a, b, c, d, and e, respectively ($p < 0.05$).

CONCLUSIONS

We first examined the effects of changing the hand-and-foot space at the starting posture on the subsequent starting performances. It was found that a higher external horizontal power was significantly enhanced when the hands were positioned further away from the feet in the set posture compared to that in the preferred posture. The long length of "bridge" at the set posture may allow sprinters to accelerate more largely. Conversely, in the athletic sprint event, the longer hand-and-foot space increased the running distance from the forefoot. Therefore, sprinters should select a balanced set posture considering the negative effect of increasing the subsequent running distance.

INTRODUCTION

A pole vault event is a competition in which athletes compete in the maximal height of an upward leap, following an approach run using an approximately 2 kg bar (pole). Previous studies reported that the higher the peak approach-run speed, the higher the maximal height of centre of mass (COM) during a leap [1]. The most common measurement device for analysing approach-run speed uses a laser displacement meter or high-speed camera to obtain the position of the jumper's body [1,2]. During the approach run until the pole plant, the vaulter not merely runs with holding the pole but also immediately tilts it forward before plunging into the box. Therefore, the mass and forward-leaning motion of the pole should be considered in the rigid-body model as a whole system when analysing the approach-run speed. Therefore, the purpose of this study was to test the agreement between the approach-run speeds of pole vaulters calculated using three different methods: 1. using the COM position of the body-only model (body-only method), 2. using the COM position of the whole-system (body + pole) model (whole-system method), and 3. using the position of the jumper's back position obtained using a laser displacement meter (laser method).

METHODS

The participants were 15 male collegiate athletes (height: 1.72 ± 0.05 m; mass: 66.6 ± 5.4 kg; personal record: 4.20 ± 1.03 m) with adequate experience in pole vault competition. A high-speed camera (RX IV, SONY, Tokyo, Japan) was placed at approximately 90 m from the right side of the running course to capture all trials during the competition. The sampling frequency of the high-speed camera was 240 Hz. A Laser displacement meter (LDM301S, Jenoptik, Germany) was placed on a 1.2-m tripod 48 m behind the vault box. The sampling frequency of the lase displacement meter was 100 Hz. A total of 19 trials were used for further analysis. The body-only model was created with a 14-segment rigid-body model. The mass of the pole and its centre position were measured directly before the trials and used for the whole-system model. The two-dimensional positions of the whole body and poles were obtained in the sagittal plane using a digitising software (Frame-DIAS 5, Q'sfix, Tokyo, Japan). Approach-run speeds in the body-only and whole-system methods were calculated using the first-time derivatives of the COM and pole position. To quantify the agreement between the methods, Bland–Altman tests were used between the whole-system and the other two methods for several variables of approach-run speed.

RESULTS AND DISCUSSION

A large proportional bias was observed in the peak approach-run speed when the laser method was used (r = 0.75; Figure 1). By the laser method, the peak approach-run speed of over 8.0 m/s was overestimated; in contrast, that of less than 8.0 m/s was underestimated. The great record in the pole vault is related to the approach-run speed [1]; therefore, it is suggested that comparing approach-run speeds between different record groups should be avoided because overestimated differences are largely observed. In addition, a random error of ± 0.44 m/s was found in peak approach-run speed in the laser method (Figure 1). Koyama et al. (2019) found that the difference of 0.10 m jump height is related to the difference of approach-run speed of 0.09 m/s by its regression equation [3]. Hence, changes in the approach-run speed of an athlete should be carefully assessed using the laser method.
As the other result, there was a fixed bias of −0.06 m/s in decreases in approach-run speed at the pole plant in the body-only method.

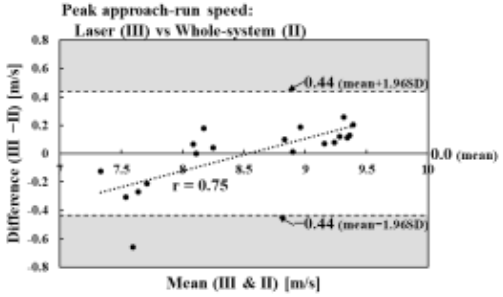

Figure 1 The degree of agreement between the two methods for the peak approach-run speed according to the Bland-Altman analysis.

CONCLUSIONS

Bland-Altman analysis revealed that a proportional bias or fixed bias was involved in the laser and body-only methods, indicating that these methods should be carefully used when assessing the differences between groups or changes within athletes.

Does the lower limb muscularity relate to long-sprint performance in 400-m sprinters?

INTRODUCTION

The generation of large torques by muscles crossing the lower limb joints is necessary for superior sprint performance in sprinters. The joint torque is largely determined by the size of agonist muscle group. We and others previously determined that larger sizes of specific muscles, particularly the hip extensor and flexor muscles (gluteus maximus [GM] and psoas major [PM]), of the lower limb are related to better 100-m sprint performance in sprinters [1-3]. Thus, the lower limb muscularity plays an important role in achieving superior 100-m sprint performance in sprinters. Despite the close relationship between lower limb muscularity and 100-m sprint performance, it is unknown whether the lower limb muscularity plays an important role in achieving superior long-sprint performance in sprinters. In this study, we examined the relationships between lower limb muscle sizes and long-sprint performance in 400-m sprinters.

METHODS

The cross-sectional areas (CSA) of seven muscles of the lower limb in 30 male 100-m specialized sprinters and 30 male 400-m specialized sprinters were measured using magnetic resonance imaging. The seven lower limb muscles included the GM, PM, adductors, quadriceps femoris, hamstrings, dorsiflexors, and plantar flexors. To minimize the effect of difference in body size among individuals, the relative CSA normalized to body mass was also used for analyses of this study. The International Amateur Athletic Federation (IAAF) score was used as a parameter for 100-m or 400-m sprint performance based on the personal best time of the sprinter in each group. Comparisons of the lower limb muscle CSA variables between the 100-m and 400-m groups were performed using an unpaired *t*-test or Mann–Whitney U test. Relationships between lower limb muscle CSA variables and IAAF score in each group were evaluated using a Pearson's product moment correlation coefficient.

RESULTS AND DISCUSSION

Absolute and relative CSAs of all seven lower limb muscles did not differ significantly between 100-m and 400-m sprinters (all *P*s > 0.05). The absolute and relative CSAs of the GM and PM of 100-m sprinters were significantly correlated with the corresponding IAAF scores (Figure 1A: r = 0.455 to 0.538, all *P*s < 0.05). This result is consistent with those of previous studies [1-3]. In contrast, there were no significant correlations between the absolute and relative CSAs of all seven lower limb muscles, including the PM and GM (Figure 1B), of 400-m sprinters and the corresponding IAAF scores (r = –0.303 to 0.337, all *P*s > 0.05). A series of our studies reported that favorable morphological variables of the lower limb bones (e.g., longer forefoot bones) and joints (e.g., greater knee extensor moment arm) were related to better long-sprint performance in 400-m sprinters [4, 5]. Therefore, the bone and joint structures rather than the muscle size of the lower limb may be important morphological factors contributing to superior long-sprint performance in 400-m sprinters.

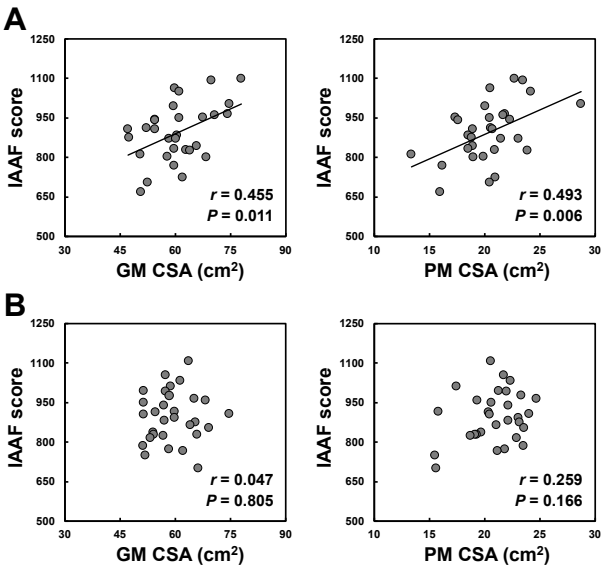

Figure 1. Relationships between CSAs of the GM and PM and the IAAF scores in 100-m (A) and 400-m (B) sprinters

CONCLUSIONS

We found that the lower limb muscularity may not play an important role in achieving superior long-sprint performance in 400-m sprinters. Therefore, the present findings suggest that specific morphological factors contributing to superior sprint performance may differ between 100-m and 400-m specialized sprinters.

INTRODUCTION

Short reaction time to external stimuli is an important ability in various sports involving sprint running. In childhood and adolescence, muscles and nerves develop with age [1]. Therefore, the reaction time and related electromyographic (EMG) latencies of the lower limb muscles would change based on growth. This study aimed to elucidate age-related differences in whole-body reaction time and EMG latencies of the lower limb muscles during sprint initiation.

METHODS

Fifty-four boys aged 5 to 18 years (age, 14.5 ± 5 years; mass, 44.8 ± 22.2 kg; height, 156.6 ± 20.9 cm) participated in this study. The participants performed five sprint starts of 2.0 m on the experimental track. They were instructed to perform sprints, starting from their preferred standing postures. The timing and intensity of the go signal were fixed at 2.0 s and 80 dB, respectively, to reduce the standard deviation of the reaction time [2].

The ground reaction force (GRF) data for both feet were recorded separately using two force plates (9281CA, Kistler Holding AG, Winterthur, Switzerland). Surface EMG activities of the rectus femoris (RF), longer head of the biceps femoris (BF), and lateral head of the gastrocnemius (GS) muscles from both legs were recorded using a wireless surface EMG system (WEB-7000, Nihon Kohden, Tokyo, Japan). The sampling rates of the GRF and EMG data were set to 1000 Hz.

The reaction time of each foot and EMG latency of each muscle were determined by using the onset when the signal first rose above the value of the mean plus four times the standard deviation during the baseline zone (from −0.500 s to 0 s of the go signal; Figure 1).

RESULTS AND DISCUSSION

Chronological age was significantly related to the rear-leg reaction time ($r = -0.64$, $P < 0.05$) and EMG latencies of the rear-leg BF muscle ($r = -0.49$, $P < 0.05$). In contrast, chronological age was not significantly related to the other EMG latencies or reaction time of the front leg. In standing sprint start, the reaction time needed to react to a go signal can be divided into four durations: (1) that taken for the input information to reach the auditory receptors, (2) that taken for the brain to process the information and issue commands to the periphery, (3) that taken for the commands to pass through the spine and peripheral nerves, and (4) that taken for the muscles to exert force towards the ground following the onset of muscle contractions. Therefore, at the sprint initiation, older boys seem to shorten the rear-leg reaction time by shortening all or part of the processing durations in the central and peripheral nerves above-mentioned in the (1)-(3).

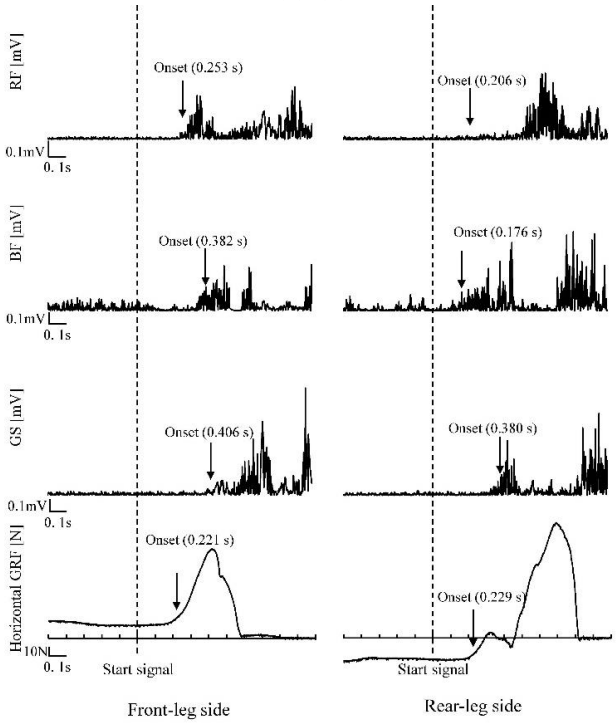

Figure 1. Example of a typical time-series data of the horizontal GRF and EMG signals of the RF, BF and GS muscles at sprint initiation in a boy aged 5 years. Vertical lines represent the timing of the go signal.

CONCLUSION

The findings from this study suggest that the growth and development of speed in sprint initiation is likely caused by shorter muscular latencies of the rear-leg BF. These findings may deepen our understanding of the development of sprint initiation in childhood and adolescence.

CORRELATION BETWEEN CUE TIP SPEED AND KINEMATICS OF 9-BALL BREAK SHOT

Pui Wah Kong[1], Jing Wen Pan[1], John Komar[1] and Chen Yang[2]
[1] Physical Education and Sports Science Academic Group, National Institute of Education, Nanyang Technological University, Singapore.

INTRODUCTION

Break shot is the first shot in cue sports, serving to separate the racked object balls in games. A break shot requires a high cue tip speed, as confirmed by a previous study which revealed that the break shot had a greater acceleration at impact than other types of shots (e.g., top spin shot, back spin shot) [1]. In the literature, there is generally a lack of biomechanical investigations of the human movements while performing cue sports shots. Previous work examined the kinematics of the upper body movements such as joint range of motion (ROM) and peak angular velocity without considering the temporal characteristics associated with these variables [2]. Since temporal characteristics may provide useful information regarding joint movement sequences, it could help researchers and practitioners better understand the cueing movement. Therefore, this study aimed to incorporate temporal aspect to analyze the upper body kinematics that could be related to cue tip speed during 9-ball break shots.

METHODS

This present study was approved by the Nanyang Technological University Institutional Review Board (Protocol Number: IRB-2019-06-37). Twenty-two male, active cue sports players [mean (standard deviation); age 25.2 (5.5) years old; playing experience 5.8 (4.9) years; height 171.8 (5.2) cm; body mass 68.4 (10.2) kg] were recruited. All participants had at least one-year playing experience at the time of the study.

After warm-up, each participant performed 8 break shots with the cue ball remaining on the pool table after the shot. To facilitate kinematic analysis, a 3D motion capture system with 8 infrared cameras (250 Hz, Vicon MX, Oxford Metrics Ltd., Oxford, UK) was used. Retro-reflective markers were placed on the upper body landmarks of the participants and the cue stick.

Kinematic data were analyzed using the Visual3D software (v2021.09.1, C-Motion, Germantown, MD, USA). Data during the movement phase were extracted from the start of forward swing to the end of follow-through. Joint ROM was obtained for negative humeral elevation, elbow flexion/extension, and wrist abduction/adduction. In addition, time to peak angle was determined and time normalized to the movement phase (100%). A Pearson correlation coefficient was computed to examine the linear relationship between cue tip speed and each upper body kinematic variable using JASP (version 0.16.4).

RESULTS AND DISCUSSION

The mean (SD) cue tip speed at impact was 4.7 (0.5) m/s across all 22 participants. There was a significant and positive correlation between the cue tip speed and time to peak elbow flexion/extension angles (Table 1, r = 0.447, p = 0.037).

Table 1: Correlations between cue tip speed at impact and each upper body kinematic variable.

	Mean (SD)	r	p
Range of motion (deg)			
Shoulder	21.2 (13.3)	-0.307	0.165
Elbow	107.2 (43.4)	0.300	0.176
Wrist	28.6 (11.9)	0.217	0.332
Normalized time to peak angle (%)			
Shoulder	74.5 (24.1)	0.014	0.952
Elbow	79.0 (19.2)	0.447	**0.037***
Wrist	78.3 (26.5)	0.063	0.779

Shoulder denotes negative humeral elevation; Elbow denotes elbow flexion/extension; Wrist denotes wrist abduction/adduction.

CONCLUSIONS

This study found that time to peak angle may play a more important role than joint ROM in contributing to cue tip speed at impact in 9-ball break shot. Reaching peak elbow flexion at a later phase of the cueing movement might indicate a greater utilization of the momentum generated from shoulder. This, in turn, can increase the cue tip speed and enhance break shot performance.

Potential injury mechanisms in ulnar collateral ligament injuries; magnitude and variability of elbow load in repetitive baseball pitching

Bart van Trigt[1,1], Thomas van Hogerwou[2,1], Ton (A.J.R) Leenen[3,2], Marco (M.J.M.) Hoozemans[4,2], Frans (F.C.T) van der Helm[5,1], DirkJan (H.E.J.) Veeger[6,1]

INTRODUCTION

High performance in sports is closely related to overuse injuries. A common overuse injury in baseball pitching is the Ulnar Collateral Ligament (UCL) injury, this is due to high and repetitive loads on the medial side of the elbow [1]. To be able to prevent UCL overuse injuries, it is important to understand the effect of repetitive pitching on the UCL load magnitude and variability [2]. We investigated if repetitive pitching influences the elbow load magnitude and variability and if a relationship is present between repetitive pitching and elbow muscle activation.

METHODS

Fifteen asymptomatic male baseball pitchers threw 60 to 110 fastballs until reporting fatigue. Body kinematics were recorded with a motion capture system at 400 Hz. The peak external valgus torque was calculated for every pitch with an inverse dynamical model. Electromyography of three elbow muscles (flexor pronator muscle group (FPM), biceps, and triceps) was recorded at 2000Hz during every pitch. The area under the curve (AUC) of the rectified EMG signal was calculated over a window of 150ms before maximal external shoulder rotation. Co-contraction index (CCI) was calculated for the biceps-triceps muscle pair. A moving window of ten pitches was applied to all variables and moved over a single subsequent pitch. Linear mixed models were used to investigate the relationships between repetitive pitching and the following four outcome variables: (1) within-individual peak external valgus torque magnitude and (2) valgus torque magnitude variation, (3) flexor pronator muscle group activity and (4) biceps-triceps co-contraction index.

RESULTS AND DISCUSSION

The results of the linear mixed models (table 1) showed no significant relationship between the external values torque magnitude and within-individual variability with repetitive pitching on a group level; but both variables showed significant variance in the association across participants (Figure 1, colored lines). On a group level, the FPM activity was not significantly related to repetitive pitching. In addition, the biceps-triceps co-contraction index showed a trend but was not significant in relation to repetitive pitching. The FPM activity and the biceps-triceps co-contraction index showed significant variance in the association across participants. The results indicate the importance of individuality in association with repetitive pitching.

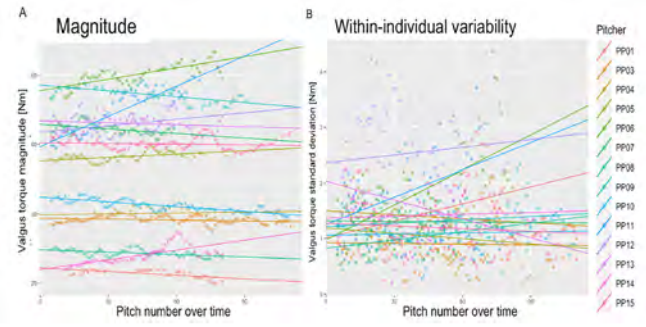

Figure 1 *peak external valgus torque magnitude (A) and variability (B) for each participant associated with repetitive pitching.*

CONCLUSIONS

Significant large differences exist between pitchers in their individual courses in elbow valgus torque and muscle activity with repetitive pitching. This shows the importance of individuality in relation to repetitive pitching. To arrive at effective elbow injury prevention in baseball pitching, individual characteristics of changes in elbow load magnitude and variability and muscle activity in relation to the development of UCL injuries should be investigated.

SEX-SPECIFIC EFFECTS OF FATIGUE ON MUSCLE ACTIVATION DURING A SINGLE-LEG LATERAL JUMP LANDING TASK

Davine Yang, Tailynn Chang, Samuel Lamanuzzi and Julie N. Côté
Department of Kinesiology and Physical Education, McGill University, Montreal, Canada.
Email: davine.yang@mail.mcgill.ca

INTRODUCTION

Knee injuries are common in direction-changing sports, with injury risk increasing with fatigue [1]. Females exhibit around 3 times greater risk of injury than males [2], despite showing similar levels of central fatigue [3]. Imbalances in muscle activation can contribute to injury. Females are known to have greater quadriceps (Q) to hamstring (H) activation [4], as well as lower activation of the lateral H under fatigue [5]. These factors may contribute to dynamic knee instability. However, sex and fatigue effects on muscle activation during typical tasks involved in direction-changing sports are unclear. The objectives of the study were to examine the effects of sex and fatigue on activation amplitude of the Q and H muscles during a single-leg jump landing. We hypothesized that with fatigue, both sexes would have similar decreases in activation amplitude, but that females would have greater increase in muscle coordination ratios.

METHODS

Twenty-five participants (15F; age 21.7 ± 1.8 yrs) were included in the study. Participants were recruited from university varsity sports involving running and/or cutting. Surface electromyography (EMG; Trigno, Delsys) readings were collected from the vastus lateralis (VL), rectus femoris (RF), vastus medialis (VM), biceps femoris (BF), and semitendinosus (ST) muscles of the dominant leg at 2000Hz (Vicon Nexus, UK). Maximal voluntary isometric contractions (MVIC) were conducted for the Q and H muscles. Participants performed the jump landing task before and after a fatiguing cycling protocol of 9 x 30s sets of high-intensity cycling, interspersed by 90s of rest. Three successful jump trials (i.e. when the participant could land on 1 foot and stay for 5s) were taken in each fatigue condition (before, after) for data processing. EMG data were collected for the duration of each jump trial.

All data were processed using custom written Matlab script. Raw EMG data were bandpass filtered and normalized to MVICs. The root mean square (RMS) was calculated during the landing phase of each jump. The group average EMG RMS value across the successful trials was taken for statistical analysis. Effects of sex and fatigue on EMG data were assessed using General Estimating Equations in SPSS.

RESULTS AND DISCUSSION

Significant sex x fatigue interactions on Q activation (P=0.001) and Q:H activation ratio (P=0.002) were found. Females had a decrease in Q activation amplitude and Q:H activation ratio with fatigue, whereas males experienced insignificant changes (Figure 1). No significant effects were found for hamstring activation. Main effects of sex and fatigue were observed on VM and VL activation ratio. Females had a higher VM:VL activation than males (P=0.021) and VM:VL showed an increase in fatigue (P=0.001).

A decrease in Q:H activation towards a 1:1 ratio suggests that muscle coordination imbalances that contribute to knee injury risk may be more related to mediolateral differences. Higher VM:VL activation may contribute to increased medial pull of the knee when landing.

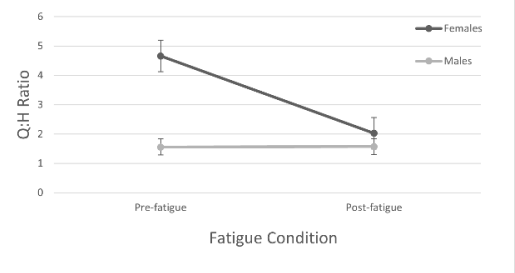

Figure 1 Q:H activation ratio across fatigue conditions, where Q = $\bar{x}$ VL, RF, VM and H = $\bar{x}$ BF and ST EMGRMS.

CONCLUSIONS

The current findings show that females' muscular patterns of knee stabilisation when landing are affected differently by fatigue than males, particularly in Q activation. Decreases in muscle activation may lead to loss of control and instability of the knee joint. Different fatigue protocols, paired with lower extremity kinematics and sideways sporting manoeuvres are worth examining to further understand how changes in muscle activation contribute to knee injury risk in sport.

Effect of taping on muscle activity during squatting exercise

Mao Zeniya[1], Mayumi Mizumura-Kuno[1]
[1] Humanities and Science, Ochanomizu University / Graduate School, Tokyo, Japan.
Email: ma0.zeniya@gmail.com

INTRODUCTION

In squat exercises, the hip, knee, and ankle joints are involved. In this motion, each joint affects the ROM of the other joints [1]. Taping stabilizes joints, however, it can lead to joint restriction. Therefore, squatting with restricted ROM by taping may restrict muscle activity and may not provide sufficient benefits from training. Previous studies on landing motion have reported that ankle dorsiflexion ROM restriction due to taping may decrease muscle activity in the soleus and other muscles [2]. This study aimed to examine the effect of taping on the muscle activity involved in the movement of the three lower extremity joints during squatting.

METHODS

Ten healthy adult women without lower extremity pain participated in this study. They were asked to perform squats while sitting back until their thighs were parallel to the floor. The speed of the movements was standardized using a metronome to achieve a rhythm of 60 beats per minute. They performed descending, stopping, and ascending phases, each lasting for 4 s. Two conditions were compared: a control condition (SQ) and taped condition (TSQ) in which ankle joint restrictions were applied using taping.

The three lower extremity joint angles were calculated using the Frame-Dias system (DKH) with markers affixed to the acromion, greater trochanter, head of the fibula, lateral malleolus, and fifth metatarsal. The subject muscles were the tibialis anterior (TA), rectus femoris (RF), and soleus (SOL) muscles. Muscle activity was measured using surface electromyography. The analyzed section was divided into 12 phases, 1–4, 5–8, and 9–12 for descending, posing, and ascending, respectively. In the descending and ascending phases, normalization was performed with the hip ROM from phases 1–4 reflected as 100%, increasing by 25% in each phase of the ROM. The root mean square value for the muscle in each phase was calculated and normalized using the maximum voluntary muscle contraction.

RESULTS AND DISCUSSION

During the descending phase 4, only muscle activity in the RF was significantly higher in the TSQ condition than in the SQ. No significant differences were observed in the TA and SOL muscles during any of the phases.

In this study, the maximum knee joint angle in the SQ condition was higher than that in the TSQ. This result is consistent with previous studies in which ankle dorsiflexion restriction affected knee flexion [3]. In addition, previous studies have shown that during squatting, quadriceps muscle activity peaks when the knee joint reaches 80°–90° and then stabilizes [4]. It is possible, therefore, that the muscle activity of the RF reached a higher value during the SQ muscle activity because of the difference in knee ROM between the two conditions during phase 4. However, significant differences were only found in the RF muscles, suggesting that muscle activity of the three lower limb joints during squatting may be slightly affected by the presence or absence of taping.

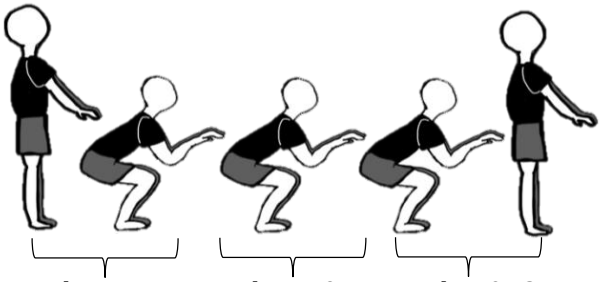

Figure 1 The analyzed section

CONCLUSIONS

The results of this study suggest that ankle dorsiflexion restriction by taping may not affect the amount of muscle activity during squatting.

INTRODUCTION

Discus throw is a track and field event in which athletes throw a discus of a specified weight and compete over a distance. Discus throwing motion is highly complex and intricate, comprising both rotational and translational movements. The delivery phase is the most important phase of the discus throwing motion, as the discus velocity is primarily gained during this phase. Internal rotation of the right lower limb is a crucial movement for acceleration of the body–discus system in this phase [1]. An inclined board, which is placed under the right foot, is employed as a training method to learn the body's acceleration during the delivery phase. The right foot plays a crucial role in the acceleration and rotation of the body during discus throw. However, there is a lack of conclusive evidence regarding this training method. By contrast, an inclined board is also utilized in the training of the take-off technique in long jump [2]. This approach can alter movement naturally and lead to the acquisition of better techniques. Thus, the present study aims to clarify the effects of an inclined board on body acceleration and rotation in a standing discus throw drill that imitates the delivery phase of discus throw.

METHODS

The participants were 15 male right-handed discus throwers (height: 1.77 ± 0.05 m, weight: 82.6 ± 11.0 kg). They were asked to perform the standing throw motion without a discus, which is one of the technical drills of the discus throw, under four different inclined board conditions: 0°, 4°, 8°, and 12°. To avoid the influence of the order of the tests, they were performed in a random order. In three inclined conditions (4°, 8°, and 12°), the right foot was placed on the incline board, which was fixed on the force plate. The ground reaction forces (GRF) of both feet were measured using a force plate (9281 B, Kistler, Switzerland) at 1 kHz. The coordinate data of the anatomical landmarks of the body were captured using a motion capture system (Vicon Vero v2.2, Vicon Motion Systems, UK) at 250 Hz. The moment of the GRF about the vertical axis through the body's center of mass (CoM) was calculated as the cross product of the position vector from the CoM to the center of pressure and the GRF. A one-way analysis of variance for repeated measurements was conducted to test the main effect of the inclined board (SPSS Ver.29, IBM, USA).

RESULTS AND DISCUSSION

Figure 1-a demonstrates that the impulse of the throwing direction component of the GRF was significantly greater in the 12° condition than in the 4° and 0° conditions and in the 8° condition than in the 0° condition, but no significant difference was found between the 12° and 8° conditions and between the 4° and 0° conditions. This result suggests that the effect of using an inclined board may accelerate the body in the throwing direction. The maximal moment of the GRF about the vertical axis through the CoM was significantly greater in the 12° and 8° conditions than in the 4° and 0° conditions, but no significant difference was found between the 4° and 0° conditions (Figure 1-b). This result suggests that a steeper inclined board generates a moment about the vertical axis. In baseball batting, the internal rotation of the right lower limb generates the moment of GRF about the vertical axis through the CoM, and it contributes to the rotation of the lower trunk [3]. Even in discus throw, when the right lower limb generates a moment, it accelerates the body during the delivery phase.

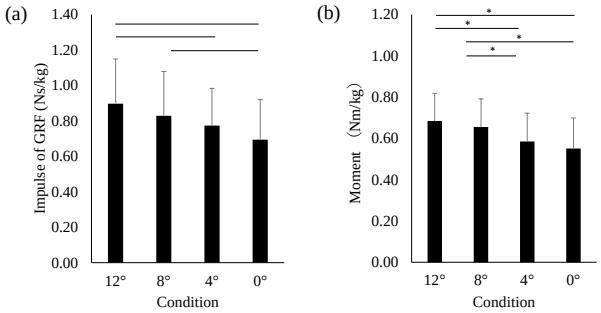

Figure 1 (a) Impulse of the throwing direction component of the GRF (right) and (b) the maximal moment of the GRF (right) about the vertical axis through the CoM.

CONCLUSIONS

The results revealed that the inclined board increased the throwing direction component of the GRF impulse and the moment of the GRF about the vertical axis through the CoM. Therefore, the inclined board improves the body–discus system acceleration, which might be attributable to the right lower limb motion.

INTRODUCTION

The baseball batters can estimate the trajectories of the fastballs from the pitching forms. This is because the pitching form was strongly correlated with the orientation of spin axis [1] and the orientaiton generally determines the trajectories of the fastball [2]. Then, can baseball batters estimate the trajectory of the breaking balls from the pitching form? We aimed to investigate the relation between the pitching forms and the trajectories of each pitch type.

METHODS

Fifteen male collegiate baseball pitchers, who used an overhand, three-quarter, and side-hand throw style, participated in this study. They threw all the pitch types they would normally throw in a game. This study focused on the fastballs, curveballs, sliders, changeups, and cutters. Three high-speed cameras were used to record the pitching motion and pitched ball. The relation between the pitching forms and the trajectories of each pitch type was quantified by the correlations between the throwing arm angle (Figure 1) and the angle of each pitch (θ). The throwing arm angle was defined as the angle between the vector from shoulder to wrist at ball release and the horizontal plane from the viewpoint of second base (Figure 1). The angle of each pitch was calculated as the angle between the X-axis and the line from the origin to the deviation of each pitch in the vertical and horizontal deviation plane (Figure 1). The vertical and horizontal deviations were simulated as the differences between the coordinates at the ball arrival position with and without considering ball spin.

RESULTS AND DISCUSSION

The angles of fastballs ($\theta_{fastballs}$) and curveballs ($\theta_{curveballs}$) were significantly correlated with the throwing arm angle. This means that the fastballs and curveballs pitched by overhand pitchers had less horizontal and more vertical deviation. On the other hand, the fastballs and curveballs pitched by side-hand pitchers had more horizontal and less vertical deviation. The results indicated that the batters can estimate the trajectories of these pitch types from pitching forms. However, the angles of sliders ($\theta_{sliders}$), changeups ($\theta_{changeups}$), and cutters ($\theta_{cutters}$) were not significantly correlated with the throwing arm angle. This is because the deviations of these pitch types varied regardless of the pitching forms. The deviations of these pitch types were across multiple quadrants in Figure 1 whereas those of fastballs and curveballs were almost within a single quadrant. Therefore, it was thought that the sliders, changeups, and cutters were difficult to estimate the trajectories from the pitching forms.

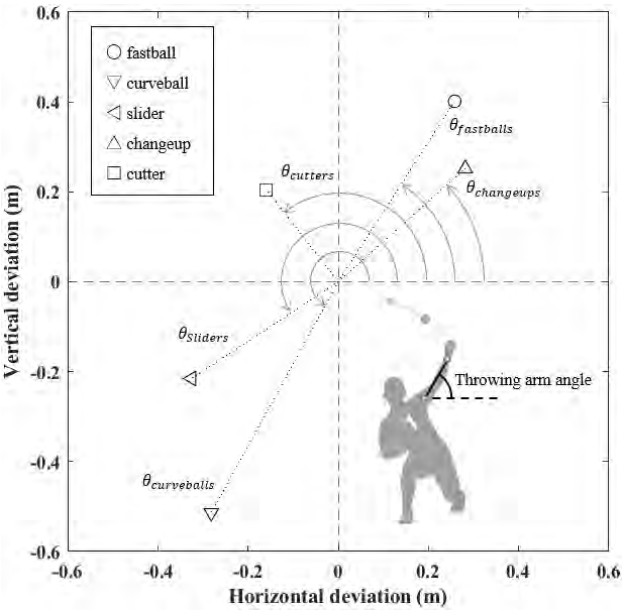

Figure 1 Definitions of the angle of the pitch (θ) and throwing arm angle.

CONCLUSIONS

We found that the directions of the deviations in fastballs and curveballs were correlated with the throwing arm angle. This result indicated that batters can estimate the trajectories of fastballs and curveballs from pitching forms.

INTRODUCTION

Modern golf statistics indicate that the putter accounts for only 15% of a player's score while the remaining 85% is attributed to shot accuracy [1], so the importance of shot precision in determining one's score cannot be overstated. The function of iron clubs is to effectively strike the ball over a desired distance with a high degree of accuracy. The adjustment of the horizontal ground reaction force of the target leg has been identified as a crucial factor in attaining the desired distance when using the same iron club [2]. While simulations suggest that club length accounts for 20% and loft angle for 80% ball distance [3], their exact contribution to human players remains unclear. This study aimed to assess the impact of club differences on ball distance through a comparative analysis of the swinging motion of a one-length iron club and a conventional iron club.

METHODS

Eighteen male collegiate golfers (age: 20.7 ± 1.4 years; height: 174.3 ± 4.0 cm; body mass: 69.6 ± 9.4 kg; Best score: 70.1 ± 3.9) participated in this study. The subjects performed swings on two Kistler force plates (operated at 1 kHz) using their iron clubs and a custom-made one-length iron club. The experimental trials comprised five swings per club, with three swings selected for analysis based on a content report scale rated four or higher. The one-length club used was a set of irons with lofts ranging from 46 degrees (Pitching Wedge) to 26 degrees (No.5), all adjusted to a length of 37 inches (Fig.1 A). The kinematics of the swings were captured through motion capture (VCION, Oxford, operated at 200Hz), with the analysis period defined as the time frame from address to impact. The swing data, including distance, number of revolutions, and swing speed, were recorded using a distance trajectory measurement system (Trackman).

The swing data, including distance, number of revolutions, and swing speed, were recorded using a distance trajectory measurement system (Trackman).

RESULTS AND DISCUSSION

Figure 2 shows the correlation between loft angle and carry for both a one-length and a conventional iron club. As the loft angle decreases, the distance for both types of clubs increases. Conversely, the disparity in distance between the one-length and conventional iron clubs elevates from 4.5 to 8.4 yards as the loft angle decreases, yet the average overall distance difference was only about 4.2%, which was not statistically significant. Previous research has reported that the horizontal component of the ground reaction force at the target leg affects distance control when iron clubs of the same number are used [2]. However, in this study, no disparities were detected in the peak ground reaction force resulting from the different club structures. The fact that distance remained constant, despite variations in club length, suggests that the participants adjusted the distance by accommodating the clubs to their preferred equipment.

CONCLUSIONS

The findings of this research imply that one-length iron clubs, capable of decreasing length-induced swing errors, are a viable option, particularly for amateur golfers seeking to attain consistent distance control.

[3] Institute of Medical Science and Technology, National Sun Yat-Sen University / Kaohsiung, 80424, Taiwan
Email: shiaujk@gmail.com

PURPOSE

In this study, quantitative methods were used to assess forearm muscle strength and fatigue characteristics during a screw-driving task to understand whether screw-driving-related operations increase the potential risk of forearm muscle fatigue.

MATERIALS AND METHODS

1. Participants

A total of 12 healthy adults (10 males and 2 females; age range: 21–38, mean age: 26.2 ± 6.5 years), participated in this experiment. The body height and the weight of the subjects were 170.5 ± 8.6 cm and 67.5 ±13.2 kg (mean ± SD), respectively.

2. Methods

Twisting a screwdriver involves a combination of grip force (GF), driving torque (DT) or torsional moment, and push force (PF). The torsional moment is generated from the driver's handle through a handgrip force and friction from the screwdriver. A wooden specimen was installed on the experimental platform, and both ends of the specimen were clipped on the experimental platform for the driving test. The surface electrodes were placed on the BB, BR, and extensor carpi ulnaris (ECU) of the subject. The maximal isometric grip force, isometric driving torque, isometric push force, EMG amplitude, and insertion forces during cycling were measured

3 Statistics

The paired t-test to investigate differences in the maximum isometric forces (MIGF, MIDT, MIPF) data and EMG amplitudes between the pre-fatigue and poet-fatigue conditions were conducted. One-way ANOVA and LSD post-hoc comparison tests were conducted to identify the EMG difference between BB, BR, and ECU.

RESULTS AND DISCUSSION

Figure 1 (A), showed significant differences between the 1-st (MIDT=13.6%, MIPF=14.8%) and 8-th (MIDT=6.7%, MIPF=7%) and 4-th (MIDT=12.1%, MIPF=11.6%) and 8-th screw-driving maneuvers in terms of the amount of change in MIDT and MIPF. Figure 1 (B) shows the EMG amplitudes for the BB, BR, and ECU relative to the change in maximal isometric grip force (ΔEMG %) before the screw insertion operation, with values of 17.4%, 28.1%, and 29.7%, respectively. The percentage variation in the EMG for these three muscles was 16.7%, 39.3%, and 37.3%, respectively, for the MDT test [Figure 1 (C)].

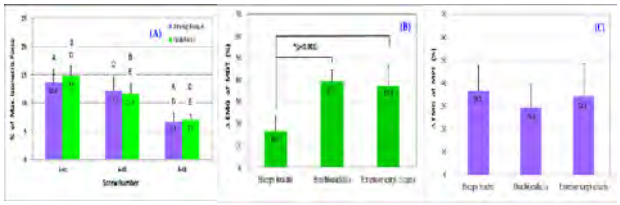

Figure 1 (A) MGF; (B) EMG-MGF; (C) EMG-MDT

Figure 2 (A)&(B) shows the DT and PF generated per minute for the insertion of each screw. A linear relationship was detected between the DT insertion rate (IR) and the screw number (R2 = 0.9791). Similar results were also observed for the IR of PF with screw number (R2 = 0.9669). The fourth screw had a significantly decreased IR compared with the first screw.

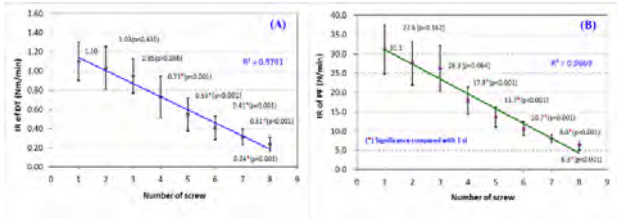

Figure 2 (A) Insertion rate of DT; (B) Insertion rate of PF

CONCLUSIONS

The major findings of this study emphasize the influence of forearm muscle strength and fatigue when screw driving. (1) Our investigation shows that the DT and PF decreased with an increase in the number of screws inserted; the screw insertion rate decreased linearly with the number of screws. (2) Both the brachioradialis and the extensor carpi ulnaris have a greater percentage of muscle loss in grip strength and torque than the biceps and are more likely to fatigue than the biceps. (3) This study presents a potential risk for muscle fatigue due to exposure to repetitive driving tasks. The risk of upper limb muscle injury to clinicians from screw-in operation still needs more clinical confirmation.

INTRODUCTION

For dental implant surgery, the osseointegration is the important factor in determining the success rate [1]. The previous researchers indicated that the primary stability of an dental implant is a good indicator of osseointegration quality. Generally, the maximum insertion torque value (ITV) and initial stability quotient (ISQ) were commonly used as the indexes of the primary stability of dental implant. Seceral researchers have evaluated the implant shape, surface treatment, and bone quality on the primary stability of dental implant. Howver, only few studies have reported on the effects of the insertion speed on primary stability. According to the American Society for Testing and Materials regulation, the implant should be inserted at a speed between 1 to 5 rpm [2]. However, in clinical surgery, the common insertion speeds used are 10, 20, and 30 rpm [3]. Therefore, the purpose of this study was to investigated the effects of insertion speed on the insertion torque value and initial stability quotient of dental implants.

METHODS

The dental implants were inserted at four speeds: 4, 10, 20, and 30 rpm, into artificial bone specimens (Figure 1). During and after the insertion process, the maximum ITV and ISQ were measured. For the statistical analysis, the Kruskal–Wallis tests were used to determine the three evaluated indexes among the four insertion speed.

Figure 1 Artificial bone specimens and dental implant used in this study.

RESULTS AND DISCUSSION

The ITV and ISQ values were 39–60.2 N·cm and 70–77 (Table 1 and Figure 2), respectively. For the insertion speed on implant primary stability, significant differences in ITVs were observed among the four insertion speeds. In general, the higher the insertion speed, the lower the ITV; especially for the ITVs for implants inserted at 4 rpm were significantly higher than which measured at 20 and 30 rpm. In addition, the ISQs differed significantly differences among the four insertion speeds.

Table 1: ITV and ISQ of dental implant at the four insertion speeds.

Stability indicator	Statistical parameters	Insertion speed (rpm) 4	10	20	30	*P*†
ITV	Median	54.5[a]	50.0[ac]	46.0[bc]	44.0[b]	0.004
	IQR	6.7	4.0	4.0	4.5	
	Max	60.2	53.0	48.0	45.0	
	Min	50.9	46.0	42.0	39.0	
ISQ	Median	72.0[a]	75.0[b]	75.0[b]	73.0[ab]	0.016
	IQR	2.0	2.0	0.5	1.5	
	Max	73.0	77.0	75.0	75.0	
	Min	70.0	74.0	74.0	73.0	

rpm: revolutions per minute; ITV: insertion torque value; ISQ: implant stability quotient; IQR: interquartile range; Max: Maximum; Min: Minimum; *P*†: Kruskal–Wallis test, Post hoc pairwise comparisons were conducted using Mann–Whitney exact tests with Bonferroni adjustment; medians with the same letter (a, b, c) do not differ significantly at the 0.00833 (0.05/6) level.

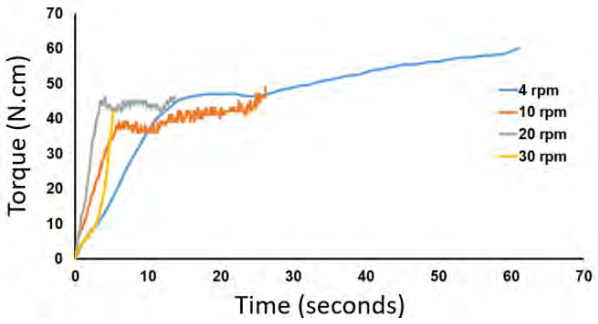

Figure 2 Torque-time curves during implant insertion.

CONCLUSIONS

The ITV and ISQ differed significantly among the four insertion speeds. The results indicated that a lower insertion speed resulting in higher primary stability.

INTRODUCTION

In the field of dental education, clinical practice education is important for students as an essential part of the core curriculum. However, most patients are reluctant to receive dental treatment from inexperienced students. Hence, to address this issue, many simulators have been introduced to the dental industry. The purpose of the study was to fabricate an upper-body prototype simulator for dental education, to try it whether it can simulate the mandibular movement and to test the possibility of the stimulator responding to stimuli during dental practice.

METHODS

A computer model was developed based on segmentation of the hard and soft tissues using CT and MRI DICOM data, and virtual muscles were also created to simulate the primary movements of the mandible. After that, the simulator was 3D printed using the PLA material for the hard tissue and the rubber material for the soft tissue. An actuator was used to generate the motion of the simulator that mimics the human temporomandibular joint (TMJ), and the response to dental treatment was controlled by water level and pressure sensors. Then, the computer simulation of the mandibular motion of the simulator was performed in a 3D simulation program. The maximum mouth opening of the actual simulator was measured with a digital vernier caliper to compare the mandibular range of motion of a human.

RESULTS AND DISCUSSION

The upper-body simulator consisted of an operational unit, an upper body with an electric device, a head with a TMJ and dentiforms (Figure 1A). The TMJ of the simulator was capable of driving two degrees of freedom, implementing rotational and translational movements, which are the most important movements in the opening and closing of the mandible (Figure 1B). The mandibular range of motion of the simulator was 50 mm, which is within the normal range of maximum mouth opening for an adult. The head of the simulator was equipped with an LED sensor that displays the state and water level of each joint. A buzzer was also used to convey the status of the simulator audibly.

Additionally, articulators are used to reproduce or simulate mandibular movements during prosthetic treatment or clinical education [1]. This simulator, as compared to commonly-used semi-adjustable articulators, have similar rotational and translational movements, with differences found in their respective degrees of freedom. The reason is that if the two actuators were located on both sides of the mandibular joint, significant vibrations due to the elasticity of linear motion could be observed. To minimize this, the actuators were located separately in the skull and mandible.

Unlike the articulator, the human upper body simulator had the advantage of directly reproducing the mandibular motion simulation comparable to a real patient and thus simulating the human body by reacting similarly using various sensors [2]. Therefore, using simulator heads can be particularly useful for presenting students about the fundamentals of mandibular movements and for providing dental clinical practice training.

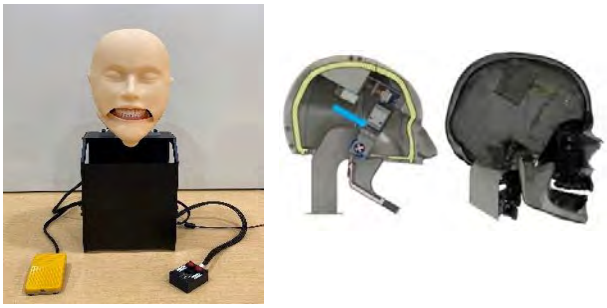

Figure 1 The upper-body prototype simulator (A) and internal structure of simulator head (B)

CONCLUSIONS

Although the prototype simulator was able to achieve the objectives, further advancements are still required to improve its efficiency and stability. Through continuous improvement and development, the simulation of the human body becomes more realistic, and it is expected to develop into a future-oriented dental education that improves student concentration and encourages them to consider how to communicate with patients.

Computational Model Verifying Effects of Ultrasound Settings on Temperature Changes in Nitinol Implants

Shaye Tiell[1], Brian Davis[1] and Josiah Owusu-Danquah[1]
[1] Center for Human-Machine Systems, Cleveland State University, Cleveland, United States.
Email: s.tiell@vikes.csuohio.edu

INTRODUCTION

A longstanding orthopedics/biomechanics issue relates to the use of metal fixation devices to stabilize fractures in pediatric patients. There are contradictory demands, namely rigidity to maintain skeletal alignment versus the need to accommodate bone growth.

Shape memory alloys (SMAs) such as nitinol are well-known for their unique ability to undergo a shape change in response to a thermal stimulus. Minimally invasive nitinol implants which can reconfigure or adjust their shape across several temperature points could provide pediatric fixation devices that allow bone growth [1-4]. In the context of orthopaedic implants, this feature would ideally require an external (non-invasive) heating stimulus. One option is therapeutic ultrasound. Ultrasound's ability to quickly raise temperatures, and transcutaneously activate shape changes in nitinol implants could represent a novel approach for eliciting a thermoelastic transformation [5].

The purpose of this study was to investigate the features of therapeutic ultrasound that correspond with temperature changes in nitinol specimens via a computational model along with experimental data.

METHODS

This study used multibody dynamic simulations [6] to assess the relative heating effects caused by ultrasound magnitude versus frequency (Table 1). The model included spring-mass elements in series as well as viscous elements to represent damping properties. The dependent variable of interest was the kinetic energy of the mass that represented nitinol.

For validation pursposes, nitinol specimens were submerged in water to a depth of about 5 cm. Two ultrasound machines (the Sonicator 750 and Dynatron 150) were separately placed on the surface of the water. Ultrasound was applied to each specimen for 2 minutes. Specimen temperatures were recorded before ultrasound was applied and after each 30 second period. Trials were performed with low and high frequency and power settings (Table 1). All analyses were done in R [7]. An analysis of covariance (ANCOVA) was used to assess differences in mean temperatures due to power and frequency parameters (Figure 1).

Table 1 Therapeutic ultrasound machines and corresponding frequency and power settings.

	Frequency (MHz)		Power (W/cm^2)	
Therapeutic Ultrasound Machine	Low	High	Low	High
Sonicator 740	1	3	1	2
Dynatron 150	1	3	1	3

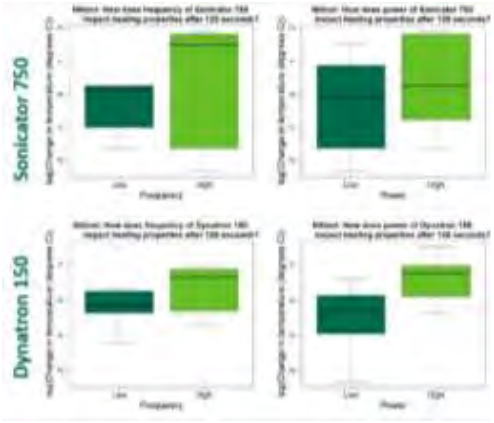

Figure 1 Four boxplots show every combination of factors (frequency and power) for the mean change in temperature after 120 seconds of heating by therapeutic ultrasound.

RESULTS AND DISCUSSION

There is a significant difference between low and high power settings on mean temperature change using the Dynatron 150 (3-way ANOVA; p=0.013). The model's predictions matched the benchtop testing data. Thus, the model verified significant effect on mean temperature due to high amplitude settings with no significant effect on mean kinetic energy at different frequency settings.

CONCLUSIONS

Nitinol implants can quickly and easily increase in temperature when applying therapeutic ultrasound. These findings could dramatically impact the design of metal implants that need to accommodate growth. Therapeutic ultrasound power settings rather than frequency settings are key to obtaining the thermal affects needed to allow nitinol implants to change shape.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Dr. Deborah Espy who provided the therapeutic ultrasound equipment and Dave Dudzinski at the Cleveland Clinic for the nitinol specimens. Funding from the National Science Foundation (Award 2131894) is also acknowledged.

Gait Event Detection Using the Single IMU on the Unilateral Electromechanical KAFO

Sumin Yang[1], Jongman Kim[1], Bummo Koo[1], Seunghee Lee[1] and Youngho Kim[1*]
[1] Biomedical Engineering, Yonsei University, Wonju, South Korea
[*]Email: younghokim@yonsei.ac.kr

INTRODUCTION

Gait parameters are one of the important evaluating factors in gait analysis and can be defined by gait events. Patients with sarcopenia or paraplegia use orthosis for assisting their gaits. A knee-ankle-foot orthosis (KAFO) helps patients to be stable during gait and embedded sensors in the orthosis measure gait signals to control[1]. Various data provided from the orthosis allow for evaluating the gait pattern of patients. In this study, a gait event detection algorithm for an electromechanical KAFO was developed using a single IMU sensor on the single-sided leg. The developed algorithm will be applied to the developing KAFO, and used for monitoring gait patterns. Four events (initial contact(IC), opposite initial contact(OIC), toe off(TO), and opposite toe off(OTO)) were determined by the single IMU on the thigh.

METHODS

Fourteen healthy adults (9 males, 5 females, 22.3±1.4yrs, 167.2±9.2cm, 65.2±13.0kg) participated in the experiment. Two IMUs (Xsens Technologies BV, Netherlands; 60Hz) were attached to both thighs. Force plates (AMTI, USA; Kistler, Switzerland; 1000Hz) and a 3D motion capture system (Vicon Motion System Ltd, Oxford, UK; 200Hz) were used for the reference.

Accelerations of the vertical axis(Z) and the mediolateral axis(Y) and the pitch angular velocity (GyroY) were used to detect gait events. AccZBP and AccLSA [2] were obtained by filtering the acceleration data using a 1.9~2.1Hz band-pass filter and a least square acceleration (LSA) filter, respectively. AccYBP was also obtained using a 0.95~1.05Hz band-pass filter. Two local minima in AccYBP represented one gait cycle. AccRB was calculated by subtracting AccZBP from the raw acceleration data. Then, peakLSA was determined by the peak point of AccLSA between two local minimums of AccZBP. The local maximum point of AccRB within a certain section based on peakLSA was defined as an IC. GyroY3 and GyroY12 were obtained using 3Hz and 12Hz low-pass filter from GyroY, respectively. TO was defined by the minimum point in GyroY12, and OTO the first local maximum point after IC. OIC was defined by finding the zero-crossing after OTO in GyroY3. The error rate was defined by dividing the difference between the detected events and the reference data by one gait cycle. In addition, stance and swing phases were determined.

RESULTS AND DISCUSSION

The errors in detecting gait events were 0.65±1.02%, 5.32±3.73%, 1.45±1.20%, and 2.35±1.96% for IC, OTO, OIC, and TO respectively (Figure 1). Stance and swing phases were 61.02±4.67% and 38.98±4.67% respectively based on our algorithm, which showed errors of approximately 2.40% in both phases compared with the reference data (Table 1). These errors would be originated from the errors detecting OTO.

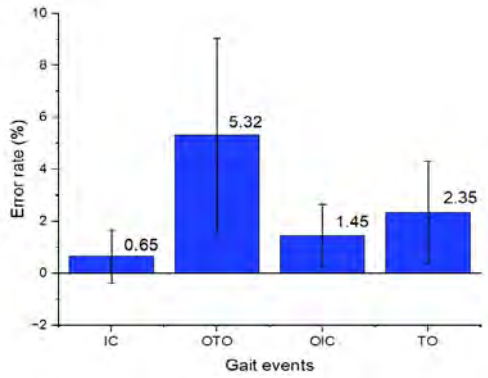

Figure 1: Errors in gait event detection of the present study

CONCLUSIONS

The gait event detection algorithm was developed using a single IMU on the thigh. The error rates of the gait event detection were 0.65±1.02%, 5.32±3.73%, 1.45±1.20%, and 2.35±1.96% for IC, OTO, OIC, and TO respectively. In the future, the present algorithm will be implemented to the electromechanical KAFO and validated in the real-world situation.

INTRODUCTION

In front crawl swimming, the upper limbs play a role to exert the propulsive force. On the other hand, the motion of lower limbs is known as flutter kicks, and their conbributions and importance in swimming performance has been discussed. Ichikawa et al. (2020) reported that the propulsive force exerted by the flutter kick on the water surface and in the underwater conditions differently depending on swimming speed [1]. There are no reports or literature that mention the differences in the motion of the flutter kick. The purpose of the study is to clarify the kinematical differences of the flutter kick between the surface and the underwater conditions.

METHODS

The subjects were six male university swimmers with competitive experience. The trial consisted of a 25 m flutter kick with the maximal effort. The swimmers performed the trials under the conditions of the surface and the underwater with high-intensity LED markers attached to the swimmers' right wrist, shoulder, greater trochanter, knee, ankle and 5th MP-joint. Swimming movements were recorded from the swimmer's right side using an underwater camera with 60Hz as sampling frequency. The coordinates of the body markers during the 10m-15m section in trials were calculated using the two-dimensional DLT method. The angles of the four segments, such as the trunk, thigh, shank and foot with respect to the horizontal plane were calculated. The angles of the hip, knee and ankle joints were also calculated respectively. Swimming speed was calculated as the time derivative of the horizontal displacement of the hip joint. The kinematic data for the five cycles with the smallest variance in swimming speed were extracted and compared between the surface and underwater conditions.

RESULTS AND DISCUSSION

The mean (standard deviation) value of the swimming speed were 1.37 (0.13) m/s in the underwater condition and 1.21 (0.07) m/s in the surface condition, with the underwater condition being significantly faster ($p<0.05$). The angle of shoulder, hip, knee and ankle joint on the sagittal plane showed the similar patterns between the conditions. The trunk had a maximum, minimum and mean angle that was greater on the water surface than in the water ($p<0.05$). The minimum and mean angles for the thigh were greater under the surface condition than the underwater ($p<0.05$). Statistical comparisons of the shank and the foot were not performed because the foot markers moved above the water surface and were not visible, so complete one-period kinematics data could not be obtained under the surface condition. It was observed that each segment maintained a horizontal posture in the underwater, whereas the head side was higher and the foot side was in a deeper position in the surface condition (Fig. 1). The inclination of the segments in the surface condition increases the frontal projected area during the flutter kick, resulting in larger resistance. Therefore, the swimming speed would be lower in the surface condition than in the underwater condition.

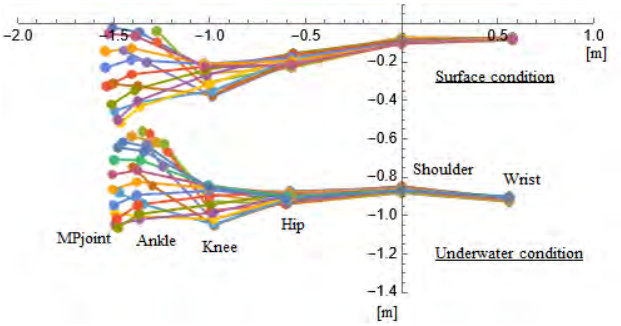

Figure 1 Stick pictures of flutter kick swimming on the sagittal plane under the surface and the underwater conditions.

CONCLUSIONS

Kinematical differences in flutter kick swimming between surface and underwater conditions were attributed to whole-body inclination, which would affect swimming speed. The differences in swimming speed between the conditions may be different from those expected by swimmers and coaches.

INTRODUCTION

Surface electromyogram (sEMG) is one of the non-invasive and objective method to evaluate muscle function, and applications in the fields of sports training and rehabilitation are expected. Some researchers reported sEMG amplitude values increase, frequency values decrease, and muscle fiber conduction velocity (MFCV) decrease with muscle fatigue [1]. However, the values of these indicators also change depending on the difference in force of muscle contraction, and there are individual differences in the values and change rate of values. Hence, levels of assessment in muscle fatigue have not yet been reached. sEMG signals are interference pattern of the activity of individual motor units, and the value of amplitude or MFCV different depend on motor unit. Therefore, this study examined the relationship the amplitude and MFCV each waveform in short section with muscle fatigue.

METHODS

Ten healthy males participated in this study. The subjects were seated in a chair and sustained isometric contractions of the right elbow at the elbow joint angle of 90 degrees during 40 % of maximum voluntary contraction. sEMG was recorded from the right biceps brachii muscle and the electrode that composed of eleven silver wires (diameter of 1 mm, length of 10 mm) attached on the muscle belly. The distance between the electrodes was 5 mm. Ten signals were derived bipolarly from adjacent wires filtered by band-pass from 5 Hz to 1 kHz and were digitized with sampling frequency of 10 kHz. In the data, the signals were sampled 5 seconds every 10 % between 0-100 % of endurance time and the root mean square (RMS) of the amplitude and MFCV were calculated each waveform that exceeds 0.05 mV in maximum value during 8ms. In addition, the distributions of RMS and the inverse number of MFCV were calculated to examine the relationship between RMS and MFCV with muscle fatigue. It consists of 126 classes, and RMS was divided into 14 classes (0 to 0.7 mV) and the inverse number of MFCV was 9 classes (0.05-0.5).

RESULTS AND DISCUSSION

The mean of RMS and SD for all subjects increased from 0.07 ±0.03 (0%time) to 0.15±0.08 (100%time) mV, and the reciprocals of MFCV also increased from 0.17±0.06 to 0.21±0.06. A paired t-test for the results were conducted and found a significant difference between RMS ($p<0.01$). The results match past study, and these are supposed to be caused by increasing the number of active moto units and shifting active muscle fibers from fast twitch to slow twitch with muscle fatigue [2]. However there are individual differences were great for the values and it was difficult to estimate the limit state of muscle fatigue using previous method. Figure 1 shows heatmaps of the ratio of the number of waveforms each %time in one subject as a representative result. As the results, It was confirmed that the distribution was concentrated along certain area that has the characteristics of low RMS and the reciprocals of MFCV at early stage of muscle fatigue. After that the distribution was quite variable with muscle fatigue. The coefficient of variation (CV) of ratio over all classes decreased from 3.67 (0 %time) to 1.47 (100%time), and the maximum ratio decreased from 24.6 % to 5.73 %. The results provide the evidence that motor unit recruitment of various sizes were required with muscle fatigue.

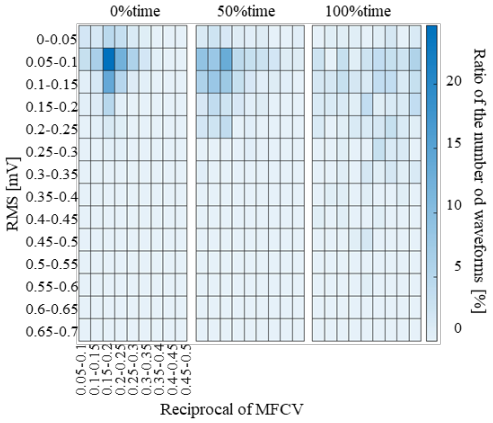

Figure 1 Heatmap of the ratio of waveforms.

CONCLUSIONS

In this study, we examined the relationship between MFCV and RMS with muscle fatigue and MFCV and RMS were calculated each waveform in short section. As the results, the indicators were remarkably different depend on waveform and it is necessary to consider the relationship between MFCV and RMS each waveform in addition to the mean values with muscle fatigue.

INTRODUCTION

Computerized tomography (CT) based 2D/3D registration techniques using bi-plane fluoroscopy is a non-invasive method for accurately measuring *in-vivo* knee joint kinematics. Magnetic resonance imaging (MRI) is needed to create further a subject-specific cartilage model for measuring arthrokinematics. However, MRI alone is expensive, time-consuming and often fails to accurately produce bone models. Therefore, many studies have been devoted to developing methods for calculating knee arthrokinematics based solely on computerized tomography (CT) bone information. The purposes of this study were to develop a statistical shape model (SSM) of the knee bones using datasets of CT and MR images and, together with CT images and knee flexion/extension kinematic data, to reconstruct three-dimensional (3D) subject-specific knee bone/cartilage models for calculating the arthrokinematics of the joint during functional activities.

METHODS

To build the knee SSM model, this study collected 35 models of the bone and cartilage of knee joints from Asian young adults as the training models. This study also developed a method by using this SSM model for reconstructing subject-specific cartilages of the knee joint via the CT bone mode and flexion-extension kinematics. To verify the feasibility of this method, 3D knee joint kinematics during cycling were measured *in vivo* in nine healthy young males (age: 23.4±1.7 years, height: 1.7±0.04 m, weight: 69.6±12.2 kg, body mass index: 23.0±3.7) without any neuromusculoskeletal diseases of the lower limbs. The left knee of each subject was imaged by CT (voxel size: 0.586 × 0.586 × 0.625 mm^3; GE, Lightspeed 16 MDCT, USA) and MRI (3-Tesla, Verio, Siemens, Germany) for the reconstruction of subject-specific volumetric models of the knee. Each subject also performed isolated left knee flexion/extension and cycling while a biplane fluoroscopy system imaged the knee joint. Their subject-specific knee models were reconstructed using MRI and CT, and the arthrokinematics during cycling were calculated [1] and considered the gold standard to verify the accuracy of SSM and the contact obtained. The reconstruction error of the 3D cartilage model, namely femoral, medial and lateral tibial cartilage, and the root-mean-square error (RMSE) of the contact points on the medial and lateral tibial compartments was then obtained as a measure of the performance of the proposed method.

RESULTS AND DISCUSSION

The cartilages of each subject were reconstructed (Figure 1), and the shape error of the SSM reconstructed cartilage was 1.88 ± 0.74mm on the femoral cartilage, 1.18 ± 0.29mm on the medial tibial cartilage, and 1.55 ± 0.44mm on the lateral tibial cartilage. Moreover, the contact point error calculated on the medial side of the knee joint was 1.33 ± 0.71mm in the anterior-posterior (AP) direction, and 2.64 ± 1.48mm in the medial-lateral (ML) direction. The contact point error calculated on the lateral side of the knee joint was 0.77 ± 0.37mm in the AP direction, and 2.26 ± 1.48mm in the ML direction.

Figure 1 The reconstructed cartilage of a typical subject.

CONCLUSIONS

The current results demonstrated that the proposed SSM-based method is a feasible and acceptable technique for reconstructing the cartilage morphology and contact patterns without MR imaging, as proven by the comparative analysis of contact points against the reconstruction of the knee joint based on flexion-extension kinematics and the CT bone model.

INTRODUCTION

Inspired by the histological characterization of cortical bones, in this study, we developed a novel braiding strategy for mechanical and fatigue properties improvement of artificial ligament by using two different kinds of PET threads to mimic overlapping bone lamellas layers consisting of soft collagen fibrils and hard hydroxyapatite [1,2].

METHODS

The artificial ligaments were composed of a shell and core. The shell part was designated as a hollow tubular braided structure with three independent layers. Threads consisting of fibers with a density of 150 D (denoted as “stiff fibers”) for tensile strength to meet clinical demands, while the ones consisting of fibers with a diameter of 0.3 mm (denoted as “hard fibers”) are adopted to resist fatigue failures. The core part was braided by stiff fibers, while the shell part was by a combination of stiff and hard fibers with three different amount ratios. Mechanical and fatigue tests were used and conducted after heat treatment of different durations to compose a sample matrix (Table 1).

RESULTS AND DISCUSSION

Tensile test results confirmed adequate tensile strength for short-term clinical recovery, among which H1S1 attained up to a maximum tensile force of 3776N, while friction tests indicated a proportional decrease in the COF with a quantity increase of hard threads (Figure 1). Besides, longer heat treatment duration contributed to stabilizing texture constructs under different friction conditions as seen from the error bars.

CONCLUSIONS

A novel method to improve biomechanical performance of artificial ligaments was proposed in this work. We successfully improved the tribological performance of braided ligament by 25% compared to the control group on the guarantee of adequate mechanical strength for short-term clinical recovery. This work provides an alternative for biomechanically accountable scaffold design and basis of potential bioactivity improvements, which is on the list of our future work.

PRE-IMPACT FALL DETECTION DURING ELECTRIC SCOOTER RIDING

Seunghee Lee[1], Bummo Koo[1], Sumin Yang[1], Jongman Kim[1], Dongkwon Kim[1] and Youngho Kim[1]
[1] Department of Biomedical Engineering, Yonsei University, Wonju, Korea.
Email: younghokim@yonsei.ac.kr

INTRODUCTION

Electric scooters (e-scooters) have been widely used as the personal mobility because it is easy to drive and has a reasonable price. The number of serious e-scooter accidents in Korea was 900 in 2021 and has been doubled annually [1]. Wearable devices such as an airbag system have been under development to protect the rider from the serious impact injury during e-scooter riding. A pre-impact fall detection algorithm for e-scooter riders was developed using an IMU sensor in this study.

METHODS

20 healthy adults (23.3 ± 1.7 years old, 173.0 ± 6.7 cm, 74.5 ± 13.2 kg) were recruited from Yonsei University for the study. Four normal drivings and one fall movement were performed by subjects with an e-scooter (Ninebot Segway ES2, Xiaomi, China). An IMU sensor (Xsens Dot, Xsens Technologies B.V., Netherlands) was attached to T7 position of the subject to measure three-axis acceleration and three-axis angular velocity with 60Hz sampling frequency. The data obtained from the IMU sensor was filtered to remove noise using a second-order Butterworth low-pass filter (cutoff frequency: 5 Hz). Sum vector magnitudes of acceleration and angular velocity (A_{SVM} and G_{SVM}), and roll angles were calculated from the IMU sensor data. Algorithm 1 used threshold values of both A_{SVM} and G_{SVM}. On the other hand, Algorithm 2 also used roll angles as well as A_{SVM} and G_{SVM}. Grid search was applied to determine the thresholds for the algorithm from 16 subjects, and the test was made from the rest 4 subjects.

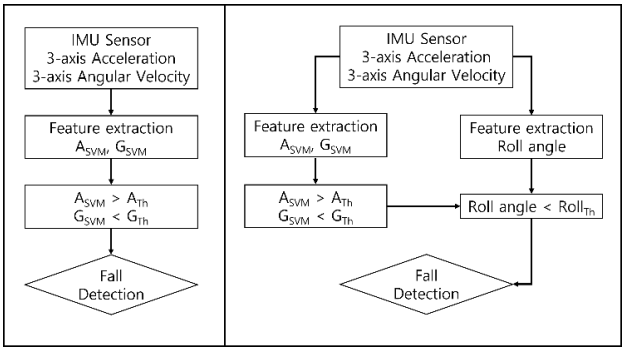

Figure 1. Flow chart of the algorithm (left: Algorithm1, right: Algorithm2).

RESULTS AND DISCUSSION

Table 1 showed the performances of algorithms. The specificity of both algorithms was 100%. Algorithm 2 that considered roll angles as well as A_{SVM} and G_{SVM} showed higher specificity and accuracy than Algorithm 1. In addition, Algorithm 2 resulted in smaller lead-time than Algorithm 1. Although the lead-time slightly decreased in Algorithm 2, it was sufficient for airbag deployment. Algorithm 1 showed 100% sensitivity, being widely accepted in detecting falls in a motorcycle [2], but revealed only 90% specificity in e-scooter riding. Algorithm 2 failed to detect only one normal e-scooter riding. A significant improvement in the specificity was obtained, as roll angles were additionally used in Algorithm 2. In the future, machine learning-based pre-impact detection algorithm will be studied to improve the performance.

CONCLUSIONS

Two different threshold-based algorithms were applied to detect pre-impact falls during e-scooter riding. Both algorithms showed 100% sensitivity in detecting falls during e-scooter riding. Algorithm 2 using A_{SVM}, G_{SVM}, and roll angles showed better specificity than Algorithm 1 using only A_{SVM} and G_{SVM}. This study successfully detected e-scooter falls using threshold-based algorithms.

INTRODUCTION

Previous epidemiological studies have shown that the risk of head injury in judo is relatively high, particularly when being thrown backwards with osoto gari [1]. In addition, the biomechanical studies have suggested that the magnitude of the impact on the head when thrown is greater when thrown with the osoto gari than with other judo throwing techniques [2]. However, the previous biomechanical studies have only estimated the biomechanical quantities applied to the head during throwing in a laboratory setting. Therefore, it is unclear whether the previous results accurately reflect the head impact during being thrown in actual judo situations. The aim of this study was to quantify the head impact caused by different judo throwing techniques during actual judo sparring practice.

METHODS

Participants were four male collegiate judokas belonging to the same university judo club. A mouthguard-type inertial sensor (The Nexus A9 Smart Mouthguard, HitIQ Ltd., VIC, Australia) was placed in the mouth to obtain linear (*g*) and angular (rad/s^2) head accelerations as an indicator of the head impact during judo practice. Video images of each participant during judo sparring practice were also recorded with date and time stamps. The head impact data were then matched to the video images to time-synchronise the head impact in the situation in which the participant was thrown.

RESULTS AND DISCUSSION

There were no definite or suspected cases of head concussion among the participants during the study period.

After analysis of a total of 39 training sessions, 377 throwing situations were identified from the video footage, of which 11.4% (43/377) resulted in head impacts with accelerations of 10 *g* or greater.

The median [95th percentile] peak linear and rotational head accelerations were 16.1 [25.7]*g* and 1219.6 [2435.6] rad/s^2 respectively. The result also showed that most of the head impacts were distributed in the relatively low impact range of linear acceleration below 15*g* and/or angular acceleration below 1500rad/s^2 (Figure 1).

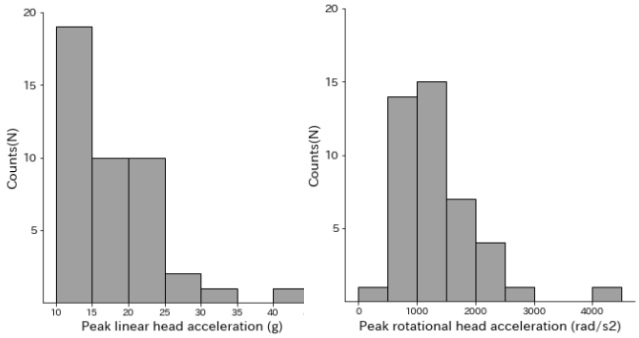

Figure 1 Distribution of head impact magnitude in 43 cases.

Of the 377 scenes, the most common situation was thrown with seoi-nage(58/382,15.2%) and uchimata (58/382, 15.2%), followed by osoto-gari (47/382, 12.3%), and the most common head impact situation exceeding the 10*g* threshold was when thrown with uchimata (13 cases), followed by seoi-nage (9 cases) and kosoto-gari(including kosoto-gake) (6 cases).

Previous studies have suggested that being thrown with osoto-gari may put judokas at high risk of head injury. However, we did not find any situation in which the participants were thrown with osoto-gari exceeding 10*g* impact during the recorded session, although the osoto-gari was the third highest throwing technique observed across all throwing situations. Our findings suggest that careful consideration should be given to the relationship between the risk of head injury and the judo throwing techniques.

CONCLUSIONS

We quantified the head impact applied to the head in actual judo situation. About 10% of the head impacts above the threshold were identified in the being thrown situation, and most were considered to be in the low impact range. The results of laboratory studies may differ from actual situations as to whether the risk of head impact differs between different techniques.

INJURY-RELATED GAIT VARIABLES DURING RUNNING AND LOADED WALKING IN U.S. ARMY TRAINEES DIFFER BY SEX, BUT NOT PHYSICAL ACTIVITY LEVEL

Caleb D. Johnson[1], Lauren K. Sara[2], Molly M. Bradach[2], Katelyn I. Guerriere[1], Leila A. Walker[1], Stephen A. Foulis[1], Julie M. Hughes[1], David R. Mullineaux, Irene S. Davis[3]

INTRODUCTION

Low levels of physical activity (PA) and fitness are associated with increased rates of lower-extremity musculoskeletal injury during U.S. Army Basic Combat Training (BCT).[1] A large proportion of these injuries result from running and walking with load carriage (loaded walking) activities. While less is known about loaded walking, early stance ground reaction forces (GRFs) and peak tibial accelerations (TAs) have been associated with injury in runners.[2] Further, runners have shown differences in gait mechanics and injury rates based on training volume and experience.[3-4] Finally, injury rates have been shown to be higher in female vs male trainees.[1] Therefore, our purpose was to compare running and loaded walking GRFs and TAs across PA and running experience levels, as well as sexes, in Army trainees. We hypothesized that females and those with lower PA and no running experience would show higher GRF and TA metrics.

METHODS

Data from 306 Army trainees (179 male, 117 female) were collected in the first week of BCT. An inertial measurement unit was attached to the distal tibia. Participants ran (2.68-2.90m/s) and walked with an 18.1kg pack (1.21-1.34m/s) on an instrumented treadmill. For both, 7 strides of data were collected after a 3-minute warm-up. Early stance peak vertical and resultant TAs (VTA/RTA) and vertical instantaneous GRF loading rates (VILR) for the dominant leg were calculated for both tasks and averaged across strides. Vertical stiffness for running and the first peak vertical force for loaded walking were also calculated. Participants were grouped based on self-reported exercise habits in the 2 months prior to BCT as: low (0-2x/wk), medium (3-4x/wk) and high (>4x/wk) PA. Participants who reported substantial changes in exercise prior to BCT were excluded (n=105). Groups were also formed based on competitive running experience at the high school level or higher. ANOVAs were used to test for the effects of PA grouping and sex on GRFs and TAs. T-tests were used to assess the effects of running experience on running variables only.

RESULTS AND DISCUSSION

There were no significant main effects of PA grouping (F=0.087-1.188, p=0.31-0.92) or interactions with sex (F=0.439-2.013, p=0.14-0.65). There were significant main effects of sex, with females having higher VTA and RTA during running, and higher VTA, RTA, and VILR during loaded walking (Table 1). No significant differences were found between trainees with competitive running experience compared to without (t=0.045-0.466, p=0.65-0.96).

Our hypotheses were not supported for PA levels or running experience. This may be partially due to the need for more detailed data to accurately group trainees, such as the exercise types and intensity for PA and training volume for running experience. For example, Paquette [3] demonstrated significant differences in gait mechanics between active runners, solely based on training volume. We did find higher peak TAs and GRF loading rates in females vs males during both tasks, with small to moderate effect sizes.

CONCLUSIONS

Our results demonstrate significantly higher loading in females during running and walking with load carriage. Further work is needed to confirm whether these differences are a contributing factor to the higher injury rates seen in female vs male trainees during BCT.

ESTABLISHING SCIENTIFICALLY MEANINGFUL EFFECT SIZES FOR KNEE ABDUCTION MOMENT CURVE REDUCTIONS IN SIDESTEPPING USING 1D POWER ANALYSIS

Hazel Tucker[1], Todd C. Pataky[2], Jos Vanrenterghem[3] and Mark A. Robinson[1]

INTRODUCTION

The knee abduction moment (KAM) is often used as a primary outcome measure in biomechanics. In the context of knee injury risk, high KAMs are undesirable and can be reduced through training interventions [1]. Although researchers often focus on reducing the peak KAM, knee loading is also cumulative so a reduction in the moment curve may be desired.

An empirical aim of altering the KAM curve requires a 1D effect of interest (i.e. the shape of the curve) and an effect size, both required for 1D (curve-based) power analysis [2].

The aim of this study was to (1) establish a scientifically meaningul KAM curve and effect size for 1D power analysis, and to (2) contrast sample size estimation results using 0D and 1D power analyses.

METHODS

A systematic search of Scopus and Web of Science was performed to extract papers assessing the KAM during sidestep cutting. To determine KAM effect sizes, we identified studies reporting a pre to post change in peak KAM following a training intervention (>4 weeks).

To establish a typical KAM curve, a second group of papers were selected from the initial search that visually reported a 1D KAM curve. These studies had to have tested healthy participants, used an approach run, clearly labelling of direction, use clear units over 100% stance and other criteria. Where data were not directly available KAM curves were digitized using WebPlotDigitizer.

Using the resulting 1D curve and an informed range of effect sizes [0.2, 0.4, 0.6, 0.8, 1.0] literature-informed reduced KAM signals were created using a negative Gaussian pulse applied to the 1D effect signal closest to the mean curve from all studies. 1D sample size estimation was conducted using power1d (v.0.1.1, https://github.com/power1d) in Python [3].

Omnibus power (i.e., power associated with effect detection anywhere in time) was calculated and the minimum sample size where power>0.8 was estimated across the range of effect sizes. For comparison, 1D sample sizes were compared to 0D sample sizes using the same effect sizes with alpha at 0.05 and a power of 0.8.

RESULTS AND DISCUSSION

Effect size: Eleven papers reported sidestepping pre-post peak KAM changes following a training intervention. Effect sizes ranged from 0.06-0.77 (equivalent to 0.03-0.14 Nm/kg). The most successful intervention was a 6-weeks of technique training [1]. Whilst a range of effect sizes might be expected for different interventions it makes choosing literature informed effect sizes challenging. Interestingly, the effect sizes chosen for power analysis in the intervention studies were all >0.65 or not explicitly reported.

Effect curve: Twenty papers had visually reported a KAM curve (figure 1). There was some surprising dissimilarity between curves with respect to KAM curve shape, magnitudes, direction and key features.

Power analysis: 1D sample sizes ranged from 310 (effect size of 0.2) to 18 (effect size of 1.0). In comparison 0D sample sizes ranged from 8-148. Differences between 0D and 1D sample sizes ranged from 10-162 samples, similar to previous work [2].

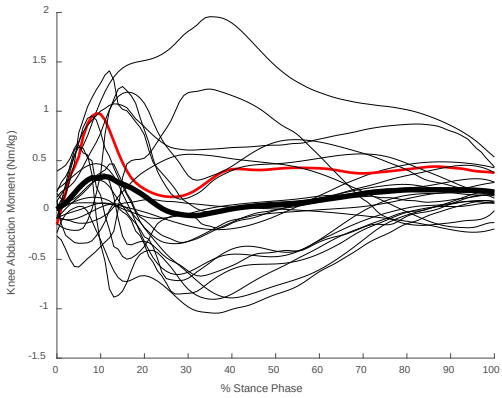

Figure 1. KAM curves during sidestepping (mean curve – bold; closest to the mean curve – red). The red "effect" curve was used for subsequent 1D power analysis.

CONCLUSIONS

Conducting robustly powered interventions to reduce KAM curves is challenging due to inconsistent effect sizes and profiles. Critical reflection on the suitability of the KAM as a primary outcome measure is required, e.g. concerning inter-lab (in)consistencies.

INTRODUCTION

Distal radius fractures are the most common upper extremity fractures. They are often the subject of rehabilitation, and the primary outcomes are joint range of motion and muscle strength. On the other hand, there are some cases in which recovery of these outcomes does not necessarily lead to use of the disabled upper limb in daily life. Recently, monitoring with accelerometers has attracted attention as a method to objectively measure impaired upper limb activity in daily life [1,2]. For distal radius fractures, the affected side of the fracture is one of the factors that affect the use of the disabled upper limb in daily life. The human hand has a laterality, with the dominant hand generally performing the primary movement and the non-dominant hand performing complementary. Therefore, it is thought that a dominant hand fracture affects the use of the disabled upper limb more than a non-dominant hand fracture, and that symmetrical upper limb activity is less likely to occur, but this is still unclear.

METHODS

Subjects were recruited that aged 65 years or older with a diagnosis of distal radius fracture who visited the Nagoya Ekisaikai Hospital, between May 1, 2019 and September 30, 2021. This study was conducted after approved from the institutional review board of the affiliated institution.

Accelerometer: The Actigraph GT-3XBT (Actigraph, Pensacola, FL) is a compact and lightweight 3-axis solid-state accelerometer (46 mm × 33 mm × 15 mm, 19 g) with a sampling rate of 30 Hz and a ±8 G range. In this study, measurements were taken by attaching the accelerometer to the wrist using a wristband. The data was measured continuously for 24 hours.

Data processing: The activity count (0.001664 g/count), a unit unique to the acceleration, was calculated after applying a bandpass filter from 0.25 to 2.5 Hz and setting the epoch time to 1 second. The values of the three axes (x,y,z) were combined by the root-mean-square process to obtain a vector value (VM; Vector magnitude) as data.

Laterality index (LI): Laterality in upper limb activity was calculated using the laterality index (19, 20, 21) with the following formula;

$$LI = VM(Rt)-VM(Lt) / VM(Rt)+M(Lt)$$

RESULTS AND DISCUSSION

There were 42 subjects, all of whom were right-handed. Of the 42 subjects, 19 had injuries to the dominant hand (right) and 23 to the non-dominant hand (left). There were no significant differences in age, gender, fracture type, time from injury to surgery, and start of rehabilitation between dominant and non-dominant hand injuries group ($p<0.05$). Regarding longitudinal recovery, LI quickly approached 0 (bilaterally symmetrical) at 4 weeks postoperatively in the dominant hand injured patients, while LI was significantly higher than the dominant hand injured group in the non-dominant hand injured group even at 12 weeks postoperatively ($p<0.05$, split-plot design ANOVA) (Figure 1).

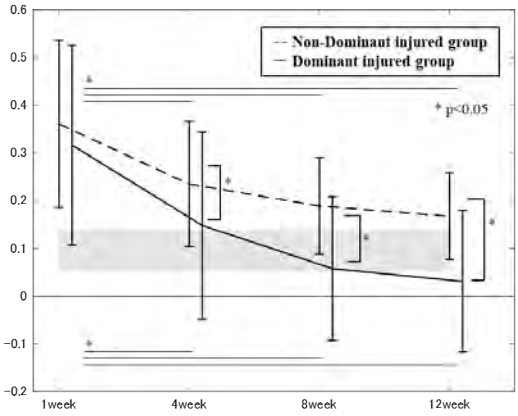

Figure 1

Recovery of laterality index in the distal radius fracture patients.

・X-axis; postoperative weeks, Y-axis; laterality index. 0" indicates bilateral symmetry. For the dominant injury group, the laterality index is multiplied by "-1". Thus, a positive value indicates "use on the non-fracture side" and a negative value indicates "use on the fracture side".

・Gray areas indicate LI averages for healthy subjects.

CONCLUSIONS

The injured side affected the longitudinal recovery of upper limb activity; especially, the recovery tends to be delayed in the upper limb use for non-dominant injured patients. Further rehabilitation methods should be considered.

INTRODUCTION

Knee osteoarthritis (OA) is common, and incidence will rise with the aging Asian population in countries like Singapore and as obesity rates increase [1]. However, there is currently a lack of understanding of the biomechanical factors that predate knee OA [1]. Also, the ankle and foot biomechanics have potential influences on knee OA development [2,3]. Plantar pressure distribution changed with knee OA [2][3] but data for people at high-risk knee OA are lacking. Having foot/ankle symptoms increased risk of developing knee OA but plantar insole pressure was not collected [4]. This research therefore aimed to address the current knowledge gap in how plantar pressure influences the onset of knee OA. We evaluate the plantar pressure differences among normal, high-risk and early knee OA Asian participants.

METHODS

Twenty-one normal (age: mean 49.8 (SD 12.2) years old, height: mean 1.59 (SD 0.11) m, weight: mean 52.3 (SD 9.5) kg)), 13 high-risk (age: mean 46.9 (SD 12.4) years old, height: mean 1.63 (SD 0.10) m, weight: mean 62.8 (SD 15.5) kg)) and 5 early knee OA (age: mean 59.4 (SD 7.5) years old, height: mean 1.61 (SD 0.05) m, weight: mean 67.5 (SD 8.6) kg) participants were recruited. Normal participants were defined as: BMI < 23; waist circumference < 80cm for females and < 90cm for males; had no pain in the past six months; no occupation history of high-risk activities of prolong loading of the knees and no family history of OA. Rest of participants were sent for Xray and graded using the Kellgren/Lawrence (KL) method. Only participants with KL grading of 2 and below were recruited and were sent for a doctor evaluation to further categorize these participants into 'normal', 'high-risk' or 'early OA'. The Knee injury and Osteoarthritis Outcome Score (KOOS), Singapore English and Chinese versions LK 1.0 was also collected. Participants walked at a self-selected fastest velocity over a flat 10m walkway in provided shoes (Adults Aquashoes 100, Decathlon, France). Plantar insole measures were measured using the Moticon insole sensors (Moticon ReGo AG, Munich, Germany).

RESULTS AND DISCUSSION

Overall average KOOs score was 97 (SD 4), 95 (SD 5) and 84 (SD 13) for normal, high-risk and early OA participants respectively. Figure 1 shows a representative of the differences in average peak pressure among normal, high-risk and early OA participants. A Mann-Whitney U test ($\alpha = 0.05$) showed that high-risk and early OA participants (combined as one group) exhibited significantly higher maximum pressure ($p = 0.01$ to $p = 0.02$) than normal participants at sensors in the boxed area (Figure 1). As compared to high-risk participants, early OA participants exhibited higher mean peak planter pressure especially at the lateral side of the mid and forefoot (Figure 1D). This is the first study that recruit high-risk participants and results suggest that high-risk or early knee OA participants might be identified through plantar pressure differences. A bigger sample size should be used to further validate this result.

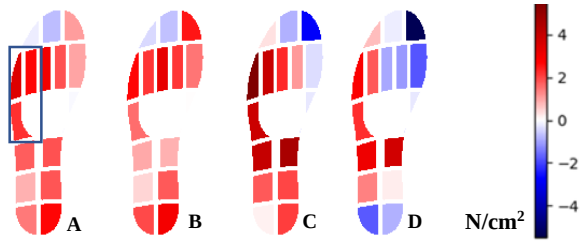

Figure 1 Plantar pressure differences between (A) combined high-risk-early OA minus normal, (B) high-risk minus normal, (C) early OA minus normal and (D) early OA minus high-risk. Boxed region was significantly higher in maximum plantar pressure for high-risk and early knee OA participants as compared to normal participants.

CONCLUSIONS

High-risk and early OA participants combined exhibited significantly higher plantar pressure than normal participants at the lateral aspect of the mid and forefoot during walking. This could provide a method of identification of high risk and early OA participants.

INTRODUCTION

As the number of people with low vision is increasing worldwide [1], their safe mobility is an urgent issue. These challenges are long-lasting in progressive eye diseases such as retinitis pigmentosa. Patients with ocular disease present not only with visual impairment but also with visual field disturbances and reduced contrast sensitivity [2]. Therefore, a different movement strategy is required when straddling a gap than when walking on level ground. This study aimed to clarify the effect of afferent tunnel vision on lower limb movements when straddling a gap.

METHODS

Eight healthy young adults with normal vision were recruited from the university community (male, n = 2: age 22.5 ± 0.7 years; female, n = 6: age 23.3 ± 1.9 years). Participants were instructed to walk and cross over platforms with a gap at the same level (0 cm) and raised platform (+15 cm) under two vision conditions: normal or corrected eyesight and tunnel vision (10°) simulation goggles (M. TAKATAOPTICAL Co., Ltd, Japan). The dimension of the origin platform was 1.1 m (L) × 1.1 m (W) × 0.3 m (H), and two target platforms namely the same level and raised were 1.1 m × 1.1 m × 0.3 m and 1.1 m × 1.1 m × 0.45 m, respectively. A 10 cm gap was designated between the platforms.

Cortex™ 3D motion analysis software, consisting of 8 infrared cameras (Motion Analysis Corporation, Santa Rosa, CA, USA) and 9.5 mm diameter reflective markers, was used to record the participants' motion using the Helen Hayes marker set. Gait kinematic parameters of the leading foot (LF), such as the ROM of the hip, knee and ankle joints and the highest point of toe clearance were calculated using the KineAnalyzer software (Kissei Comtec Co., Ltd, Japan).

RESULTS AND DISCUSSION

Two-way repeated-measure ANOVA was used to analyze the effects of vision and platform conditions. For D2, the main effects of vision and platform are not significant. However, the vision × platform showed significant interaction ($p < 0.05$). Post hoc analysis showed participants exhibit a higher D2 at platform 45 cm compared to platform 30 cm ($p<0.05$) at tunnel vision condition (Figure 1a). The ROM of the hip and ankle joints up to LF ground contact was characterized differently depending on the visual condition (Figure 1b, c, d).

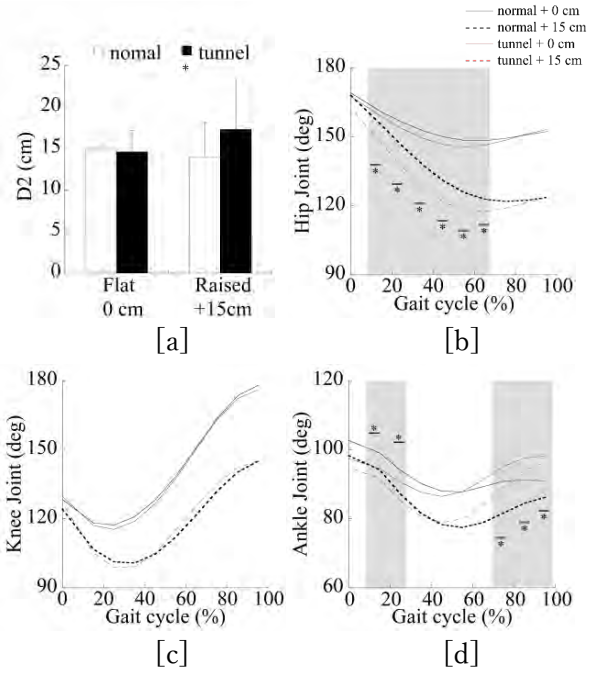

Figure 1 [a]Highest points of the LF(D2), ROM Joint [b; Hip], [c; Knee], [d; Ankle] Changes during gap cross-over. *: $p<0.05$

CONCLUSIONS

At raised 15 cm platform, participants with tunnel vision condition lifted their legs higher to perform the movement than those in the normal or corrected vision condition. These results suggested that participants employ adjustment with the hip and knee flexion-extension movement to complete the cross-over movement under reduced visual field conditions. Generally, when visual sensory input is reduced due to visual field impairment, participants will experience difficulties with object perception and postural control occur [3]. Therefore, in order to reduce the risk of tripping and falling on steps with tunnel vision condition, participants attempted to straddle with higher feet raise.

INTRODUCTION

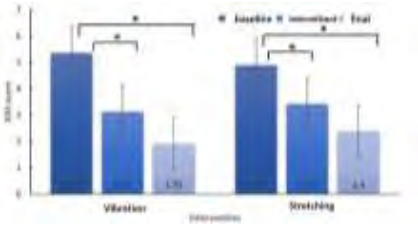
The prevalence of self-reported musculoskeletal disorders (MSD) among school teachers ranges between 39% and 95%.[1,2] Neck pain was the most common teaching-related musculoskeletal disorders.[2] A recent survey from patients with chronic non-specific neck pain showing myofascial pain syndrome (MPS) were prevalent (93.75%) in the upper trapezius.[3] Self-management strategies are considered essential to the management of persistent musculoskeletal disorders. Although studies examined vibration therapy (VT) and stretching exercise (SE) in myofascial pain syndrome (MPS),[4,5] no study has yet compared these two treatments. The purpose of this study was to comparite the effect of self-administered vibration therapy and stretching exercise in the upper trapezius on teachers with myofascial pain syndrome.

METHODS

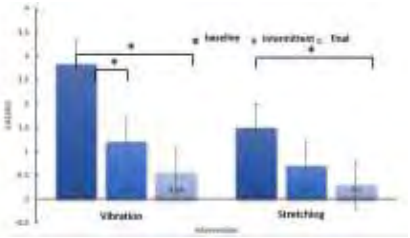
30 teachers with upper trapezius myofascial pain were enrolled into two treatment groups: vibration therapy group and stretching exercise group. All participates received the treatments for 2 weeks, and 3 times a week. Visual Analog Scale (VAS) of Pain, VAS of Pain threshold with a force of 2 kg/cm2 (VAS $_{2KG}$), Pressure Pain Threshold (PPT), and the range of motion (ROM) of neck sidebending to the opposite side were assessed at baseline and intermittent after the first, and final treatment sessions.

RESULTS AND DISCUSSION

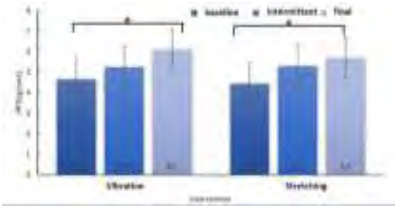
In the vibration massage group, the VAS of Pain ($p<.001$), the VAS of Pain threshold with a force of 2 kg/cm2 ($p=.01$), the PPT ($p=.02$), the side bend ROM of the neck ($p<.001$) had significant improvement after intervention. In the stretching exercise group, the VAS of Pain ($p<.001$) and the side bend ROM of the neck ($p=.02$) had significant improvement as well. (Figure 1)..



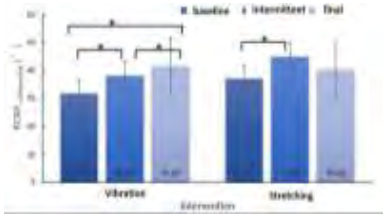
(A) VAS score



(B) VAS$_{2KG}$



(C) PPT



(D) ROM$_{sidebending}$

Figure 1 Differences in related parameters before, intermittent, and after intervention. (A) VAS score (B) VAS $_{2KG}$ score (C) Pressure Pain Threshold (D) Neck ROM of sidebending

CONCLUSIONS

Either vibration massage or stretching exercise had an immediate improvement in relieving pain. The vibration therapy is slightly better than the stretching exercise. Therefore, it is recommended that teachers with upper trapezius myofascial pain can apply vibration therapy or stretching exercises to relieve the pain and improve the joint function.

Influence of pelvic and lower limb joint kinematics on hamstring muscle-tendon strain during the late swing phase of maximal speed sprinting

Teumitsu Miyazaki[1] and Norihisa Fujii

INTRODUCTION

Hamstring strain injuries would occur during the late swing phase of high-speed running [1]. The biceps femoris long head (BFlh) has a higher incidence rate of strain injuries than the other hamstring muscles. Although a previous study have investigated differences in sprint kinematics between lower limbs with and without hamstring strain injuries [2], the pelvic and lower limb joint kinematics that affect hamstring muscle-tendon unit (MTU) strain during maximal speed sprinting remain unclear. Thus, we aimed to identify the pelvis and lower limb joint kinematics which has a greater impact on the hamstring MTU strains during the late swing phase of maximal speed sprinting using an angle-driven simulation.

METHODS

Forty male collegiate athletes (age, 20.1 ± 1.2 years; height, 170.5 ± 5.5 cm; body mass, 70.5 ± 7.4 kg) participated in this study. All participants performed several 50 m sprinting trials with their maximal effort (sprint velocity, 8.95 ± 0.6 m/s). A three-dimensional motion capture system sampling at 250Hz (VICON-MX, Vicon Motion Systems Ltd., UK) was used to record three-dimensional marker trajectories attached to the whole body. We simulated sprint motion, which increases the BFlh MTU length during the late swing phase from experimental sprint motion, using a single averaged musculoskeletal model consisting of the pelvis and right lower limbs [3]. The optimization was performed by minimizing an objective function with a constraint that the simulated sprint motion was equal to the targeted BFlh MTU length. The targeted BFlh MTU length was increased from the MTU length of the experimental sprint motion. To minimize the differences in the sprint kinematics and kinetics between simulated and experimental sprint motions, the objective function was the sum of three components with weighting factors: squared error between the experimental and simulated (1) angular acceleration, (2) joint torque, and (3) residual force and moment exerted to the pelvis for each degree of freedom. We calculated the change ratios of pelvic anterior/posterior tilt, and hip and knee flexion/extension joint angles at the simulated sprint motion from the experimental sprint motion. These change ratios were compared between the pelvis, hip, and knee joints using one-way analysis of variance with repeated measures. If the main effect was significant, pairwise comparisons were conducted for all pairs using a paired two-tailed t-test with Bonferroni correction. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

The peak BFlh MTU length of the simulated sprint increased compared to that of the experimental sprint (Figure 1a). The pelvic anterior tilt, hip flexion, and knee extension angles of the simulated sprint were greater than those of the experimental sprint. Additionally, the change ratio of pelvic anterior/posterior tilt angle was larger than those of hip and knee flexion/extension angles (Figure 1b; $p < 0.001$). The results indicate that the pelvic anterior tilt would have a more significant impact on BFlh MTU length during the late swing phase, compared to hip and knee flexion/extension angles. Pelvic anterior tilt might be a biomechanical factor associated with the risk of hamstring strain injuries [3]. Thus, the findings of this study imply that training strategies aimed at decreasing pelvic anterior tilt during the late swing phase of maximal speed sprinting could be effective in preventing hamstring strain injuries.

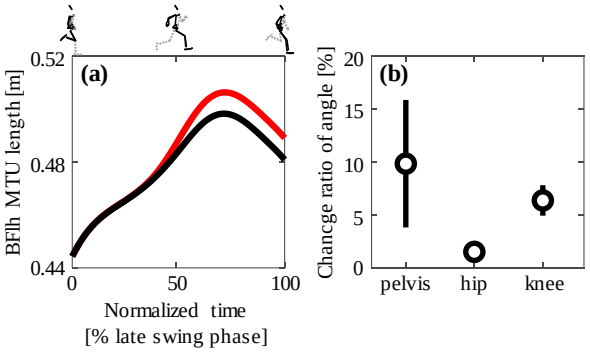

Figure 1 (a) Mean simulated (red line) and experimental (black line) BFlh MTU length during the late swing phase of maximal speed sprinting. (b) Mean values (open circle) and standard deviation (vertical line) of change ratios of pelvis, hip, and knee joint angles.

CONCLUSIONS

This study simulated sprint motion that increases BFlh MTU length during the late swing phase of maximal speed sprinting using an angle-driven simulation. Our results demonstrate that an increase in pelvic anterior tilt angle has the greatest impact on an increase in BFlh MTU length during the late swing phase of maximal speed sprinting compared to hip and knee joint angles.

INTRODUCTION

Total hip replacement (THR) is an alternative surgical option for chronic hip injuries including severe hip osteoarthritis and dysplasia [1]. It has been stated that Mongolian national hospitals have been performing THR since 1998. Domestic clinical studies have utilized patient-reported surveys and qualitative approaches to evaluate the outcome of THR, and it is favorable in Mongolia. However, from a biomechanical viewpoint, there is no quantitative evidence of THR on recovering functional motion and improving hip joint mobility for patients with hip dysplasia. Therefore, the current study was purposed to quantitatively investigate hip joint motion before and after THR for patients with hip dysplasia using a wearable motion capture system.

METHODS

Two male subjects with chronic hip dysplasia participated in this study. For patient 1 (32 years old, male), the right-sided THR surgery was performed and for patient 2 (47 years old, male), bilateral THR was performed with a single experienced surgeon (15 years of experience). A conventional posterior approach was used to perform THR surgeries with commercial hip implants (K-Implant, Germany) [2]. The wearable motion capture system (MVN, Xsens technologies, Netherlands) was utilized to capture hip joint motion during walking and squatting before and after THR [3]. Three-dimensional hip range of motion (ROMs) was recorded during clinical tests conducted by an experienced surgeon. Also, the pre-operative and post-operative hip joint kinematics were compared to the control group (10 healthy male subjects).

Table 1: Comparison of hip ROM during clinical tests before and after THR

		Flex	Int	Ext	Abd	Add
Patient 1	Before	44º	8º	8º	10º	7º
(right hip)	After	59º	22º	32º	27º	16º
Patient 2	Before	50º	9º	8º	10º	11º
(right hip)	After	42º	12º	22º	11º	4º
Patient 2	Before	58º	7º	9º	8 º	6º
(left hip)	After	64º	25º	8º	20 º	7º

RESULTS AND DISCUSSION

The results of clinical tests relieved that post-operative ROM in hip flexion, internal and external rotation, abduction, and adduction were mainly increased after THR (Table 1). However, a decrease in hip flexion and adduction was observed in the right hip of patient 2. Such a result may be related to the consequence of the bilateral THR procedure. Although post-operative hip kinematics were improved during walking and squat, it was not fully recovered as normal subject data (Figure 1).

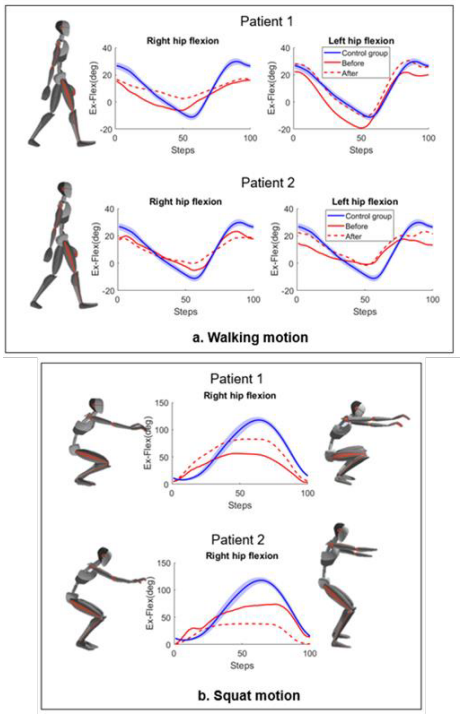

Figure 1 Hip flexion-extension during walking and squat before and after THR

CONCLUSIONS

This is the first quantitate report of the kinematic comparison before and after THR surgery in Mongolia. The result could provide new insight to the surgeons to assess joint functionality, and surgical outcomes and to improve rehabilitation protocol.

Stair Ambulation Reveals Greater Medial Meniscus Extrusion in Healthy Young Volunteers

INTRODUCTION

Medial meniscus extrusion (MME) expands with greater mechanical stress. Increase in MME during gait was correlated with mechanical stress [1] whereas it is still unknown the dynamics of MME during stair ambulation. The mechanical stress is known to be higher in stair ambulation than that in gait, and the increase in MME might expand according to the greater mechanical stress. Then, the aim of this study is to investigate the effect of mechanical stress during stair ambulation on increase in MME.

METHODS

Twenty healthy participants (females: 10, age: 22.3 ± 0.9 years) were recruited in this study. They were asked to perform in three tasks of gait, stair ascent and descent. The vertical grand reaction force (GRFz) as the representative mechanical stress and knee flexion angle during stance phase were obtained by three-dimensional motion analysis system. The MME was evaluated by ultrasonography. A prototype transducer with a flat-shaped linear-array was placed longitudinally on the medial joint space and recorded the dynamics of meniscus during task on video mode. The value of MME was shown as the distance from the medial tibial plateau cortex to the outermost edge of the medial meniscus. Moreover, the increase in MME was identified as the difference in MME at the maximum and the initial contact during task.

RESULTS AND DISCUSSION

The GRFz and increase in MME during stair ascent and descent were higher than that during gait (Table1). Moreover, there were no correlation between the GRFz and the increase in MME for three tasks. Although a previous study reported that a mechanical stress was correlated with the increase in MME [2], our result including task of the stair ambulation did not support it. Stair ambulation requires motion with deep knee flexion compared with gait. The medial meniscus has the feature of movement to posterior and lateral direction during knee flexion, and it raise concern about masking the effect of mechanical stress on the increase in MME. Therefore, the increase in MME during stair ambulation could occur by a combination of the mechanical stress and knee flexion motion. These results may contribute to understand the dynamics of medial meniscus during motion with deep knee flexion on the knee.

CONCLUSIONS

Stair ambulation revealed the greater increase in MME.

INTRODUCTION

Bone mineral density (BMD) generally increases until the age of 20 to 44 y/o, but BMD of 2 to 18% decreases during from 35 to 59 y/o [1]. It has been reported that the decrease of BMD is cased by the shorter bone metabolism period and longer bone formation period [2]. To understand the mechanism of the bone metabolism, in this study, we calculated the bone metabolic step and reproduced the change of BMD due to aging.

METHODS

In this study, we conducted bone remodelling simulation to reproduce the bone metabolism. To obtain the distribution of the bone mineral, we took Multi-detector row computed tomography (MDCT) images, which is higher resolution than a single-detector row CT and allows us to take images for the human. MDCT is lower resolution than μCT, and one pixel of the image includes the bone trabecular structure and cavity. Therefore, the CT value expresses an average between the brightness of the bone and cavity. In this study, we divided one pixel size of MDCT into subpixel sizes of μCT, and estimated the ratio among the bone, cavity, and calcification. In this study, the brightness of the bone was assumed white, the cavity was black, and the calcification was gray respectively, and the averaged brightness corresponded to the brightness of the MDCT. The subdivided pixels for μCT had one of the characteristics of the bone, calcification, and cavity, but they did not assume to reflect the microstructure of the trabecular bone. In this study, the subdivided pixels of the bone and calcification were metabolized, and then the brightness was changed. The metabolism consisted of the resorption, formation and rest as shown in Figure 1 (a). After the step of the metabolic calculation, the averaged brightness was calculated for the size of MDCT pixel. The changes of BMD were evaluated through the cycle [1][3].

In this study, to reproduce young age, the resorption, the formation, and the rest were assumed as 4, 16, 80% respectively, while to reproduce elderly age, they were 12, 48, 40%.

Also, to reproduce the bone porosis, the maximum brightness of each subdivided pixel was reduced by 10%. This reduction was applied after 100th step, and more 100 steps were calculated.

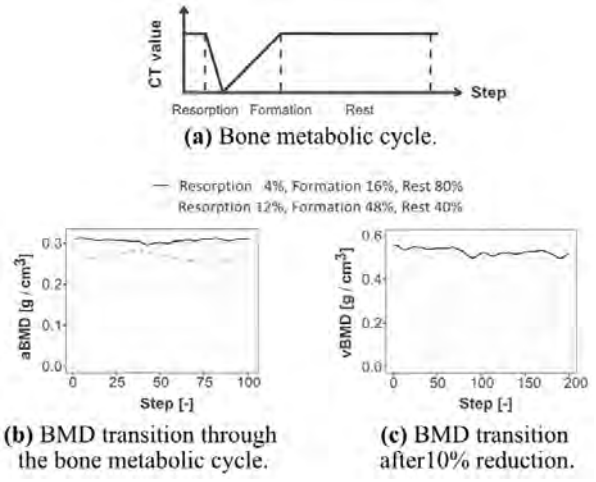

Figure 1 Bone metabolic cycle and BMD transition.

RESULTS AND DISCUSSION

As shown in Figure 1 (b), the elderly age shows low areal BMD (aBMD) value through the cycle, with compared to the young age. In the simulation of the elderly age, 60% of the bone and calcification was metabolized, and then the many of the subdivided pixels were in the process of the calcification duration. This should result in the low aBMD value. Figure 1 (c) shows a change of volumetric BMD (vBMD) through two metabolic cycles. After one cycle of the bone metabolism (100th step later), the vBMD decreases by 3.5%, with a maximum reduction of 10.9% through the later cycle. After the 10% reduction, the subdivided pixels become the maximum values sequentially. Therefore, the vBMD could show uneven waveforms, not flat waveforms. Thus, the two conditions in this study could reproduce the process of the osteoporosis caused by age.

CONCLUSIONS

The bone metabolism simulation considering the ratio of the resorption, formation and rest, and the changes of baseline of BMD could allow us to reflect the BMD due to aging.

INTRODUCTION

High frequency and intensity and long duration of exercises with insufficient recovery can deteriorate the structural integrity of articular cartilage, which may lead to joint degeneration such as osteoarthritis [1]. Cross-sectional comparisons between athletes with different types of mechanical loading (e.g., compressive vs compressive with rotational) and untrained individuals of the morphological characteristics of the femoral cartilage could suggest cartilage health in response to a long-term adaptation of physical activity in terms of volume and type. Therefore, this study compared the cross-sectional area (CSA) and thickness (medial, lateral, and intercondylar) of the femoral cartilage between archery and badminton players to non-athlete individuals.

METHODS

Thirty-four male archery players (20.2 years, 173.9 cm, 76.4 kg, career: 10.2 years), 37 male badminton players (20.2 years, 177.5 cm, 72.1 kg, career: 11.3 years), and 36 non-athlete males (21.5 years, 174.9 cm, 71.3 kg, ≥150 min of exercise per week) participated in this study. Individuals with a history of musculoskeletal surgery were excluded. After giving informed consent, subjects were seated with their knees fully extended for 20 min to remove the effect of preceding weight-bearing activities. Afterwards, the testing knee was flexed to 140°, and a 10.0 MHz linear probe (30 fps with a depth of 3.0 cm) was placed between the medial and lateral femoral condyles and then rotated to visualise the clear view of the cartilage. Three images on each leg were obtained (dominant: the leg to kick a ball). The CSA and thickness (medial, lateral, and intercondylar) were then calculated using ImageJ software. Values on three images from each dependent measurement on each side were averaged and analysed using two-way (side × group) analysis of variances; and Tukey tests were performed. Cohen's d effect sizes (d) were calculated for the statistical significances.

RESULTS AND DISCUSSION

There were no statistical interactions on any of the dependent measurements ($F_{5,210}$≥28.03, p≥0.46, Table 1). Regardless of side, the femoral cartilage CSA ($F_{2,208}$=35.87, p<0.0001) and medial ($F_{2.208}$=26.76, p<0.0001), lateral ($F_{2,208}$=31.43, p<0.0001), and intercondylar thicknesses ($F_{2,208}$=69.05, p<0.0001) were different between groups. Specifically, the badminton players showed greater femoral cartilage CSA compared with the archery players (18%, p<0.0001, d=1.07) or non-athlete individuals (19%, p<0.0001, d=1.33). The same pattern was observed with thicknesses: badminton players showed thicker medial (≥13%, p≤0.0011, d≥0.54), lateral (≥18%, both p<0.0001, d≥0.89), and intercondylar (≥29%, both p<0.0001, d≥1.55) thickness compared with archery players and non-athlete individuals. Greater CSA and thickness may have been due to cartilage enlargement and hypertrophy [2] as a long-term adaptation of sport-specific movements in badminton.

CONCLUSIONS

Badminton players showed greater CSA and thicker femoral cartilage than archery players and non-athlete individuals. Our data suggest that rotational force could be the primary contributing factor on articular cartilage health.

INTRODUCTION

Mechanical fatigue of load bearing bone is an inevitable consequence of physical activity. Over time, cyclic loading of the skeletal system causes microdamage accumulation that reduces the overall quality of bone and leads to an accumulation of residual strain with continuous loading. In life, however, people do not cyclically load their bones continuously; rather, physical activity bouts are interrupted by periods of inactivity. It has been illustrated that residual strains in bone are recoverable when periods of unloading are provided [1,2], but whether or not this may serve as a self-healing function that extends the fatigue-life (i.e., number of cycles to failure) of bone has never been tested. The purpose of this project is to quantify the influence of test interruptions on fatigue life measurements of cortical bone.

METHODS

Twenty cortical bone specimens were extracted from bovine tibiae and machined into prismatic beams (20 x 3 x 3 mm). The samples were evenly allocated (n = 5 each) to two loading groups (continuous or interrupted) and two loading levels (140 or 150 MPa) balanced by bone apparent density. All samples were cyclically loaded in a 4-point bending configuration on an E3000 (Instron) while submerged in phosphate-buffered saline at room temperature. Cyclic tests were conducted in load control to the prescribed peak magnitude with a load ratio (i.e., minimum-to-maximum stress) of 0.1 and a frequency of 2 Hz. The continuous load group was tested without rest until failure or a predefined runout of 500,000 cycles. The interrupted group was loaded for 1 hour, followed by 2 hours of rest, and this order was repeated until failure or runout. A survival analysis was conducted to examine differences in log cycles to failure between groups with a criterion alpha level of 0.05.

RESULTS AND DISCUSSION

Fatigue-life measurements varied several orders of magnitude, which is in line with previous cyclic tests of cortical bone. Bones loaded at 150 MPa did not have a significantly lower fatigue-life than bones loaded at 140 MPa (p=0.073), and no differences between continuous and interrupted loading groups was observed (p=0.581).

During cyclic tests of this nature, bone may accumulate damage as a function of loading cycles (fatigue damage) and/or loading duration (creep damage). Creep strain recovery has previously been demonstrated *in vitro* [1,2], and we wondered if a similar phenomenon may delay damage accumulation and increase fatigue-life measurements when rest was incorporated into fatigue tests. Although we did not detect a significant effect of continuous vs. interrupted loading, our sample size was relatively small. In the future, we plan to test additional samples at lower load levels, which may better demonstrate difference between groups, as viscous strain may be more recoverable at low loads. It is important to remember that this study focused on understanding mechanical mechanisms that influence fatigue life in vitro. *In vivo*, bone remodeling and adaptation have an important influence on fatigue life.

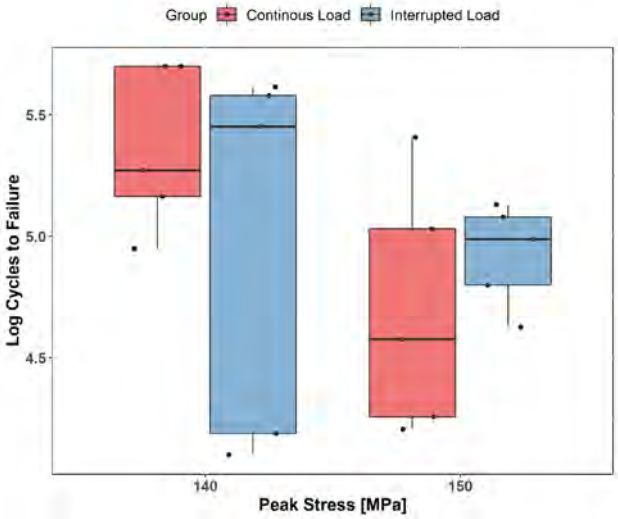

Figure 1 Fatigue life of continuous and interrupted groups.

CONCLUSIONS

Cyclic loading interruption did not have a significant effect on the fatigue life of bovine cortical bone, but a larger samples size and additional load levels may be needed to confirm this finding.

INTRODUCTION

Articular cartilage is responsible for load transmission, shock absorption and allows smoothness of articulation. It is composed of a dense extracellular matrix with mainly proteoglycans and collagen fibers, and cells. The distribution of these components defines three main zones: a superficial zone in which the collagen fibers are packed and parallel to the articular surface, a transitional zone where the collagen fibers are less packed and obliquely oriented, and a deep zone characterized by collagen fibers perpendicularly oriented. These differences define an anisotropic and inhomogeneus behavior and the characterization of the resulting variation of mechanical properties is a critical challenge due to the microscopical scale. Methods have been developed to investigate the depth dependent compressive and shear properties of cartilage [1]. Work has also been performed to capture tensile properties throughout depth [2], but the study was limited by the thickness of the slices that excluded the superficial zone. The aim of this study was to characterize the tissue in terms of tensile properties, with a sufficient spatial resolution that included all zones of cartilage. We hypothesized that cartilage shows depth dependent tensile properties.

METHODS

N=8 cartilage explants from four 8 months old bovine stifle joints were used. The explants were obtained from the medial side of the joint parallel to the antero-posterior line and were washed in $CaCl_2$ solution for 1h. Dogbone shaped samples were cut from each explant according to ASTM D638 for tensile testing type IV. The samples were then frozen in OCT and after 2 days they were cut into 9 slices of 80µm thickness each using a cryostat. In order to obtain flat dogbones, from each sample an average of 30µm depth was removed from the surface. Additionally, 20µm were discarded between each of the following slices until 900µm depth were reached. Each slice was moved into a well plate with PBS solution to avoid dehydration. Tensile tests were then run at a strain rate of 1% strain per second until rupture of the sample. During testing the sample was kept hydrated by constantly dropping PBS solution onto the tissue. Stress-strain curves were obtained from each slice and 4 parameters were identified for analysis: Ultimate tensile stress (UTStress), Ultimate tensile strain (UTStrain), Elastic modulus (EM), Toe modulus (TM). A repeated measures ANOVA was performed on the above parameters to investigate whether cartilage depth influences tensile properties.

RESULTS AND DISCUSSION

UTStress, EM and TM demonstrated similar tendencies (Fig. 1). All three parameters had their minima at approximately 200µm. Also, intermediate values were found in the most superficial layer, and the highest values were found in the deep layers. The repeated measures ANOVA indicated a significant effect (Tab 1). In contrast, UTStrain showed similar values throughout depth.

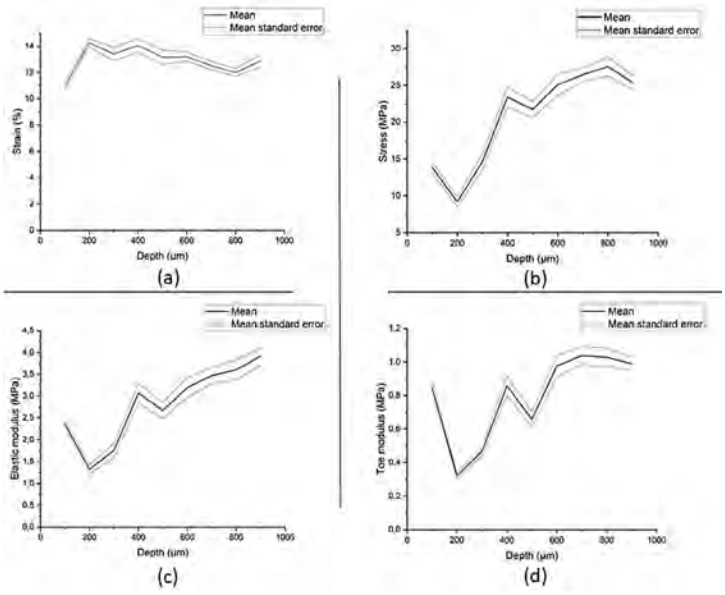

Figure 1 (a) UTStrain, (b) UTStress, (c) Elastic modulus, (d) Toe modulus for 80µm thickness slices from 30µm to 900µm depth.

Parameter	*p-value*
UTStrain (%)	$p = 0.246$
UTStress (MPa)	$\mathbf{p < 0.001}$
Elastic modulus (MPa)	$\mathbf{p < 0.001}$
Toe modulus (MPa)	$\mathbf{p = 0.028}$

Table 1: p-values of the repeated measures ANOVA.

CONCLUSIONS

Most tensile properties of articular cartilage are dependent on cartilage depth. A spatial resolution of smaller than 100 µm was necessary to capture this effect.

INTRODUCTION

Knee osteoarthritis (OA) is one of the most common diseases caused by articular cartilage degeneration, which affects the movement of the joint and leading to joint pain and stiffness. **High tibial osteotomy** (HTO) surgery, a joint-preserving surgery, is a widely used surgical method for patients with medial compartment OA [1] and with the inter-articular distance being one of the decisive index for predicting post-surgery prognosis. However, no study has investigated the effects of pre- and post-HTO surgery during functional activities and measured the *in vivo* inter-articular distances. Current study aimed to measure the *in vivo* three-dimensional kinematics of the knee joint pre- and post-HTO surgery during functional activities using biplane fluoroscopy.

METHODS

Fifteen subjects with OA (age: 58.07 ± 9.51 years; BMI: 28.56 ± 5.27 kg/m^2) performed isolated knee flexion pre and post-HTO surgery with the motions of bones measured by a bi-plane fluoroscopy system. Three-dimensional bone geometric models of the femur and tibia were then reconstructed from computed tomography images. The 3D fluoroscopy method [2] was used to determine the motions of the bones overall image frames, which were used to calculate the angles of the tibiofemoral joints against the motion. The data were then used to calculate the inter-articular distances of the medial and lateral compartment of the joint during motions to quantify the effects of HTO on the joint during isolated knee flexion. Paired-T test was used for comparisons between pre and post data with α=0.05.

RESULTS AND DISCUSSION

The pre-surgery inter-articular distance in both the medial and lateral compartments of the joint were compared with the post-surgery inter-articular distance (Figure 1 (a), (b)) and the results indicated that subjects who underwent HTO surgery showed significantly greater inter-articular distance in the medial compartment during isolated knee flexion at 35° to 65° but there was no significant difference in the lateral compartment throughout the whole motion. The current results showed that after the HTO surgery, the change of the tibial alignment lead to medial condylar lift-off, which increased the distance between the medial compartment and may stop the progression of medial compartment osteoarthritis of the knee. The current results suggested that patients with medial compartment knee OA can expect improvement in clinical outcomes after HTO surgery.

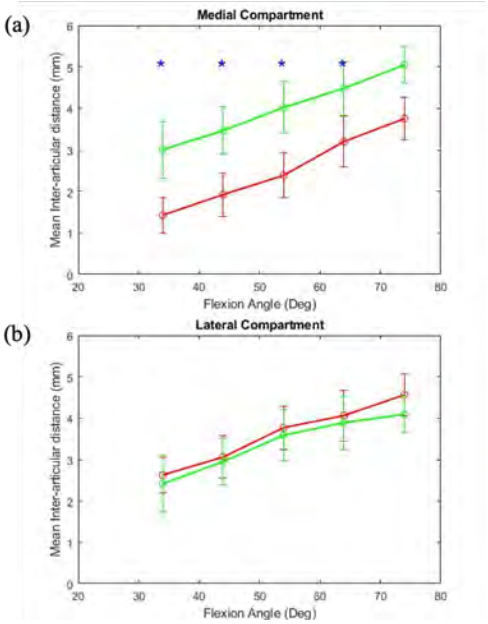

Figure 1 (a) Mean values (standard deviations) of the inter-articular distances of the pre (red) and post (green) HTO operation of the medial and (b) lateral compartment of the tibiofemoral joint.
* Significant difference between pre-OP and post-OP group.

CONCLUSIONS

The mean inter-articular distance in the medial compartment was found to increase after HTO surgery, and the medial condylar liftoff is likely to unload the involved joint compartment. The current findings may contribute to a better understanding of the underlying mechanism for the treatment of medial compartment arthritis.

ADAPTING THE PROSTHESIS EVALUATION QUESTIONNAIRE TO ASSESS SEX DIFFERENCES IN THE PROSTHETIC NEEDS AND PRIORITIES OF LOWER LIMB AMPUTEES

INTRODUCTION

Despite ~30% of lower limb amputees (LLAs) being female [1], the majority of LLA and prosthetics research is focused on males [2]. Female LLAs also experience different challenges than males, including having a higher risk of osteoarthritis, lower functional abilities, higher prosthesis rejection rates, and greater overall dissatisfaction [3]. A key aspect of early-stage medical device research is consulting with users to understand their specific needs [4]. Therefore, studying sex differences in the prosthetic priorities of LLAs through survey methods may improve understanding of female-specific needs as well as inform the design of sex-specific prosthetics. However, as females have been historically underrepresentated or overlooked, most prosthesis questionnaires neglect what may make them different. To this end, we took a user-centered design (UCD) approach to adapting the Prosthesis Evaluation Questionnaire (PEQ) [5] to better capture and assess sex differences in LLA prosthetic needs and priorities.

METHODS

A committee of 5 female LLAs (i.e., prosthesis users) was formed to engage them in developing a modified questionnaire. We met with these users to assess and adapt the original PEQ. In doing so, they contributed to the creation of a modified instrument targeting technical and personal aspects of a user's prosthesis, and sex and gender related topics. In the adapted questionnaire, 7 of the 9 validated PEQ subscales were retained and new questions were added to better target the study's objectives. Closed questions were scored on Likert scales from 1 (negative) to 10 (positive). Results were analysed using Mann-Whitney U tests in SPSS.

RESULTS AND DISCUSSION

The questionnaire was completed by 18 LLAs (9 female, 9 male). No statistically significant sex differences (i.e., $p < 0.05$) were found in participant demographics, making these good comparative groups. Although no significant sex differences were found in the validated PEQ subscales, differences were found in individual questions on mobility and psychosocial factors (Table 1). Females expressed a significantly poorer ability to ambulate up or down a steep hill, potentially linking to their prosthetic and functional challenges presented in literature [3]. As well, sex-specific challenges related to mobility have major implications for the design of sex-specific prosthetics. Such challenges can also further impact psychosocial aspects of an amputee's life. For instance, female participants were significantly less interested in having children because of their amputation. However, this had no effect on men's interest. We plan to explore links between such psychosocial aspects and mobility challenges by triangulating questionnaire findings with those from planned follow-up interviews.

CONCLUSIONS

A UCD approach was taken to modify the PEQ and assess sex differences in LLA prosthetic needs. Female participants expressed poorer ambulation capabilities with their prosthetic compared with males. Sex-specific challenges with LLA mobility emphasize the need for further research addressing sex differences in physical and psychosocial aspects. Such differences have major implications for and can ultimately guide design of sex-specific prosthetics.

KINEMATICS OF DOWNHILL SKIING WITH LOWER LIMB PROSTHESIS ON TWO SKIS

INTRODUCTION

The most common technique for amputee (amp.) skiers is three-track skiing, where the amp. skis on one ski with the help of so-called stabilizers, or crutches with small skis [1]. In this technique, the amputee skier loads the axial system by unilaterally overloading the healthy leg. Theory suggests that amp. skiers can extremely overload the healthy limb during a ski turn, resulting in the same overload as non-amp. skiers on both legs, which is 6g [2]. Based on the development of prosthetics, skiers with lower limb amputation have been given a new opportunity to ski on two skis with active involvement of the amputated limb through the prosthesis. Our aim is to compare the kinematics of movement during the skiing turn of skiers with and without amputation (WA), this is pilot research in laboratory conditions, which will be followed by field research on the ski slope.

METHODS

We analyzed the kinematics of lower limb movement using the Qualisys opto-electrical system (figure 1 left) on the SkyTech Interactiv ski trainer (figure 1 right). The toe and little toe of the foot (prosthesis), the ankle joint axis, the outer epicondyle of the knee joint, and the lateral side of mid-thigh were identified. The following parameters were monitored during the 6 left and right ski turns: thigh motion relative to the mat in the frontal and sagittal planes, tibia motion relative to the mat in the frontal and sagittal planes, and knee joint angle during the ski turns. Individual parameters were recorded at the apex of the turn and in the transition between turns. The following groups were observed: skier with transfemoral amputation (TFA), skier with transtibial amputation (TTA), and skier WA. Amputee skiers were equipped with a special ski prosthesis ProCarve, Otto Bock, Germany. The results were analyzed using statistical method: variance of movement with 95% probability, maximum range of motion, and mean angle of each parameter.

RESULTS AND DISCUSSION

While the prosthetic ski was internal results showed maximum values of 27° in the frontal plane of the thigh in a skier with a TFA, in the skier with TTA this parameter was 19°, and for the non-amputee skier at 17° for the nondominant leg. It indicates that the TFA skier relies more on the healthy leg during the turns. Another selected parameter was the average angle of the knee joint, which was 140° for the non-amputee skier at the non-dominant leg (inner ski), 147° for the skier with TTA, at the leg with prosthesis (inner) and 144° for the TFA leg with prosthesis (inner ski) indicating a very similar biomechanical movement to the non-amputee.

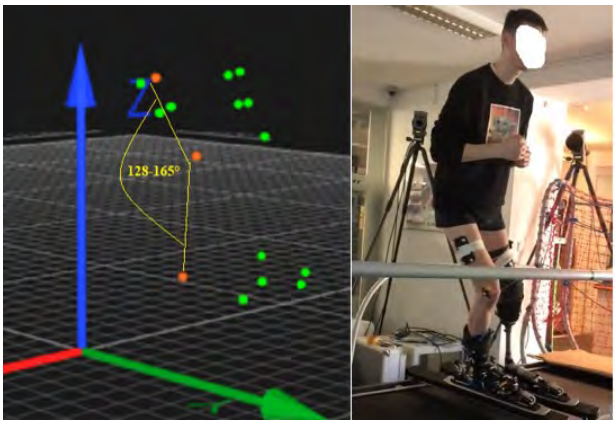

Figure 1 Qualisys software(left) and skier with TT amputation on SkyTech Interactiv ski trainer during messurement (right).

CONCLUSIONS

According to the results, the pneumatic-hydraulic prosthesis is suitable for downhill skiing even for skiers with transfemoral amputation. The adjustment of the prosthesis corresponds to the basic position of the skier WA. Future studies should consider targeting distribution of the load equally on both skies to avoid overloading of the healthy limb.

NON-LINEAR FINITE ELEMENT APPROACH FOR A PRIORI MODAL ANALYSIS OF PROSTHETIC FOOT

T M Balaramakrishnan[1], Alexander Joseph V. Paul[1], S. Natarajan[1], S. Sujatha[1*]
[1]TTK Center for Rehabilitation Research and Device Development (R2D2), Machine Design Section

INTRODUCTION

A prosthetic foot is an artificial device designed to reproduce the functionality of the foot-ankle complex absent in a person post amputation. A passive foot does not use any motors or active mechanical components. Energy storage and return (ESAR) feet (a type of passive feet) store strain energy during mid-stance and terminal stance and return it during the pre-swing phase to assist in forward progression. The usage of this energy for push-off will be most effective when the natural frequency of the prosthetic foot corresponding to the bending of the foot in the sagittal plane matches the walking step frequency [1]. Hence, the objective is to develop a methodology for a-priori evaluation of the natural frequencies and mode shapes of an ESAR foot design.

METHODS

The modal analysis is done using a finite element model of the foot at the terminal stance. A mass (that represents the mass of the human body) attached to a pylon is added to the foot (see Figure 1).

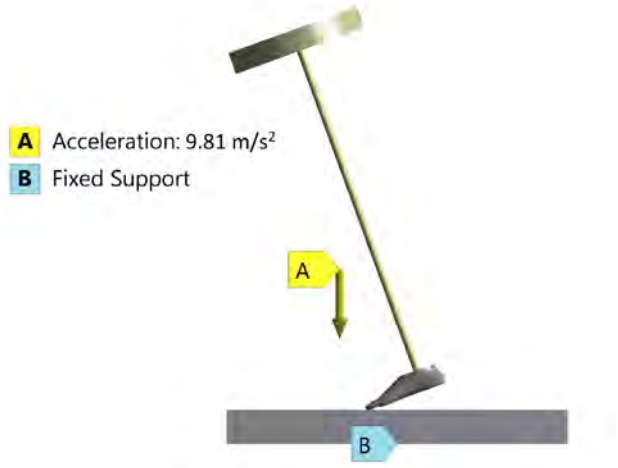

Figure 1: The complete model with the boundary conditions.

The computational model is discretized with tetrahedral elements. The neo-Hookean material model is assigned to the foot shell (to account for the non-linearity) and the contact between the foot and the ground is assumed to be frictional to replicate the conditions during walking on level ground. An acceleration field (that represents the acceleration due to gravity) creates the required ground reaction force that loads the foot. This load deforms the foot and generates a prestress in the foot. Modal analysis is then carried out on the prestressed foot to evaluate the natural frequencies and mode shapes of the system.

RESULTS AND DISCUSSION

The first mode of vibration is of concern in the case of an ESAR foot design. The mode shape for the first mode of vibration of a preliminary in-house design is shown in Figure 2.

Figure 2: The mode shape of the first mode of vibration of an ESAR foot design.

The first natural frequency of this design is evaluated to be 5.01 Hz.

CONCLUSIONS

Using analytical methods for modal analysis is very difficult with nonlinear material models and complex geometries. The finite element methodology developed by this group [2] is capable of handling these challenges. This novel approach of using finite element formulation for evaluating modal parameters of a foot from a computer-aided design model enables multiple iterations without the need for the fabrication of prototypes in the initial design phase.

INTRODUCTION

Gait is an evaluation tool and basic movement that identifies differences according to the type of disease, the characteristics of rehabilitation, or intervention with assistive device. Biomechanical studies often evaluate the mean, maximum, and minimum values of major events and sections, but data on continuous curves over time is very important in analyzing gait characteristics. In particular, utilizing time-continuous analysis such as statistical parametric mapping (SPM) has become common in human biomechanical studies and plays an important role in identifying undiscovered differences in walking cycles[1]. In particular, it is important to achieve bilateral ambulatory symmetry during walking despite morphological and musculoskeletal asymmetry due to limb loss for individuals with uneven thigh amputation. In the case of thigh amputation patients, it is important to understand the walking cycle pattern and affected and intact limbs balance through SPM.

METHODS

The subjects were approved by VHS' Bioethics Committee (IRB) for nine men (age: 62.5±9.0 height: 170.5±5.0cm, weight: 65.7±7.7 kg) who had no illusory pain at the femur terminal, and all participants participated with written consent. After warming up, the participants walked along the 12-meter sidewalk. A preference speed walking of each object person is performed, and three walking data out of a total of 10 walking data are collected and used for analysis. 44 markers were attached to the subject's body using eight Motion Analysis units operated by Cortex software for 3D motion analysis. To reduce marker noise, a secondary low pass Butterworth filter was filtered at a cutoff frequency of 6 Hz. One stride of lower limb joint angle and stance phase of vertical ground reaction force (VGRF) analyzed in Visual 3D and Cortex were normalized as a percentage. For statistical analysis, SPM was performed using MATLAB, and the significant level was set to α=0.05.

RESULTS AND DISCUSSION

There was no significant difference in the hip joint. Knee joint angle showed a significant difference in 6-18% corresponding to loading response and terminal stance and 87-92% corresponding to terminal swing, and the affected limb showed small movement. The ankle joint angle showed a significant difference in 68-75% corresponding to the initial swing, and the affected limb showed small movement. In the case of the VGRF, the difference was shown in 2-15% of the stance phase corresponding to loading response and terminal stance, and the affected limb showed small movements.

The results of this study show that the affected limb shows a small knee movement in the early stage, the VGRF is also small, and the ankle movement of the flexor forms a small VGRF. In addition, it can be seen that there is a difference in walking due to the small curvature of the knee joint during the swing phase.

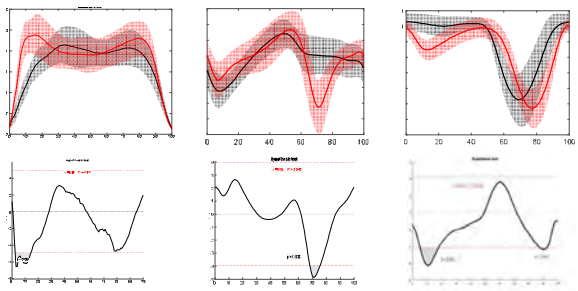

Figure 1 SPM in gait(from the left : VGRF, ankle, knee angle).

CONCLUSIONS

Gait evaluation of unilateral aboce-knee amputees through SPM is needed because differences not found in general gait evaluation can be confirmed. Since there are many type of knee device, in later study, it is necessary to examine differences according to various knee devices by studying multiple subjects.

INTRODUCTION

3D printed materials for removable prostheses showed lower flexural, bond, and impact strengths compared to heat-polymerized PMMA [1]. Therefore, some clinicians recommend 3D printed denture fabrication for interim or immediate dentures; however, there are no available 3D printed definitive dentures yet [2]. For this purpose, a filler such as silanized ZrO2 was added to the resin matrix in order to improve the physical properties of 3D printed dentures. The aim of this study was to evaluate the effect of adding ZrO2 filler in different concentrations on the physical properties of the 3D printing resin. The null hypothesis is that the addition of silanized ZrO2 to matrix resin will not increase the physical strength of the 3D printing resin.

METHODS

Double-cross-linked urethane dimethacylate resin (TC-80, Graphy Inc., Seoul, Republic of Korea) was used as a matrix component for 3D printed dentures and artificial teeth fabrication. And then, monomer and oligomer were added to ensure the low viscosity of the material. Moreover, photo-initiator composed of Bis(2,6dichlorobenzoyl)-(4-propylphenyl)-phosphine oxide (Iragacure 819, BASF, Germany) was also prepared. Silanized ZrO2 was added as a filler to composite resin in amounts of 0, 0.1, 0.2, 0.3, 0.5, 0.7, 1.0, and 1.5g, respectively, for 100g resin matrix samples. Specimens were designed with CAD software and 3D printed using the DLP method. For each specimen, flexural strength and tensile strength tests were conducted with UTM, and flexural and tensile modulus were also calculated. Flexural strength test specimens were prepared in accordance with ISO 10477, and three-point bending tests were conducted. Tensile strength test specimens were prepared in accordance with ASTM D638.

RESULTS AND DISCUSSION

The results of the material properties according to the respective concentrations of the silanized ZrO2 filler are presented in Table 1 and Figure 1. The 0.50% silanized ZrO2 added group had the highest flexural strength and modulus, with a value of 161.53 MPa. However, the 0.10% silanized ZrO2 added group showed a decrease in flexural strength and modulus compared to the control group (0%). The reason could be that the filler particles hindered the polymerization of the resin matrix when the silane ZrO2 filler concentration was increased from 0.00 to 0.20% [3]. Moreover, the tensile strength and modulus of the materials added with silanized ZrO2 peaked at a concentration of 0.50%; however, the trend of the flexural strength and modulus graph was not inconsistent. Although filler particles can strengthen the physical properties of the resin by deflecting cracks and absorbing stress [4], they can also hinder the resin matrix. It stands to reason that the tensile strength of the resin will decrease when the filler concentration exceeds 0.50%.

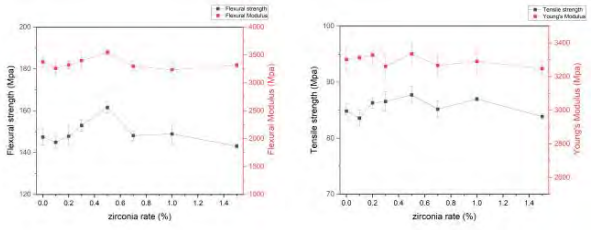

Figure 1. Flexural strength and flexural modulus (right) and tensile strength and Young's modulus (left) of composited resin with different concentration of silanized ZrO2.

CONCLUSIONS

This study evaluated the effect of adding silanized ZrO2 filler on the flexural and tensile strengths and modulus of the 3D printing resin. Flexural strength and tensile strength were the highest when 0.50% of filler concentration was added.

INTRODUCTION

Functional Anterior Cruciate Ligament (ACL) orthoses are prescribed to patients with the goal of preventing anterior tibial translation (ATT) and valgus moments at the joint. The limited and inconsistent data available on knee orthoses (KO) biomechanics make it difficult to assess the effectiveness of functional ACL bracing. Advancements in finite element technology have opened the possibility for accurate and quantitative assessments of subject-specific knee orthoses.

The purpose of this study was to determine how effective custom ACL bracing is in preventing ATT. The contact pressures of custom ACL orthoses obtained by Ghadikolaee et al. [1] were replicated in the patient-specific finite element models. Our previously developed baseline knee models [2] were utilized to determine how effective this orthosis design is in preventing ATT when subject to Lachman and pivot shift tests.

METHODS

22 CT images of juvenile knees were utilized (ages: 9-18). FEBio was used to construct each tibiofemoral joint. Following data established by Ghadikolaee et al. [1], two sensor pads (C1 = 5.08 kPa; C2 = 6.75 kPa) were placed along the tibial crest (Figure 1). To replicate the Lachman test, anteriorly directed forces of 67 N, 89 N, and 133 N were applied to the tibia. To simulate the pivot shift test, an anteriorly directed force of 133 N was applied to the tibia in addition to a combined rotatory load of 4 Nm internal tibial torque and 10 Nm valgus [3]. A 95% confidence interval (CI) was used to determine statistical significance between the bracing and non-bracing groups for each loading condition.

Figure 1 FEBio model of juvenile knee with pad placement.

RESULTS AND DISCUSSION

As expected, the custom ACL orthosis simulation resulted in less ATT than the non-bracing models for both loading conditions (Table 1). The 95% CIs demonstrate that the custom ACL knee orthosis provides a significant ($p<0.05$) resistance to ATT compared to the non-bracing models.

The finite element simulations showed that custom KO designs statistically minimize ATT when subject to loading conditions that can harm the healing graft. The custom KO design resulted in approximately 1 mm less ATT than the non-bracing options. This highlights the importance of accurately fitting a KO to a patient. If the fit of the orthosis is not sufficient, it is likely that the device will not be effective in preventing ATT. This is especially significant if there is a gap of 1 mm between the orthosis and the tibia as this might result in minimal resistance to ATT.

Future studies will utilize this methodology to assess the biomechanical effectiveness of the different KO designs (four-point force system vs total contact; custom vs custom-fit/off-the-shelf) to determine which offers the greatest protection to an ACL-deficient knee.

CONCLUSIONS

Utilizing finite element technology makes it possible to assess knee orthosis biomechanics in manner that cannot be assessed in a clinical setting. Custom functional ACL knee orthosis provide a significant resistance to anterior tibial displacement.

DYNAMIC FINITE ELEMENT ANALYSIS FOR THE METAMATERIAL PROSTHETIC LINER OPTIMIZATION

Vasja Plesec[1], Gregor Harih[1]
[1] Laboratory for Intelligent CAD Systems, Faculty of Mechanical Engineering, University of Maribor, Slovenia.
Email: vasja.plesec@um.si

INTRODUCTION

Lower limb prosthetic liners are mostly made of solid elastomers or foam-like polymers, providing limited customisation and often a costly solution. Previous authors have proposed 3D-printed metamaterials to address this problem and improve limb-prosthesis interaction [1]. Instead of a lengthy and costly trial-error approach of physically testing different designs to optimise liners, this study proposed an explicit finite element method to analyse and optimise metamaterial liners in a virtual environment. Various unit cells were numerically evaluated, and based on the results, specimens were 3D-printed and tested to validate the numerical model. The explicit finite element method allows effective simulation of complex time-domain problems by solving second-order differential equations directly. This enables a cost-efficient and rapid evaluation of complex structures and helps optimise metamaterial liners by reducing the contact pressure on the limb surface while maintaining the stability of the prosthesis.

METHODS

To prove the applicability of the newly developed metamaterial liner, a numerical analysis was performed using a recently developed generic transtibial model and the results were analysed in terms of contact pressure, stress-strain and deformation [2]. The metamaterial structures were evaluated both numerically using the explicit dynamic method and experimentally by a uniaxial compression test of 3D-printed flexible thermoplastic polyurethane samples. The stress-strain results from the uniaxial compression test were used to validate the numerical model results and to design a homogeneous material model of the metamaterial structure, which was used in the following simulation of the transtibial limb-prosthesis system. The generic transtibial model with definitive patellar tendon bearing prosthesis was used to simulate the newly designed liner for three loading scenarios, namely: donning of the socket, heel strike and push-off loading cases according to ISO 10328.

RESULTS AND DISCUSSION

The results regarding the contact pressure at the limb-liner interface as well as liner deformation, were analysed to assess the applicability of the newly developed metamaterial liner. The criterion for socket optimisation was to minimise contact pressure while maintaining the prescribed deformation of the liner. The relative comparison with the frequently used silicone liners shows that the customisable metamaterial liners can further reduce contact pressure while preserving adequate deformation, thus improving comfort, and maintaining stability.

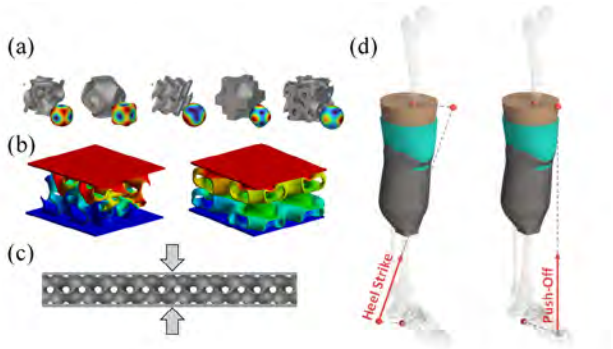

Figure 1 (a) Metamaterial unit cell evaluation, (b) explicit dynamic finite element simulation of the metamaterial samples, (c) uniaxial compression test, (d) generic transtibial limb-prosthesis model for liner evaluation.

CONCLUSIONS

In this study, a novel approach was adopted to investigate the 3D-printed metamaterial prosthetic liners in a virtual environment by using explicit dynamic finite element methods. The proposed low-cost and rapid numerical solution assists in developing optimised metamaterial liners that improve comfort by reducing contact pressure while providing adequate stability for the prosthesis wearer. Advanced 3D-printing technologies combined with nonlinear dynamic simulation could deliver an improved customisable socket-liner system faster and at lower cost.

INTRODUCTION

There are more than 3 million upper extremity amputees in the world, of which 80% live in Low-Middle Income Countries (LMIC) [1]. In LMIC, where most of the jobs are mainly labour intensive, the upper extremities amputees face socio-economic problems. Even though there are several commercially available prosthetic hands, they usually cost more than 20,000 USD and are designed based on rigid links. This high price makes them unaffordable for most amputees living in LMIC [2]. Various research have been conducted to develop affordable prosthetic hands based on soft robots made from compliant materials that could be actuated using pressurised fluid. This reduces the need for a complex mechanical system and makes the prosthetic cheaper and also lighter. This paper discussed a new type of soft robot that is designed with stiffening structures to mimic the kinematics of human fingers. The grasping ability of this soft prosthetic design is then discussed and compared with the human hand and a prosthetic hand with rigid links.

METHODS

The soft fingers were manufactured using EcoFlex™ 00-30 (Smooth-On, Inc. USA). Two strain-limiting layers were employed to achieve optimum bending motion: 1) helical winding to limit radial expansion and 2) a cloth to limit the axial expansion on one side of the chamber. Simulations were performed to determine the rigid structures' parameters to optimise the soft finger's kinematics. The fingers were then attached to a 3D-printed palm covered with silicon to improve friction during the grasping (Figure 1a). All fingers were controlled using a single 3/2-way pneumatic valve to reduce the number of components. The fingers were then tested to grip several objects, i.e. a cube, a bottle, a mug, a tennis ball, and a table tennis ball. The pressure on each finger was measured using Force Sensitive Resistors (FRS).

RESULTS AND DISCUSSION

To achieve a 240° bending, the pressure of the finger is 0.5 bar (Figure 1b). The bending shape mimics the kinematic of the human finger. It requires only an on-off control to grasp the objects due to the compliant nature of the fingers. The soft prosthetic hand can grasp all four objects. Compared to the rigid prosthetic hand, all fingers on the soft prosthetic hand have a similar pressure (Figure 1c). It means that the tip of the soft hand can still touch and provides enough pressure. Finally, the weight of the prototype is 270 g, and the manufacturing cost for the whole system is below 500 USD, which is suitable for LMIC

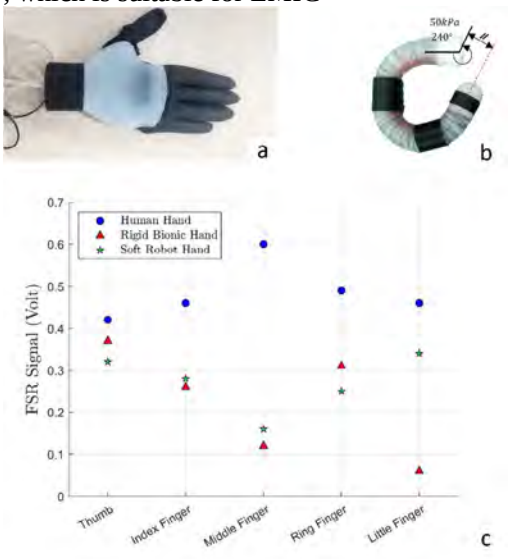

Figure 1 a) The prototype of the soft robot hand; b); the bending of the soft robotic finger; c) the pressure measurements of the fingertips while grasping a tennis ball.

CONCLUSIONS

This paper discusses the design and performance of an affordable soft robot prosthetic hand with rigid structures. The rigid structures generate a similar kinematic of the finger to that of human fingers. Grasping experiments show that the soft robot prosthetic hand could properly grasp objects with various shapes. The compliant nature of the robot also shows that there are more surface contacts between the fingers of the soft robot compared to its rigid counterpart.

INTRODUCTION

IMUs are an option for motion analysis due to their low cost and ability to evaluate the kinematics of free-living environments. [1]. Suggestions from previous research [2] show that validation studies for groups of prosthesis wearers must look at the optical (motion capture (OMC) for gold-standard comparisons with IMUs. So, this study aimed to assess the IMU accuracy of IMU measures of the walking ankle joint angle of transtibial amputees (TTA) compared to OMC.

METHODS

The Siriraj Ethical Review Board approved the study. Thirty TTA's were recruited and underwent simultaneous motion capture from two systems. The key kinematic parameters were compared. To compare the IMU and OMC protocols, a paired t-test with a significance level of = 0.05 was used, followed by Bonferroni-corrected t-tests (= 0.005).

RESULTS AND DISCUSSION

Table 1 shows typical gait parameters and their SD over 30 TTAs. The highest standard deviation values were observed for Ankle ROM Ab/Adduction calculated by the IMU (17.1°). Statistic significant differences in joint parameters caused by a change in the protocol were evident in the out-of-sagittal plane ($p < 0.05$) on the amputated side.

Table1: Ankle ROM by the IMU and OMC

Parameters	IMU (SD)	D3 (SD)	Value-p	P< 0.05	P<0.001
Sound Ankle ROM					
Plantar/dorsiflexion	(7.8)28.1	(6.0)29.9	0.6587		
Ab/Adduction	(17.1)11.0	(2.7)8.7	0.0628		
Inv/Eversion	(6.4)16.0	(5.1)14.0	0.0477	*	
Amputated Ankle ROM					
Plantar/dorsiflexion	(14.0)17.0	(6.7)11.7	0.1931		
Ab/Adduction	(16.8)10.9	(2.3)2.5	0.0295	*	
Inv/Eversion	(6.5)16.0	(2.2)1.7	0.0000	*	**

CONCLUSIONS

All comparisons of ankle ROM between the IMU and OMC systems support the idea that the IMU and OMC give similar kinematic results. The IMU can provide accurate motion data in the sagittal plane for a transtibial prosthetic gait study, showing that it is valid. Nonetheless, this study's results revealed that, compared to the typical OMC system, the IMU may produce accurate results and is a feasible device for evaluating the gait of amputees.

Biomechanical Analysis based on the Skull Model to derive the Optimal Screw Configuration of the 3D Printing Patient-Specific Reconstruction Plate used for Maxillofacial Bone Defects

Dong-Young Je[1], Won-Hyeon Kim[1], Ho-Joon Shin[1], Jisung Kim[1], Youjeong Son[1], Seoyoung Won[1], Sung-Ho Lee[1], Jungwon Lee[2], Young-Jun Lim[2] and Bongju Kim[1]

INTRODUCTION

Bone defects of mandible caused by factors such as tumors and traumatic injuries was primarily treated with reconstruction plates[1-3]. Conventionally, the widely used mini and reconstruction plates have weak strength and aesthetic issues [2-3]. Although, patient-specific reconstruction plates with Three-dimensional (3D) printing technology have been used in recent years, previous studies analyzing biomechanical properties in reconstructive design were inadequate. Therefore, in this study, we compared various designs and tried to derive the optimal plate.

METHODS

The 3D bone models were constructed using the mimics innovation program based on the cone beam computed tomography (CBCT) images of a Korean male. In order to distinguish between the cortical and cancellous bones, the cortical bone was set a constant thickness of 2 mm. The surgical models of mandibular bone defect were assumed a frequently occurring class 2 fracture type, and the number of screws of the anterior and posterior plates was set to 6 each. In order to derive the optimum screw configuration, a total of 72 models were constructed considering the anterior 8 and the posterior 9 (Fig 1). Three load conditions of the incisor, canine, molar teeth were applied to analysis the stress distribution of the plate and screw.

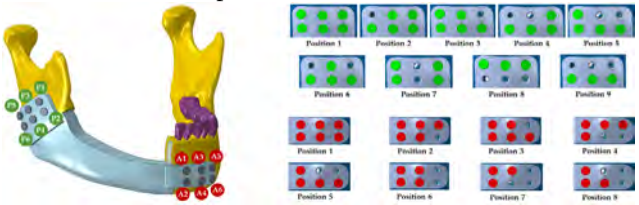

Figure 1 Surgical model and anterior-posterior screw configuration.

RESULTS AND DISCUSSION

It was confirmed that the stress distributions of the plate and screw showed similar tendencies in all models (Fig 2). In the incisor loading, the stress distribution of the plate and screw showed the highest value in the anterior 6 and 7 positions and the posterior 2 and 7 positions (Fig 2). On the other hand, the anterior 5 and 8 positions and the posterior 7 position showed the lowest values (Fig 2). In the canine loading, the stress distribution of the plate and screw showed the highest value in the posterior 8 position (Fig 2). However, the Peak von Mises stress (PVMS) was no difference in the anterior screw configurations (Fig 2). On the other hand, the posterior 2, 4 and 7 positions showed the lowest values (Fig 2). In the molar loading, the stress distribution of the plate and screw showed the highest value in the posterior 8 position (Fig 2). While, the anterior 8 position was showed the lowest value. In the posterior region, the 4 position of screw and the 3 position of plate were showed the lowest value (Fig 2). The 8 position of the posterior plate was high at all three loads, so it is predicted that there is a high failure risk after surgery. On the other hand, the screw configuration of the posterior plate showed lower stress in 4 and 7 positions compared to other screw configurations, and in the 8 position of the anterior plate showed lower stress than the other screw configurations. Therefore, it is expected that the reconstruction plate should be designed in consideration of the anterior 8 position and the posterior 4 and 7 positions for the initial stability after surgery.

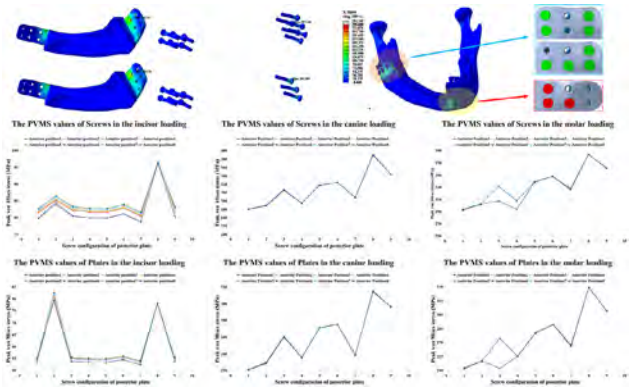

Figure 2. The PVMS results for 3 loads and screw configurations.

CONCLUSIONS

Based on our study, the posterior screw configuration was considered as a factor that significantly influences the stress distribution. As for the posterior screw configuration. The posterior 4 and 7 positions and the anterior 8 position are considered to have a high initial stability because the stress distribution was lower than those of the other configurations. Therefore, in the future manufacturing of patient-customized reconstructive plates, it is proposed to consider the anterior 7 position and the posterior 4 and 7 positions.

DEVELOPMENT OF A FINITE ELEMENT MODEL FOR SIMULATIONS OF COLD FLOW AND NECK-LINER IMPINGEMENT IN HIP PROSTHESIS

INTRODUCTION

Wear and failure of the ultra-high-molecular-weight polyethylene (UHMWPE) component after total joint replacement cause serious clinical and biomechanical reactions [1], thus restricting the longevity of artificial joints. In retrieved UHMWPE acetabular cup liners of hip prostheses, catastrophic wear and failure are frequently observed as shown in Figure 1 [2]. It appears that cold flow and neck-liner impingement in hip prosthesis contribute to significant increases in wear and failure of the UHMWPE acetabular cup liner.

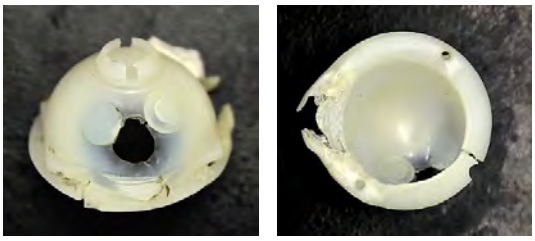

Figure 1 Retrieved UHMWPE acetabular cup liner of hip prosthesis showing catastrophic wear and failure (290 months in vivo).

METHODS

The main purpose of this study is to investigate the influences of cold flow and neck-liner impingement in hip prosthesis on the wear and failure of the UHMWPE acetabular cup liner. Development of a finite element model for simulations of cold flow and neck-liner impingement in hip prosthesis, and finite element simulations of these phenomena were performed.

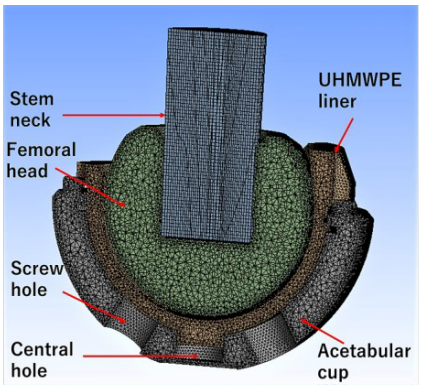

Figure 2 Finite element model of hip prosthesis for simulations of cold flow and neck-liner impingement.

Finite element model of the hip prosthesis developed in this study is shown in Figure 2. Metallic components were modelled as rigid bodies. UHMWPE acetabular cup liner was modelled as an elasto-plastic body. 3D solid modelling was performed by using the SolidWorks. The finite element simulation was performed by using the Ansys Workbench.

RESULTS AND DISCUSSION

An example of the finite element simulation results is shown in Figure 3. In the simulation of cold flow, it was found that stress concentrations near the edge of screw holes have significant influence on the states of contact stresses and plastic deformations in the surface and backside of the UHMWPE acetabular cup liner. In the simulation of neck-liner impingement, it was found that high contact stresses which exceed the yield stress of UHMWPE and considerable plastic deformations occurred in the rim of the liner.

The results of this analytical study suggest that change in mechanical states due to the occurrence of cold flow and neck-liner impingement in hip prosthesis is the cause of catastrophic wear and failure of the UHMWPE acetabular cup liner.

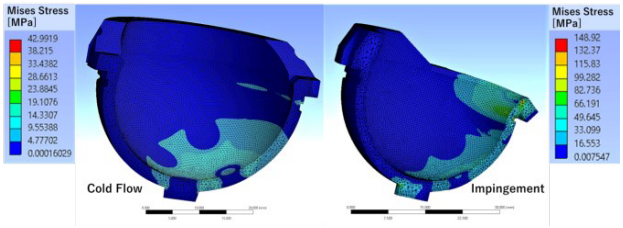

Figure 3 Contour plot of contact stress (von Mises stress) of the UHMWPE acetabular cup liner shown in Figure 2.

CONCLUSIONS

It is necessary to improve resistance to the occurrence of cold flow and neck-liner impingement in order to decrease the wear and failure of the UHMWPE acetabular cup liner and to increase the longevity of hip prosthesis.

INTRODUCTION

Implant stability is an important factor in implant success, including promotion of bone formation and load sharing[1-2]. In order to measure the implant stability, two measurements have been used, such as the resonance frequency analysis and percussion method[3]. However, the initial stability was affected by various factors such as measurement method, equipment, and angle etc. Therefore, in this study, we aimed to analyze the reliability of the two measurement methods and analyze the correlation according to factors such as bone densities and implant lengths.

METHODS

Two composite bones with low density(15 pcf) and high density(30 pcf) were used to compare the measurement reliability by normal and osteoporotic bones. The ten implants each having a length of 7.3 mm, 10 mm and 13 mm were inserted in the two different bones, for a total of 60 implants. Using Osstell Beacon (resonance frequency method) and Anycheck (percussion method), the measurements were repeated five times per implant by three observers. In order to compare the differences between Osstell Beacon and Anycheck, we analyzed the intra- and inter-observer reliability. In addition, the effects of changes in bone density and implant length on stability were analyzed. The intra- and inter- observer reliability was analysed using Cronbach's alpha. Correlation analysis was performed using Pearson's correlation coefficient.

RESULTS AND DISCUSSION

In the intra- and inter-observer reliability, the results were identified that Cronbach's alpha coefficients were all 0.8 over, confirming that the measurements of observers showed high reliability (Table 1). In order to compare the stability according to the change of the implant length, the ISQ(Osstell Beacon) and the IST(Anycheck) values were measured. In the low density, it was confirmed that increasing the length of the implants showed higher stability(Fig 1). On the other hand, the stability values of the high density tended to be similar with changes in implant length(Fig 1). The ISQ and IST values with changes in bone density showed a trend of increasing stability for the two measurement methods with increasing bone density for all implant length types(Fig 2). In the low bone density, the stability was confirmed to be higher with longer implant length(Fig 1). Furthermore, the stability was confirmed to be higher with higher bone density regardless of change in the length of the implants(Fig 2).

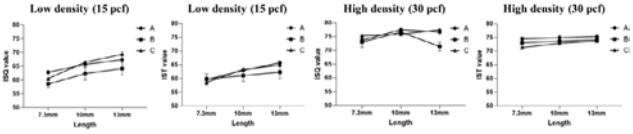

Figure 1. The ISQ and IST values depending on the implant lengths.

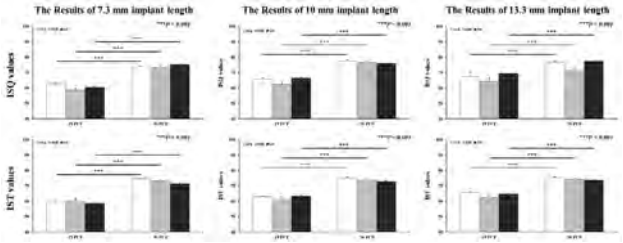

Figure 2. The ISQ and IST values depending on bone quality in the three implant lengths.

CONCLUSIONS

Based on our results, both Osstell Beacon and Anycheck showed the similar trend according to the change in implant lengths and bone densities. Therefore, it considered that the stability measurements between the Osstell Beacon and Anycheck show comparable levels of reliability with respect to various factors (bone density and implant length). Additionally, the results of our study is expected that the stability measure does not affect the change of implant length at high bone densities, whereas it may affect the stability measure at low bone densities.

Influence of Prosthetic ankle-angle and walking speed on Pylon moments in the Two Axis aDaptable Ankle

Mechanical Engineering Department, University of Wisconsin Madison, Madison, WI, U.S.A.
Email: knichols@wisc.edu

INTRODUCTION

Persons with lower-limb amputations can replace their lost limbs using passive, active, or semi-active prostheses. Semi-active prostheses attempt to recover more of the biological ankle mechanics and can give functional benefits of prosthetic adaptability, low cost, and low weight compared to passive and active devices [1]. The Two Axis aDaptable Ankle (TADA) [1] is a novel semi-active prosthetic ankle that allows for independent modulation of sagittal and frontal ankle angle (±10 degrees).

Boone et al. (2013) found that sagittal and frontal misalignment of transtibial prostheses at the pylon joint significantly affects pylon (socket) moments around 75% of stance, compared to nominal alignment (clinically-based) [2]. The TADA allows more biomimetic ankle angle control that can give users influence over their joint mechanics.

This study aims to investigate the influence of various TADA angles and walking speeds on prosthetic pylon moments while users walk over flat ground. The main hypothesis is that the peak averages of sagittal and frontal pylon moments will be higher at non-neutral TADA angles and larger walking speeds.

METHODS

Ten participants with no amputations will be chosen for this study, approved by the UW-Madison IRB. This abstract presents preliminary data for one participant (n=1). The participant walked on flat ground at three consistent self-selected speeds (slow, medium, fast) while wearing a full-body set of Xsens motion sensors. The TADA was mounted laterally to the participant's right foot using a custom-made ankle bypass orthosis.

The participant walked with various TADA stance angles including neutral (90° ankle dorsiflexion and no eversion), Plantarflexion (PF), Dorsiflexion (DF), Eversion (EV), and Inversion (IV). Three successful strides were collected for each TADA angle and speed totaling 45 strides. The peak pylon moments (sagittal and frontal) of the successful trials were averaged for each speed.

The TADA controller uses the Robotic Operating System (ROS) programs (C++/Python), involving dual motor control with hall sensor feedback, load cell between the TADA and pylon, shank IMU motion reconstruction, data collection, and a user interface. In addition, the Xsens suit will give a secondary source of validation for the kinematic data of the ankle/foot, lower and upper legs, and center of mass.

Table 1: a partial set showing the typical anatomical ankle angles, polar coordinates, and their respective average peak sagittal and frontal pylon moments for the medium speed.

TADA Ankle angles	Polar coordinates (PF, EV)	Average Peak Sagittal Pylon moments (Nm)	Average Peak Frontal Pylon moments (Nm)
Plantarflexion	(10, 0)	1374	543.7
Dorsiflexion	(-10, 0)	1400	355.3
Neutral	(0, 0)	1235	433.3
Eversion	(0, 10)	1315	289.0
Inversion	(0, -10)	1206	496.0

RESULTS AND DISCUSSION

These results show the average peak sagittal pylon moments decrease with increasing walking speed and that the frontal pylon moments than sagittal pylon moments are more sensitive to changes in TADA angles. The hypotheses were not supported, but the results can be used to create a moment-targeting controller to accommodate for walking speed and attempt to lower peak pylon moments by adjusting the TADA angles. For example, at a medium speed, moving a neutral foot (peak of 433Nm) to a more dorsiflexed angle would lower the peak frontal moment (peak of 355Nm).

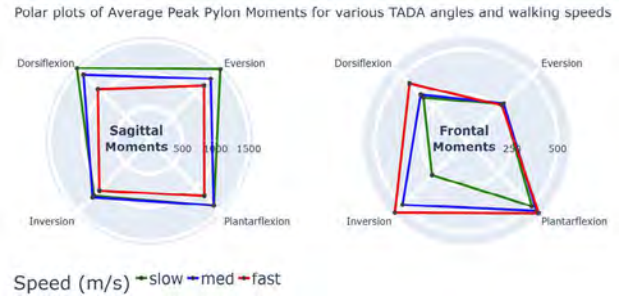

Figure 1 Polar graphs showing average peak sagittal and frontal pylon moments for various TADA angles and walking speeds. The background grid represents the TADA angles, and the line colors represent the peak pylon moment for a given walking speed.

CONCLUSIONS

The TADA could enable modulation of lower-body mechanical outcomes by controlling the 2D TADA angles due to its systematic relationship with ankle angle, walking speed, and pylon moment. Automated, real-time moment-targeting control could allow users to adapt to terrain conditions such as stairs and ramps, or to alter biomechanical loads such as undesirable knee moments.

PATIENT-SPECIFIC OPTIMISATION OF CUSHIONING STIFFNESS IN DIABETIC FOOTWEAR

Panagiotis Chatzistergos[1], Alfred Gatt[2,1], Cynthia Formosa[2,1], Jonathan Sinclair[3,1] and Nachiappan Chockalingam[1,2,3]

INTRODUCTION

The use of appropriate cushioning materials in diabetic footwear or orthoses is very important for their capacity to offload the foot-at-risk [1] and therefore for their ability to protect against diabetic foot ulceration (DFU). Previous research has shown that optimum cushioning is strongly affected by the magnitude of plantar loading [2,3]. Indeed, people who load their feet more heavily appear to need stiffer cushioning materials for optimum offloading. As a first step towards clinically applicable optimisation of cushioning in diabetic footwear/ orthoses, this study explores whether optimum cushioning stiffness can be predicted using simple demographic and anthropometric parameters that are linked, in the literature, to the magnitude of plantar loading.

METHODS

Sixty-nine adults with diabetes at risk of developing a DFU were recruited from the population attending diabetic foot clinics at the main general hospital of Malta (age= 67y ± 11y, BMI= 26.8kg/m^2 ± 5.7kg/m^2). Shod plantar pressure (PP) and pressure time integral (PTI) were measured during walking (Pedar®, Novel®) without any additional cushioning material (baseline), and after adding flat 10mm thick footbeds. Seven bespoke cushioning materials [3] were used with stiffness ranging from very soft to very stiff (Figure 1). The materials that minimised PP (PP optimum) or PTI (PTI optimum) across the surface of the foot were identified for each participant. Multinomial regression was used to test whether optimum cushioning stiffness could be predicted based on demographic/ anthropometric parameters known to affect plantar loading (i.e. gender, age, weight, height, shoe size).

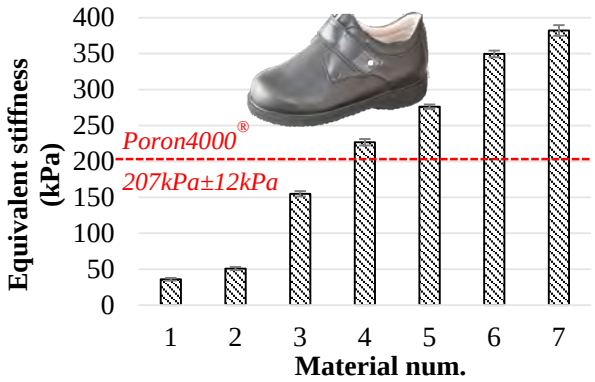

Figure 1: The diabetic shoe and the range of stiffness of the bespoke footbeds[3] (materials 1 to 7) that were used in this study. The stiffness of a cushioning material commonly used in diabetic footwear/ orthoses (Poron4000®) is also shown as reference.

RESULTS AND DISCUSSION

Comparing the materials that minimised PP against those that minimised PTI (Figure 2) showed that PTI optimum materials were significantly softer than PP optimum (Wilcoxon signed rank test,2-tailed, p<0.001).

Using simple demographic/anthropometric parameters as predictors enabled the correct prediction of optimum stiffness level in 70% of participants. The predicting capacity of this regression model was statistically significantly better than an intercept-only model (X^2(df)= 27.646(10), Sig.=0.002). In this case an intercept-only model can be interpreted as providing everyone with the same cushioning stiffness.

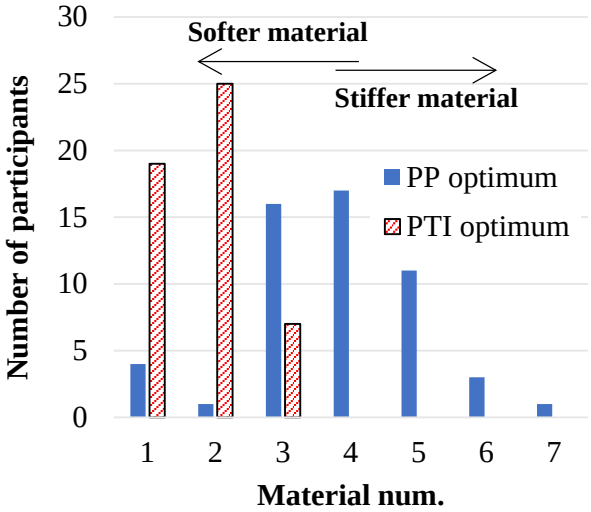

Figure 2: The frequency with which each bespoke footbed material achieved maximum PP reduction and maximum PTI reduction.

CONCLUSIONS

Patient-specific PP optimum cushioning stiffness can be predicted using five simple demographic/ anthropometric parameters. These results open the way for integrating patient-specific optimisation of cushioning stiffness into everyday clinical practice for the design of effective diabetic footwear/ orthoses.

INTRODUCTION

Digitally designed and 3D printed prosthetic sockets show much promise including advantages such as being inexpensive, light, and strong, while also being cleaner, faster, more repeatable and requiring potentially less skill of the fabricator. Socket mechanical properties must consistently meet or exceed those of conventionally fabricated sockets to realize these advantages. Preliminary work has shown high variability in socket strength including some that are not sufficiently strong to be used clinically (Gershutz, 2012; Pousset 2019). Ongoing testing by our group has shown material choice and print parameters to have a large effect on socket strength. Failure almost always consisted of cracks running predominantly along layers of the print in and near the shuttle region of the socket. Due to the multidirectional loading of a socket during actual use, this directional weakness, characteristic of a 3DP part, cannot be overcome by judicious print orientation. Methods like 3D fill compositing have recently been introduced (Nickel 2020) and are proprietary approaches that require additional materials, adhesive(s) and possibly specialized equipment to produce the composite structure (US Patent Application No.: US 2018 / 0243111 A1). We evaluated a simpler method to overcome the inherent weakness in FDM 3D printed objects that required no special equipment.

METHODS

Special samples were 3D printed for tensile strength testing (Figure 1). The *test* sample was printed with a central channel in which the insert was installed. A small 3D printed rod (6mm square cross-sectional) was manually inserted into a square hole in the test sample. When assembled, the print directions of the main part and that of the insert were orthogonal. There was interference between insert and channel into which it was designed to fit (i.e. pressure held the insert in place). Three methods were used to install the insert: 1) Press - the insert was pressed into the test specimen with a moderate manual effort (estimated 10-25lbs of downward force), 2) the insert was hammered into the specimen, and 3) combination of press and hammer. Test and reference samples were identical in all other ways (geometries, print specifications [material, infill, layer height) etc.). We explored whether insert tolerance (i.e. overlap in dimensions of insert and channel), insertion method, and insert density (15%, 30%, 50%, 75% and 100%) affected insert-strengthened parts.

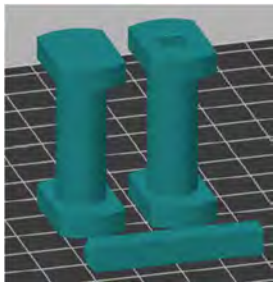

Figure 1 Tensile test samples. Reference sample (left), test sample (right) with a vertical channel in which the reinforcing insert was placed, and the rod (front) inserted into the channel; all parts were printed in the orientation shown.

RESULTS AND DISCUSSION

Composite parts utilizing orthogonal print orientations (i.e. the reinforcing insert) significantly increased part strength (Table 1). In tension, non-reinforced samples failed catastrophically at 84 pounds, on average. The reinforced samples failed at 229 pounds, on average. On preliminary analysis, insert interference had a modest effect whereas insert infill and insertion method did not have an effect. Bending tests were also run but those data have not yet been formally analyzed. Initially, it seems that reinforced parts also appear to be stronger in bending and did not fail catastrophically as did reference specimen. We developed a preliminary means to implement the insert into a socket and have prototyped that design but have not yet tested them. We also explored variable infill and layer height to strengthen without increasing weight and possibly to shorten fabrication times. Testing and data analysis is ongoing.

Table 1: The effect of insert and interference on ultimate strength.

	Strength (lbf)	#Samples
Without Insert	84 ± 45	23
With Insert	229 ± 77	94
Insert Interference		
Low x mod.	230 ± 75	15
Low x high	229 ± 81	44
Mod. x high	257 ± 29	22
Mod. x v.high	257 ± 36	6

Notes. Strength reported as mean ± standard deviation. Insert interference reported w/rt cross sectional dimensions.

CONCLUSIONS

The described approach considerably strengthens FDM based parts and warrants further study for both prosthetic sockets and any other 3D printed parts which have complex loading requirements that may not be met using judicious part orientation during printing.

ENERGETICS OF A NOVEL PASSIVE DYNAMIC CUSTOM AFO IN GAIT: ANALYSIS IN A SAMPLE OF FOOT-DROP PATIENTS

INTRODUCTION

Passive Dynamic Ankle Foot Orthoses (PD-AFOs) are orthopedic devices prescribed to patients with mild foot-drop condition. These patients are often affected by weakness of the ankle plantar-flexors, in addition to a deficit of the ankle dorsiflexor muscles. While the main requirement of AFOs is to support the foot in the swing phase of gait, the flexibility of PD-AFOS enables both energy storage and releasing during the stance phase. This study aimed at estimating the energy expenditure of a novel custom PD-AFO in a sample of mild foot-drop patients.

METHODS

Eight custom PD-AFOs were designed and modelled as to match the shape of the foot and leg of 8 patients with unilateral foot-drop condition (3F, 5M; age 62.0 ± 13.1 years, BMI 25.8 ± 2.5 kg/m^2). AFOs were produced via selective-laser-sintering of a fiberglass-reinforced polyamide powder (Windform GT®, CRP Technology). Patients were instrumented with skin markers according to a validated lower-limb kinematic protocol [1] and an 8-camera motion capture system (Vicon) recorded the markers' trajectories during walking at self-selected comfortable speed. Three reflective markers were attached to the flexible component of the AFO to establish a local reference frame for the AFO calf-shell (Figure 1, left). The relationship between the calf-shell flexion angle with respect to the foot plate, and the resisting moment to flexion due to the AFO stiffness, was determined for each AFO via an ad-hoc experimental setup [2]. The temporal profiles of flexion angles in stance were determined for each patient as the relative rotation between calf-shell and foot-plate which was assumed to move rigidly with the footwear. For each patient, the work done by the AFO was calculated as the dot product of the calf-shell resisting moment and rotation angle (Figure 1) across five walking trials. AFO power was calculated as the time derivative of the work.

RESULTS AND DISCUSSION

The estimated work done by the custom AFO during normalized stance phase was largely consistent across patients/AFOs (Figure 1). Negative work is done during ankle dorsiflexion (~40-80% of stance in Figure 1) to flex the calf-shell and this energy (positive work) is released to the ankle at foot-off (~80-100% stance in Figure 1). The average maximum energy stored by the calf-shell across all AFOs was 0.013 ± 0.005 J/kg. Some energy is also exchanged due to the bending of the anterior part of the foot-plate, but this was not accounted for in the present study.

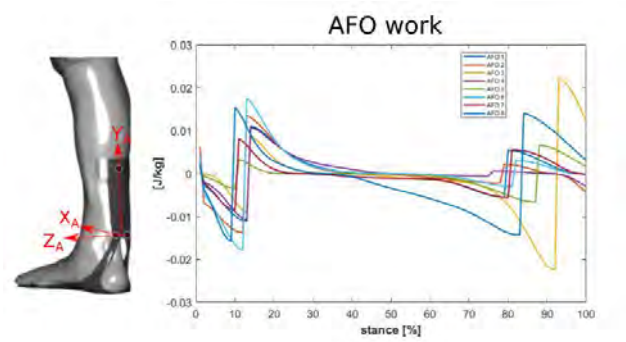

Figure 1 Left, 3D render of one of the custom AFOs made for one of the 8 foot-drop patients. Three reflective markers attached to the posterior side of the calf-shell were used to establish a local reference frame with axes Xa, Ya, and Za. Right, temporal profile of the average work normalized by body weight [J/kg] done by each of the 8 AFOs calf-shell over normalized stance phase.

CONCLUSIONS

The energy expenditure of a novel passive dynamic custom AFO has been estimated in a population of mild foot-drop patients. According to this study, the present custom AFO can store some energy at midstance, and this is released to the ankle at foot-off. This energy could be beneficial to assist those patients with weakness of the ankle plantarflexor muscles.

Footwear comfort and the effect of customised foot orthotic insoles and BMI

Lloyd Reed[1], Matthew Triggs[1,2]

Email: lreed@footmotion.com.au

INTRODUCTION

Foot orthoses have been shown to have immediate and short term sustained effects on comfort and functional biomechanics in running [1]. Mills et al [2] examined foot orthoses worn in walking and running and reported that a 10.2mm change in comfort rating, on a 100mm visual analogue scale (VAS) was clinically important. Zin et al [3] determined that there was little difference in comfort ratings of basketball footwear by subjects with either 'heavy' or 'light' BMI. This study aims were to examine the effects of customised foot orthoses on 'overall comfort' and examine if this was influenced by BMI.

METHODS

Subjects were recruited through a podiatry practice and footwear store and fifty three adults (27 females, 26 males, age 47.2 ± 15.7 yrs) completed the study. Subjects were screened for medical, foot health and footwear history to ensure there were no contraindications to treadmill walking or use of customised orthoses. Subjects were categorised as 'underweight/normal' (Group 1, BMI ≤ 24.9) and 'overweight/ obese' (Group 2, BMI ≥ 25.0) and fitted with customised orthotic insoles - 'Medical Green Insoles (MGI)' (Footbalance Systems Ltd, Vantaa, Finland). The same insoles with additional arch support (MGI+) were given to Group 3, overweight/obese subjects only. Overall comfort was assessed on a 150mm VAS after walking on an instrumented treadmill (Zebris GmbH) at comfortable walking speed for three minutes, wearing; usual footwear (including usual insoles /orthoses), usual footwear with MGI or MGI+ and usual footwear again. Subjects wore the orthoses for 4 weeks in their daily activities, then the testing was repeated. Not all completed the sixth comfort rating and it was excluded from analysis. Differences in overall comfort measures were assessed using a mixed factors ANOVA model (SPSS version 28.01 (IBM, New York, USA)), with GROUP as a between subjects factor and TIME as a within subject factor. Tukey post hoc tests were performed. Demographic characteristics of the three subject groups were assessed using ANOVA models. Alpha was 0.05 for all tests.

RESULTS AND DISCUSSION

There were no differences in mean age or height for the three groups and no difference in weight or BMI for the two overweight/obese groups 2 and 3. There was a significant GROUPxTIME interaction (F2.7, P=0.008) and Figure 1 shows the means and standard errors of comfort ratings for each group. At 4 weeks, overall comfort when wearing orthotic insoles was significantly higher than in usual shoes for Group 1 (difference 37.0±5.8 mm) and Group 3 (difference 25.7±5.9mm) and higher than the limits of agreement of ± 20mm from a Bland and Altman analysis [4]. Overweight/obese individuals with standard MGI insoles (Group 2) showed no difference in any overall comfort measures.

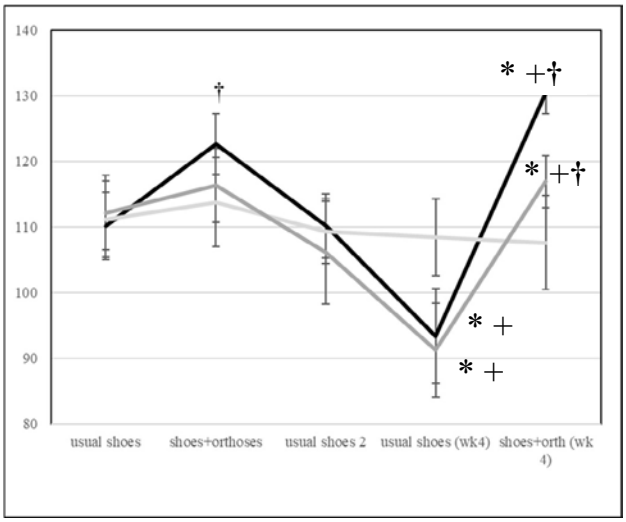

Figure 1 Mean & SEM of ratings of 'Overall comfort' (mm)
Group 1, Group 2, Group 3, * significant difference to usual shoe time 1, + significant difference to usual shoe time 2 † significant difference to usual shoes week 4

CONCLUSIONS

Footwear comfort can be increased with customised orthotic insoles. However, comfort improvements may be dependent on BMI and orthotic design. More research is needed to establish optimal design features for customised orthotic insoles for people across BMI groups.

ACKNOWLEDGEMENTS

Footbalance Systems Ltd, Vantaa, Finland for donating orthotic insoles.

INTRODUCTION

Clinical testing of body function is important in diagnosis and rehabilitation of common musculoskeletal conditions and is usually performed in dedicated facilities (hospitals, community clinics). Recent developments in artificial intelligence, particularly computer vision, could make it possible to perform clinical testing remotely, freeing up resources. We examined accuracy and concurrent validity of a semi-automated computer vision system for estimating distance and angle parameters from common functional tests recorded with a mobile phone or webcam.

METHODS

The test protocol included two stages. Firstly, the accuracy of the computer vision system was tested using different camera positions and objects with known dimensions. The second stage involved concurrent validity testing in two participant groups. The results generated by our computer vision system were compared to those of a trained clinician. A total of 62 participants (31 healthy, age 35±8; 31 with axial spondyloarthropathy, age 53±12) performed a series of functional tests whilst standing or sitting 1.5m from the camera. They repeated the movement a second time while an experienced certified physiotherapist manually measured variables of interest so that these values could be compared to the results obtained with computer vision. For a description of how the tasks were performed see [1]. A modified version of OpenPose [2] was used to detect the x,y coordinates of body keypoints, and these coordinates were used to compute angles/distances. Manual and computer vision-derived scores were compared using Bland-Altman plots and 95% confidence intervals. One-sample t-tests were used to determine whether differences between methods were significantly different to 0. Pearson's correlations between the two methods were also computed. For the sit-to-stand test, Mann-Whitney U was used to compare the number of repetitions.

RESULTS AND DISCUSSION

Our approach estimated known object dimensions to within 2% for objects of different sizes, different object-camera distances, and different angles relative to the camera. Mean differences between computer vision and manual estimates are shown in Table 1. For all tests, the correlations between the estimates of the two methods represented large effect sizes ($r^2 > 0.25$). For the sit-to-stand test, there was no statistical difference between methods in the number of repetitions performed (Mann Whitney U [n=60] = 3601, z = -0.432, p = 0.666).

Table 1: Mean differences between computer vision and manual estimates for each test.

Test (unit)	Mean difference	SD of difference	95% CI	*t* statistic	*p* value
Tragus to wall (cm)	1.4	2.5	0.6 - 2.3	4.52	< 0.001
Cervical rotation (cm)	2.5	1.2	2.1 - 3.0	16.81	< 0.001
Shoulder flexion, left (°)	2	14	−3 – 7	0.99	0.33
Shoulder flexion, right (°)	3	15	−2 – 9	1.57	0.12
Side flexion, left (cm)	−0.5	3.1	−1.6 - 0.6	−1.34	0.19
Side flexion, right (cm)	0.5	3.4	−0.7 - 1.7	1.05	0.30
Lumbar flexion (cm)	−1.1	8.2	−4.0 - 1.8	−1.05	0.30
Hip abduction, left (°)	−10	10	−13 - −6	−7.51	< 0.001
Hip abduction, right (°)	−10	10	−13 - −6	−7.26	< 0.001
Hip internal rotation (cm)	−2.1	6.0	−4.2 - 0.0	−2.78	0.007

CONCLUSIONS

Our markerless computer vision approach provided estimates of distance and angle measures that were generally statistically comparable to manual measures performed by a trained clinician. In the future, this kind of approach could be used to monitor functional capacity and to manage physical therapy remotely. Our approach is built on top of an open-source algorithm, and thus lowers potential barriers to implementing accurate movement analysis outside of a lab environment.

Development of a Neural Network for Prediction of Ovine Hip Joint Centers

INTRODUCTION

Estimation of the hip joint center (HJC) is a vital component of motion capture and subsequent kinematic and kinetic analyses. Errors in estimation of the HJC can propagate through these analyses resulting in additional error [1]. As such, accurate estimation of the HJC is critical for biomechanical calculations.

Various functional and predictive methods for estimating the location of the HJC have been developed in humans, and to a much lesser extent quadrupeds [2]. Functional methods require subjects to voluntarily move their joints through a large range of motion, which is challenging, and in some cases impossible to achieve in animal models. Alternatively, predictive methods use anatomical measurements to determine the HJC in reference to particular anatomical landmarks [3].

Since functional measurement of the HJC is not feasible in ovines, it is typically assumed to be at the geometric center of the femoral head as measured from tomographic imaging. While this has been done, it has not been applied generally to multiple animals to generate a predictive model as measured from tomographic imaging. While this has been done, it has not been applied generally to multiple animals to generate a predictive model [4]. Other estimations of the HJC in quadrupeds have utilized a marker placed on the greater trochanter of the femur, and assume this is at the HJC, and assume this is at the HJC [5]. Calculation of hip joint kinematics using this method have shown to be highly susceptible to error due to more pronounced soft tissue coverage over the joint [6]. Development of a predictive model of ovine HJC based on multiple animals would enable superior estimation of HJC, increasing accuracy of biomechanical measurements.

METHODS

Full body ovine CT scans (Siemens Biograph mCT) were segmented in 3DSlicer. Segmented bones were then exported as STL files. HJCs were estimated by fitting a sphere to the articulating surface of the femoral head, excluding the iliofemoral ligament using AutoDesk MeshMixer. 14mm spheres were then placed on anatomical landmarks of the pelvis, femur, and tibia to replicate motion capture markers (although soft tissue thickness was not accounted for) and were used to define a pelvic coordinate system.

A neural network was trained on the data from each animal. Sixteen Rambouillet sheep were used; 10 were used for training the network and 6 were used for testing and tuning the network. For each animal, CT scans were available at either ages 2 months, 7 months, or 14 months, with many having multiple time points. The test set was chosen such that there was sufficient diversity in age, sex, and phenotype among the test data. This resulted in a total of 48 training data points and 20 testing data points, with each animal being present in the data set up to three times (at the three ages noted above).

A neural network was created using Tensorflow Keras in Python, with inputs that included the age, sex, phenotype, pelvic and femur measurements, and marker positions from the CT reconstructions. Sex and phenotype data were one hot encoded while age and weight were scaled using the SKLearn standard scaler. The network consisted of an input layer, 2 hidden layers, and an output layer. The number of neurons per layer was initially chosen at random and later tuned by finding the minimum Euclidean distance between the predicted HJC and actual HJC. Rectified linear unit activation functions were used for each layer while mean squared error was used for the loss. The adam optimizer was used for the model.

RESULTS AND DISCUSSION

The neural network performed exceptionally well with mean Euclidian distance error between the actual and predicted HJC of 3.53±1.67mm. This error is much smaller than current predictive methods in humans which range from 10-40mm, despite (or perhaps because of) the relatively small set of training data [2]. Further work will be done to assess the models performance on input data containing measurement errors to more closely replicate sources of error such as the placement of markers above soft tissue, movement artifacts, and potentially erroneous marker placement.

CONCLUSIONS

A neural network was successfully created and trained that was able to accurately predict the location of the HJC in ovines using categorical and marker location data. This neural network can be used to improve kinematic and kinetic analysis of ovine gait.

THE INFLUENCE OF PROTECTIVE EQUIPMENT ON PERFORMANCE IN ICE HOCKEY

Rebecca Lennartz[1,2], Arash Khassetarash[1], Evangelos Spyrou[3], Aiden Hallihan[3], Bjoern Eskofier[2] and Benno Nigg [1]

INTRODUCTION

Understanding an ice hockey player's movements and the restrictions incurred by the protective equipment is crucial for improving the equipment and subsequently, player's performance. The optimum design of the protective equiment is specially challenging given the complexity of the movements and manuevers in ice hockey. This complexity arises from the multitude of possible variables that describe player's motion and therefore complex analysis methods are required to help direct the researcher's attention toward the right variables. The purpose of this work was to utilize artificial neural network (ANN) and layer-wise relevance propagation (LRP) [1] to understand how complex drills in ice hockey were affected by the presence of protective equipment.

METHODS

Seventeen male ice hockey players (age: 26.4 ± 7.0 years; mass: 86.4 ± 6.5 kg; height:183.8 ± 6.5 cm) skated the long axis of the ice rink as fast as possible. The sprint time over 30 meters was recorded (Brower TCi Timing system) and the movement data was captured by inertial measurements units integrated into the Xsens MVN Awinda System. The sprints were performed twice in either with (Equipment) or without protective equipment (No Equipment) conditions in a randomized order. Individual strides were defined from one ice contact to the subsequent ice contact of the same foot. A total of 24 strides were extracted for each of the participants. The trajectories of 12 joint angles (Figure 1) were extracted and normalized. All trajectories for one movement were concatenated into one single feature vector. A shallow ANN was trained to distinguish whether the sprint stride was performed in Equipment or No Equipment condition. Using LRP, the contribution of each variable to the classification result of the ANN was determined.

RESULTS AND DISCUSSION

On average, the participants performed the sprint drill 1.64 % faster in No Equipment compared to Equipment condition ($p = 0.0037$). The model was trained 17 times while leaving one participant out each time for testing, reaching an average accuracy of 99.3 %. The average relevance scores that were derived from the ANN model are depicted in Figure 1. Each row corresponds to one rotational degree of freedom, while each column depicts one percent of the stride cycle. The histograms at the top and right part of the figure show the vertical, and horizontal summation of the heatmap respectively.
The results show that the ANN can distinguish between the two conditions while observing differences in performance. Thus, it appears that protective equipment impairs performance. The presented data indicate that rotations around the medial-lateral axis (in sagittal plane) and movements associated to the shoulder, knee, and hip joint contributed the most to the classification result.

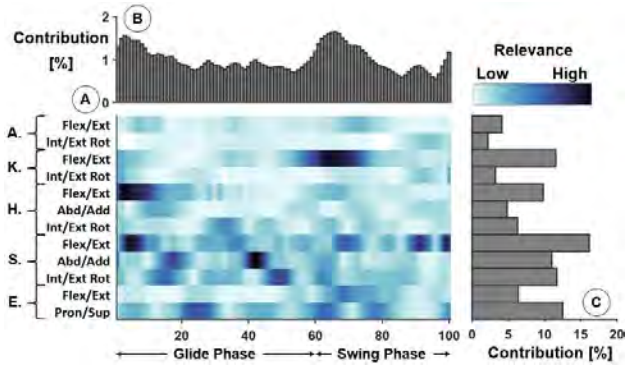

Figure 1 Averaged relevance scores per variable (A) over one sprint stride and contributions within a step cycle (B) and joint trajectories (C) using A. = ankle, K. = knee, H. = hip, S. = shoulder, E. = elbow.

CONCLUSIONS

The proposed methodology based on ANN and LRP was able to highlight the variables and time points that differ between Equipment and No Equipment conditions. We were able to distinguish the important movements that the protective equipment restricts, and future design can leverage this information. In general, this approach allows researchers to investigate a question from a holistic point of view and therefore make informed decisions in complex, multivariate problems.

INTRODUCTION

Modeling the neuromechanics of walking, particularly in neurological disorders, is challenging because current biomechanical simulations lack appropriate neural control mechanisms and constraints [1][2]. These challenges suggest the need for a more holistic approach to capturing the neuromechanical constraints of walking derived from data. Here we use a Recurrent Neural Network (RNN) model to recapitulate the dynamical features of gait in a common latent space by capturing spatiotemporal dependencies between sagittal plane lower-limb joint angles during treadmill walking in healthy and impaired individuals. Individual-specific, low-dimensional representations of the model parameters define individuals' gait dynamics (**gait signatures**), enabling direct comparison between individual and group dynamics across speeds, interpretation of inter- and intra-limb coordination patterns, and prediction of the time evolution of joint coordination across speeds. This framework may facilitate the development of future tailored gait interventions and track meaningful changes in the fundamental neuromechanical mechanism of walking.

METHODS

To capture the underlying dynamics of gait using machine learning, 15 seconds of sagittal plane kinematic data from able-bodied (AB) (N=5) and post-stroke (N=7, > 6 months after stroke) participants walking at six different treadmill speeds were input to a sequence-to-sequence RNN model trained to predict a one-step time-shifted version of the kinematic input data [3]. The RNN architecture consisted of an input layer, a hidden layer, and an output layer. To compare dynamics between individuals, individual-specific gait signatures were computed by first projecting the RNN internal activations for all individuals into a common basis using principal components (PC) analysis. The PC weights were then phase averaged over the gait cycles at each speed, producing the '**gait signature**'. Gait signatures were visualized as multidimensional trajectories over a gait cycle in 3D or projected into a coordinate map using multi-dimensional scaling (MDS).

RESULTS AND DISCUSSION

Our model's ability to predict at least one gait cycle of individuals' future kinematics supports that it encodes the neuromechanical dynamics governing gait kinematics. Resulting gait signatures revealed dynamic similarity in AB vs. heterogeneity in stroke individuals (Figure 1, A). Individuals' gait signatures were speed independent; their 6 speed gait signatures clustered together rather than with other individuals' signatures at similar speeds (Figure 1, B). The gait signatures of more impaired stroke survivors who walked at slower speeds, were located further away from AB signatures.

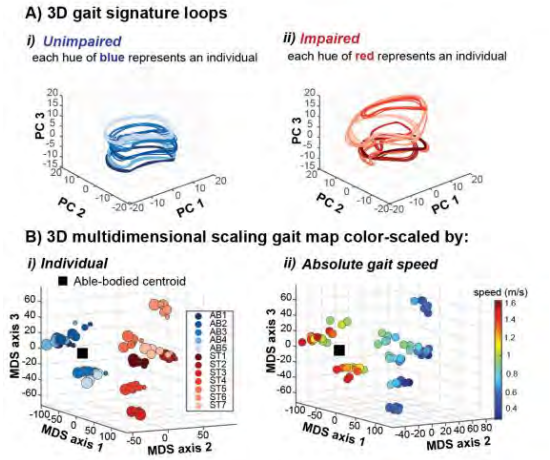

Figure 1 A) 3D unimpaired (i) and impaired (ii) individual gait signatures. B) 3D MDS map of all gait signatures coloured according to individual (i) and absolute gait speed (ii).

Further, subcomponents of the gait signature reveal biomechanically interpretable coordination (e.g., PC1 encoded hip flexion and extension) [3]. Gait signatures uncovered that 2 stroke survivors with similar Fugl-Meyer scores and self-selected walking speeds, had different gait signature components, showing promise for its use to tailor gait rehabilitation.

CONCLUSIONS

Gait signatures capture individual-specific gait differences irrespective of walking speed. This framework provides a generalizable, holistic method for characterizing and predicting cyclic, dynamical motor behaviour.

HIGH EFFICENCY BARBELL RECOGNITION MODEL BY CONSIDERING CONVOLUTIONAL NEURAL NETWORK

Jin-Yi Lin, Ching-Ting Hsu*, Wei-Hua Ho and Pao-Hung Chung
Graduate Institute of Sports Equipment Technology, University of Taipei, Taipei, Taiwan R.O.C.
Email: jingting@utaipei.edu.tw

INTRODUCTION

The barbell trajectories is an important factor for Olympic weightlifting while including much kinematic parameters to indicate the sport performance. Trajectories can be used to achieve a successful lift [1]. Furthermore, the barbell trajectory can be indicated the snatch movement successful by excellent male lifter [2]. As mentioned, barbell trajectory containing many important kinematic parameters, however, it needs scientist or experts utilizing kinematic analysis tools to obtain it. But difficultly operation makes real-time kinematic analysis difficultly utilizing in daily training or competition. Convolutional neural network (CNN) is one distribution of AI which exports for image recognition. Many pre-trained CNN models such as VGG19 provide image recognition architecture [3]. In this paper, we want to build a high efficiency barbell recognition model based on VGG19 to find the barbell from video frame and further connect as its trajectory.

METHODS

We consider pre-trained convolutional neural network, VGG19, as our barbell recognition model. VGG19 can find barbell from video frame in high efficiently and archive high performance with less model training consumption. There are two steps for creating our model. First step is sampling gathering. We collect video sequence from public competitions, the barbells are captured from each frames. We have positive and negative samples. Positive sample means that full and complete barbell. Since the colour of barbell denotes weight on the bar, thus, barbells of various colours are considered. We collect pieces of barbell, background equipment and people's body as the negative samples to make barbell recognition model learning. The second step follow by sample collected is model training. All training samples from first step will separate into three groups, and they are 80% training samples, 15% validation samples and 5% testing samples, respectively. All samples are both including positive and negative sample. After training samples are ready, we adjust model's parameters such like batch size, freeze layers and epoch for both considering training and validation results. Our proposed VGG19 barbell recognition model are 10 and 80, respectively.

When we fine trained the VGG19 barbell recognition, this model will be connected by our previous work [4] to fast track in feature frames of the video sequence.

RESULTS AND DISCUSSION

Results of our VGG19 barbell recognition model archives 95%, 100% and 87.5% for recognition accuracy, precision and recall, respectively. From the confusion matrix in Table 1, our model can both archive recognition performance and efficiency.

Table 1 Confusion matrix

		Predict class	
		True	False
True class	True	100%	0
	False	14.29%	85.71%

In this paper, we propose a VGG19 barbell recognition model combined with our previous semi-automatic barbell tracking algorithm which obtains high accuracy barbell trajectory and kinematic parameters.

Our barbell recognition model obtains barbell without reflective dots, this improvement reduces the operation procedure and makes sport biomechanics easily utilized in daily training life. In the past, since kinematic analysis software is difficult to use, thus, coaches observe athlete's gesture by their eyes with their experience. From this research, our VGG19 barbell recognition model provide both efficiency and accuracy barbell position to further provide barbell kinematic parameters from video sequence. This results not only provide the efficiently and easily gathering barbell trajectory, but also show the machine learning technique aiding the weightlifting training.

CONCLUSIONS

We propose a VGG19 barbell recognition model provides an efficiently and easily tool for kinematic analysis and indicate the machine learning technique can be suit for sport science.

INTRODUCTION

Ground reaction forces (GRF) are necessary to understand the cause of any movement [1], and joint moments provide key information to gain insight into the net muscle contribution at each joint [2]. Artificial neural networks (ANN) can facilitate the computation of these variables outside laboratories. However, most studies focused on dynamic data estimations from kinematic variables are applied to gait [3]. Joint coordinates and their derivatives might play a different role when predicting dynamic data. Therefore, the aim of this investigation was to explore the combinations of lower limb joint coordinates and their derivatives that best predict GRF and joint moments using ANN during running. Besides, the capability of the ANN to predict dynamic data from kinematics obtained using different motion capture systems was also analysed.

METHODS

The ANN training-set comprises data collected from sixteen participants using an inertial motion capture system (Xsens Technologies B.V.) and a force plate (Dinascan/IBV). Each participant performed ten running trials on a ten metres walkway at 3.3 ± 0.33 m/s. Kinematics variables and GRF were filtered using a zero-lag four-order low-pass Butterworth filter with a cut-off frequency of 10 and 15 Hz, respectively. Joint moments were computed using OpenSim. Four sets of input variables were tested to predict anteroposterior and vertical GRF as well as ankle, knee and hip flexion moments, with combinations of joint coordinates, velocities and accelerations. Thus, 20 ANN were trained finding their best structures by GridSearch hyperparameter tunning and 5-fold cross-validation. One layer and 300 neurons with a dropout rate of 5% were the hyperparameters that best performed. A leave-one-out cross-validation was performed to evaluate how well the ANN predicted unknown data. The used test-set data came from the study of Hammer and Delp [4], captured with an optical camera system and subjects running on an instrumented treadmill at 3 m/s. Finally, a repeated measures ANOVA with a pairwise comparison was performed to determine the significance of the correlation and normalized root mean square error (nRMSE) differences among the predictions using different kinematic variable combinations.

RESULTS AND DISCUSSION

Moderate-to-strong mean correlations values (r = 0.6-0.9) were obtained for the GRF and ankle and knee moment predictions (Figure 1). Hip moment correlations were low (0.1-0.4). Mean nRMSE values for the anteroposterior and vertical GRF range between 1.3-1.8 and 4.7-5.7 N/kg, respectively. Joint moment nRMSE values range between 0.8-1.2, 0.5-0.9 and 1.2-1.7 Nm/kg for the knee, ankle and hip. Knee flexion moment nRMSE ranges has similar magnitude as those found by Stetter et al. [5] while our correlation was higher.

Overall, the nRMSE showed that the use of joint coordinates alone as input to the ANN could predict the data accurately, and in some cases with significant differences ($p<.05$) with respect to adding joint coordinate derivatives as input.

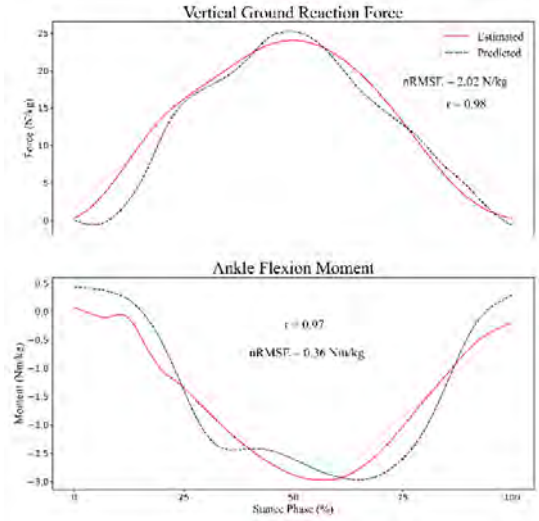

Figure 1. Estimated vs predicted vGRF and ankle flexion moment.

CONCLUSIONS

Joint angles seem to have all the information necessary to predict GRF and joint moments with good accuracy when running. This study also shows the feasibility of using the same ANN to predict GRF and joint moments with data that come from different datasets and experimental techniques.

Evaluation of deep neural networks-based frame interpolation of X-ray fluoroscopic images of dynamic knee motions

Yu-Chien Chen[1], Cheng-Chung Lin[1], Tung-Wu Lu[2], Mei-Ying Kuo[3], and Horng-Chaung Hsu[4]

INTRODUCTION

Clinical biplane X-ray imaging system can be utilized to acquire fluoroscopic images of the joint motion in a budge-efficient way, beneficial to translate motion analysis to clinical practice. However, asynchronous images captured from two x-ray units affect the accuracy of the reconstructed skeletal kinematics using 3D/2D image registration [1]. To address the issue, synthesizing a realistic middle image between two consecutive X-ray frames may help create a virtual synchronous biplane X-ray configuration. The study aimed to implement, train and evaluate state-of-art deep convolutional neural networks (CNN)-based RGB video frame interpolation techniques [2]–[4] for the synthesis of intermediate X-ray fluoroscopic images.

METHODS

Four frame interpolation CNNs namely, Softsplat[2], RRIN[3], XVFI[4] and IFR[5] were implemented. To train frame interpolation CNNs specific to the fluoroscopic image interpolation, a new x-ray dataset containing 38312 quintuplets of consecutive fluoroscopic frames at a resolution of 512×512 was first established. The 1st and 5th frames in the quintuplets were taken as the inputs, and the middle 3 frames served as the ground truth frames. Each network was trained for 300 epochs using Adam optimizer. The trained networks were utilized to generate intermediate fluoroscopic frames on the testing set comprising 1600 frames recoding the cadaveric knee motions at various speeds [1].

RESULTS AND DISCUSSION

The peak signal-to-noise ratio (PSNR) of the generated intermediate frames with the frame interpolation CNNs were shown in Fig.1. In general, the implemented CNNs enabled generating visually satisfactory images with median PSNR >31 dB. The performances of the four CNNs were degraded with the higher speeds of the skeletal motion in consecutive frames. Among the four CNNs, RRIN gave slightly higher median values of PSNR (Fig. 1) at the expense of the parameters used in the network (Table 1). While Softsplat possesses fewer parameters, it requires the highest number of flops to synthesize an image due to the use of grid network. This feature may favor dealing with difficult cases, especially in higher-speed motion scenarios. The XVFI and IFR were advantageous in lower network complexity with a slight compromise on the quality of interpolated images.

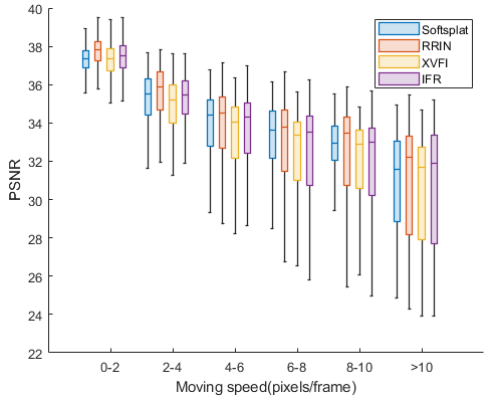

Figure 1 Boxplots show the distribution of PSNR for each net at different moving speeds of bones (pixels/frame).

CONCLUSIONS

The four frame interpolation CNNs were demonstrated to yield visually satisfactory intermediate fluoroscopic frames with median values of PSNR >32 dB after proper model training. Further studies are warranted to validate their use in the 3D joint kinematics tracking with 3D/2D image registration.

JOINT ANGLE CALCULATION AND PREDICTION VIA OPENPOSE ESTIMATION AND MACHINE LEARNING MODEL FOR RIDING POSE ADJUSTMENT IN CYCLING

Yun-Ju Lee[1*] and Yi-Jie Chen[1]

[1] Department of Industrial Engineering and Engineering Management, National Tsing Hua University, Hsinchu, Taiwan.

Email: yunjulee@ie.nthu.edu.tw

INTRODUCTION

Bike fitting aims to match the bike size and individual riding posture in cycling, which is a long-term process. It requires a lot of back-and-forth testing and fine-tuning to determine the best sweet spot of comfort and riding speed. Most importantly, great bike fitting can avoid musculoskeletal injuries. However, the current bike fitting uses anthropometric information in a standing or static riding posture without considering individuals' differences and dynamic effects.

The present study proposed a dynamic approach of joint angle calculations via the OpenPose outputs to simulate riding poses with seat height adjustments during cycling.

METHODS

Ten healthy adults (age = 24.4±0.84 years, height = 167.96±9.41 cm, body weight = 61.30±14.08 kg) participated in the experiment. The protocol was approved by the Institutional Review Board of National Tsing Hua University (REC #: 11003HE021). The participants were instructed to ride for six minutes and maintain the cycling cadence at 80~90 revolutions per minute (RPM). The RGB images of one minute (6000 frames) were taken as inputs to OpenPose and used to determine the coordination of the left and right key joint points. The toe and hip are (green points in Fig. 1) the centre of the circles, and the foot and thigh segments are the radius to make two red circles (Fig. 1). The shank segment length determines the distance between these two red circles. The segment lengths were assumed to be constant. The equations and calculations are in Fig.1, conducted in the model with ReLU and Adam to determine the seat height with the minimized violated frames of joint angles.

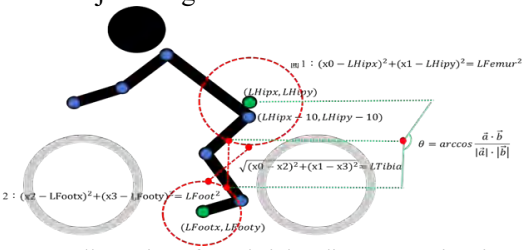

Figure 1 Illustration of seat height adjustment estimation with the coordination and the equations.

RESULTS AND DISCUSSION

The riding cadence was 84.00±1.41 RPM and 83.70±1.25 RPM (t(9)=0.709, p=0.496), and the seat height was 64.99±4.88 cm and 66.09±4.47 cm (t(9)=1.557, p=0.154) before and after the adjustment.

For the riding posture comparisons (Fig. 2), the OpenPose simulated skeletons showed an average of 9.12 degrees across all joints throughout the one-minute riding. The mean per joint position error (MPJPE) was not significantly different from the training and non-training sets in the simulated skeleton. After adjusting, the number of violated angle frames significantly decreased in the ground truth skeletons (t(9)=2.968, p=0.016).

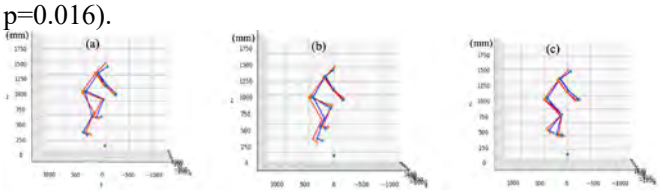

Figure 2 Illustration of the OpenPose simulated skeletons (blue) and the group truth skeletons (orange) when the right foot at (a) 6 o'clock, (b) 3 o'clock, and (c) 9 o'clock.

The similar MPJPE suggested that the model could work functionally in both situations regardless of the training set or seat heights [1]. The violated frames of joint angle showed the reduction pattern in both the OpenPose and ground truth skeletons. However, the definitions of joint centre resulted in the different number of frames between OpenPose and the group truth [2]. Finally, seven participants were suggested to increase the seat height from 2 to 4 cm, and three participants were to decrease the seat height by 2 cm. The variation indicated that our approach considered the individual joint angles and segment length instead of recommending increases or decreases in seat height.

CONCLUSIONS

The present study combined the coordination from OpenPose for constant segment length and moving joint centre with seat height in the machine learning models. The improvement of bike fitting successfully reduced the violated period of joint angle and specific adjustments for the individual during cycling.

INTRODUCTION

Up to 78% of wheelchair users experience shoulder pain or injury [1], but few data are available on shoulder loads during everyday propulsion. Quantifying shoulder torques and muscle forces could help identify the biomechanical sources of increased injury risk. Unfortunately, there are currently no commercially available instrumented handrims that can measure the hand reaction forces and moments (HRFM). Recently, machine learning has been used to predict ground reaction forces during walking gait from segment accelerations measured by inertial sensors. Thus, our objective was to evaluate whether this same approach could be used during propulsion.

METHODS

Data from a larger study evaluating exercise intensity during recumbent handcycling was used. A benefit of handcycling is the prescribed movements resulting in continuous kinetic cycles. Subjects (n=20) from the UIUC wheelchair team performed high and moderate intensity propulsion cycles. An instrumented custom handle was used to collect HRFM data along with motion capture data [2]. An upper limb musculoskeletal model was scaled to each subject and linear and angular accelerations of the hand, radius, and humerus were calculated using inverse kinematics. The resulting dataframes (n=240 cycles) were shuffled and split into training (70%), validation (15%), and test (15%) sets. Each set was standardized by subtracting its mean and dividing by its standard deviation.

Four two-layer, bi-directional long short-term memory (biLSTM) networks (200 nodes/layer, dropout of 0.4 after each layer) were created (TensorFlow 2.10.0). Model input was accelerations for a complete propulsion cycle (n=356 timesteps) and the task was to predict cycle kinetics (three forces, three moments). Models were trained for 500 epochs with each batch containing the entire training set. Mean squared error was used as the training loss function and Adam optimization algorithm was used as the optimizer (learning rate 0.0003). Models 1-3 were trained on the hand, radius, and humerus segments, respectively, and model 4 was trained on all three segments. Models were evaluated using the normalized mean absolute error (NMAE) (Eq. 1) (MATLAB R2021b and R 4.2.2).

$$NMAE = \frac{\frac{1}{N}\sum_{i=1}^{N}\left|y_{actual,i} - y_{predicted,i}\right|}{\frac{1}{N}\sum_{i=1}^{N}\left|y_{actual,i}\right|} \quad (1)$$

RESULTS

The model trained on the radius performed the best with a mean NMAE across all predictions of 0.60 (Table 1). The combined, humerus, and hand models had mean NMAEs of 0.62, 0.66 and 0.71, respectively. No model performed significantly better than any other for any prediction variable. Considering a representative cycle (median error for output F_z), our model predictions follow the temporal trends of the ground truth loads, but the magnitude of predicted values tend to be lower (Fig. 1).

Table 1: Normalized mean absolute error for each model compared across each prediction variable. Errors are expressed as Mean(SD).

Model	F_x	F_y	F_z	T_x	T_y	T_z
Hand	0.8(1.8)	0.6(1.1)	1.1(0.5)	0.5(0.2)	0.5(0.2)	0.6(0.3)
Radius	0.5(0.2)	0.5(0.2)	1.0(0.4)	0.5(0.2)	0.5(0.2)	0.6(0.4)
Humerus	0.6(0.3)	0.5(0.2)	1.0(0.5)	0.5(0.2)	0.6(0.2	0.7(0.4)
Combined	0.6(0.2)	0.4(0.2)	1.1(0.6)	0.5(0.2)	0.5(2)	0.6(0.3)

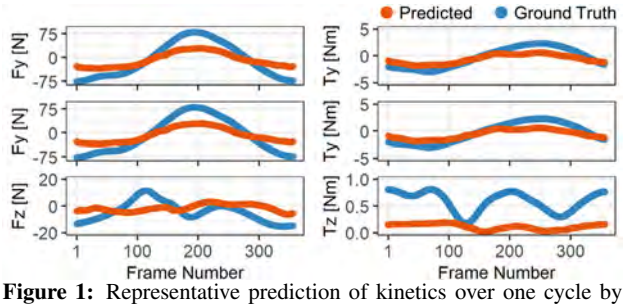

Figure 1: Representative prediction of kinetics over one cycle by model trained on hand acceleration data.

CONCLUSIONS

As there were no significant differences in model performance, a single IMU placed on the wrist (or a smartwatch) could provide enough data to predict the propulsion kinetics during handcycling. Next steps include retraining and validating the model on experimentally collected IMU data and adapting the model for more complex tasks, such as manual wheelchair propulsion.

INTRODUCTION

Recently deep learning (DL) based algorithms have emerged as best performing methods for solving classical medical image analysis problems such as image segmentation, classification, registration, and synthesis [1, 2]. Management of knee osteoarthritis (OA) routinely involves tackling image analysis problems listed above. The purpose of this paper is to report validity and reliability of DL-based methods to analyse knee OA using Magnetic Resonance Imaging (MRI) modality.

METHODS

The search was conducted on articles published in three databases (Web of Science, PubMed and Scopus) between 1990 and August 2022. Search string consisted of keywords "knee", "osteoarthritis", "deep learning", automatic" and "MRI". The study was registered in PROSPERO – an international prospective register for systematic reviews. Results of the study were categorized based on the validity and reliability of the problem area addressed. Any studies not focused on the knee joint, any review articles, studies based on imaging other than MRI, and studies not in English were excluded from this review. Selected studies were analysed based on the reported validity and reliability of DL methods to assess knee OA problems on MRI [3]

RESULTS AND DISCUSSION

A total of 431 studies were identified through database search. After removing duplicates and applying inclusion/exclusion criteria, 45 studies were found suitable for this systematic review. Selected studies were assessed based on the problems associated with Knee OA. Segmentation for OA analysis was reported by 29 studies, classification was reported by 12 studies, registration was reported by 1 study, synthesis was reported by 4 studies, and outlier detection was reported by none. There were 2 studies which addressed both segmentation and classification problems. Performance of any DL framework includes validity and reliability metrics as a part of its testing protocol. Therefore, we analysed these studies as per the reported performance measurement metrices (Figure 1). For segmentation problem, the most common metric reported is Dice Similarity Coefficient (DSC), followed Volume Overlap Error (VOE), Volume difference (VD), Average symmetric surface distance (ASSD), Root Mean Square Surface Distance (RMSD), Average Hausdorff Distance (Avg HD). For classification problems metrics of Receiver Operating Characteristic curve (ROC), Area under Curve (AUC), Sensitivity and Specificity are reported.

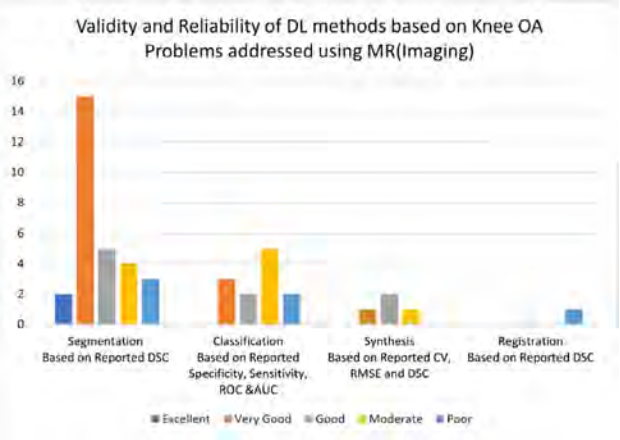

Figure 1 Systematic Review Outcome

Registration problem used DSC metric. Studies on synthesis problem used DL for synthesising super-resolution in the context of OA MRI biomarkers. They used DSC, VOE, VD, coefficients of variation (CV), concordance correlation coefficients (CCC), Root Mean Square Error (RMSE), Pearson Correlation (PC), Structural Similarity Index (SSI), Peak Signal to Noise Ratio (PSNR) and Normalized Mean-Squared Error (NMSE). After scrutinizing the studies based on the dataset used, it was evident that only OAI dataset is publicly available and has become a standard for comparing research outcomes [4]. Most of the studies addressed knee OA problems using a specific MR sequence, focusing on cartilage and tissue information only, making these DL methods highly data agnostic. A multi-tasking problem solving DL method is lacking in the literature. Current literature lacks interpretable and explainable DL models.

CONCLUSIONS

Segmentation remains the majorly studied problem area followed by classification. Standardization in validity and reliability measures is needed.

CLASSIFICATION OF EMG SIGNALS DURING CONTRA-LATERAL ARM MOVEMENT

Azmin Sham Rambely[1], Abu Bakar Yahya[1], and Nur Syahirah Izzati Zaidi[1]
[1] Faculty of Science & Technology, Universiti Kebangsaan Malaysia Bangi, Selangor, Malaysia
Email: asr@ukm.edu.my

INTRODUCTION

Characterization of EMG signals in human movements using machine learning algorithms has attracted many researches in clinical [1] and robotic applications [2]. The aim of the paper is to determine the best method among four machine learning models, which are Naïve-Bayes (NB), random forest (RF), k-Nearest Neighbor (KNN) and Support Vector Machine (SVM) in classification of EMG signals during a daily activity of touching a contra-lateral shoulder. The process consists of three parts: time division of data according to phases of movement, the EMG feature extraction based on time domain, and four machine learning models.

METHODS

The participants consisted of 20 healthy normal subjects (five male and 15 females, with mean age of 39.1 years (SD 10.3, range 24-56 yo), mean weight 72.9 kg, mean height 160.7 cm, mean right arm length 57.9 cm. All participants were free from any injury and written consent were obtained. The study was approved by research Ethics committee UKM (NN-2016-045). Arm movement of touching contra-lateral shoulder activities were recorded using a Vicon motion analysis system with a recording rate of 100 Hz. The EMG signals from deltoid, biceps, and palmaris longus muscles on the right arm were recorded using a Delsys EMG system.

The arm moved from ipsilateral thigh to the contralateral shoulder, rested on the shoulder and returned to its initial position. Three phases of arm movement were identified (lifting, static and returning the arm) and data were classified based on these phases. The data of arm movements were divided according to the arm movement angles, Figure 1.

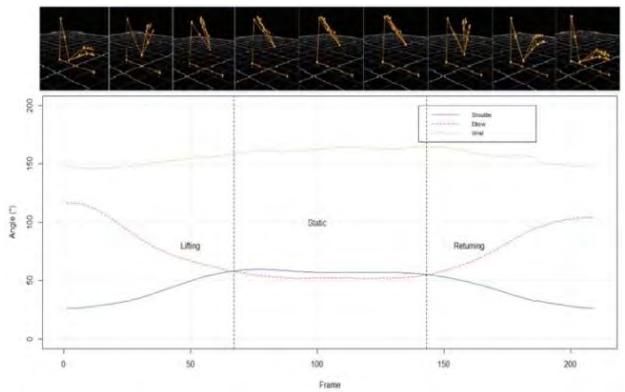

Figure 1 Angles for shoulder, elbow and wrist joints during touching contralateral shoulde

In the classification phase, three time-domain features were extracted which were maximum amplitude, mean absolute value, and root mean squared value, using supervised machine learning models. The data were divided into 80% training and 20% testing. The training data were classified using the four models.

RESULTS AND DISCUSSION

A comparison of the average percentage accuracy of algorithm classification for each time domain against the three phases of arm movement showed MVS produced the highest values. To evaluate the performance of the classification models, confusion matrices of different parameters for each model, such as accuracy, precision, recall and F-measure were obtained. The MVS model showed the best performance in all parameters with values in accuracy, precision, recall and F-score rates at 94.88, 95.10, 94.90, and 94.80, respectively, Table 1.

Table 1: Comparison of percentage evaluation of machine learning model metric scores.

	Confusion matrices (%)			
Model	Accuracy	Precision	Recall	F-measure
NB	94.02	94.00	94.00	94.00
MVS	94.88	95.10	94.90	94.80
RF	91.45	91.70	91.50	91.30
KNN	76.90	79.40	76.90	76.40

CONCLUSIONS

The results showed that all the classification models achieved accuracies ranging between 76–95%. Moreover, it was found that the MVS model had the best performance among the four tested models. However, confusion matrices of different parameters can be improved.

ESTIMATING L5/S1 FLEXION-EXTENSION MOMENT WITH AN ARTIFICIAL NEURAL NETWORK METHOD IN MANUAL LIFTING TASKS: A PRELIMINARY VALIDATION STUDY

INTRODUCTION

Manual lifting activity is one of the most commonly reported risk factors for low back pain (LBP) in the workplace. L5/S1 moment estimated by biomechanical models allows ergonomists to evaluate if the lifting tasks carried by the workers could potentially cause overexertion injuries. Conventional measurements to perform such analyses mostly require the use of laboratory-based optical motion tracking systems (OMTSs) and force plates (FPs). However, these advanced types of equipments are usually expensive and bulky. In addition, it could be a challenge to use them outside a well-controlled lab environment. Researchers had proposed alternative motion tracking methods of using the markerless skeletal model driven by joint data obtained from portable depth cameras such as Kinect (Microsoft, USA). However, the use of Kinect-identified joint location as a counterpart for the L5/S1 joint position had been found to yield significant error between 16.8 to 33.7 cm during standing [1]. In our previous study [2], we proposed the use of an artificial neural network (ANN) method to improve the accuracy of a markerless skeletal model for L5/S1 position identification. In the current study, we further investigated the accuracy of L5/S1 moment estimations based on our previously proposed work. The measurement results of the L5/S1 flexion-extension moment during symmetrical lifting are reported.

METHODS

A lifting database comprising the postural data output from the Kinect skeletal model and OMTS during various symmetrical lifting motions was collected simultaneously with the corresponding ground reaction forces measured by FPs. A total of twenty participants' data was extracted from the database and was divided into the training dataset (15 out of 20) and the validation dataset (5 out of 20). The training dataset was used to develop the ANN model for improving the L5/S1 position prediction based on the joint coordinate data output from the Kinect skeletal model as reported in the previous study [2]. Once the ANN model was developed, it was then applied to predict the L5/S1 positions for each participant in the group of validation dataset. An inverse dynamics model [3] was utilized to estimate the flexion-extension moments at the L5/S1 joint through a top-down biomechanical modelling approach based on the ANN-predicted L5/S1 positions. The flexion-extension moments at the L5/S1 joint based on the data output from OMTS and FPs for the same validation dataset group were also calculated through a bottom-up biomechanical modelling approach and were treated as the gold standard. The difference between the ANN method and the gold standard in estimating the L5/S1 flexion-extension moment was examined.

RESULTS AND DISCUSSION

The mean (SD) of the errors for estimating the L5/S1 flexion-extension moments from the ANN method during the entire duration of various liftings with respect to the validation dataset was 16.76 (8.33) Nm. A randomly selected example of the L5/S1 moment during a symmetrical lifting trial comparing the estimation based on the ANN method against the gold standard is illustrated (Figure 1).

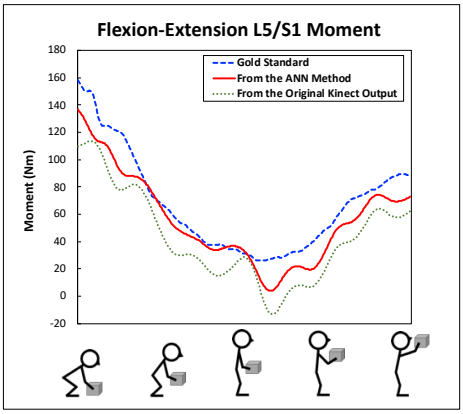

Figure 1 The ANN method estimated flexion-extension L5/S1 moments vs. the gold standard measurement

CONCLUSIONS

Applying the ANN method to obtain a more accurate L5/S1 position from the Kinect markerless skeletal model output shows the accuracy in estimating the L5/S1 moment can be improved. If a portable depth camera system such as Kinect is needed for the applications of field assessment, the ANN-based method can provide a more accurate evaluation of the L5/S1 moment in manual lifting tasks.

INTRODUCTION

Online first-person shooter (FPS) games have grown in popularity, such as Counter-Strike: Global Offensive (CS: GO), Valorant, and Fortnite. In these FPS games, the ability to shoot accurately and quickly with a computer mouse is essential. Ergonomic computer mice promote a more neutral wrist and forearm position and avoid applying external pressure to the palmar wrist region. A previous study, however, discovered that ergonomic devices did not reduce carpal tunnel pressure [1]. Although an ergonomic mouse may not reduce the risk of carpal tunnel syndrome, the different shapes of computer mouse might alter the forearm muscle activation patterns. To the best of our knowledge, no studies on the effect of computer mouse slanted angles on clicking movement have been conducted. Therefore, the purpose of this study was to compare the effects of two different computer mouse slanted angles (0° and 5°) in a quick click task.

METHODS

Eight male esports gamers volunteered to participate in this study. The CS: GO was used for this study. The gamers were asked to click left button of computer mouse as fast as possible until an enemy was killed. Hand motion data were recorded with an eight-camera Motion Analysis Corporation Kestrel motion capture system. The muscle activities of the extensor carpi radialis longus, extensor carpi ulnaris, 1st dorsal interossei, 4th dorsal interossei, abductor digiti minimi and extensor indicis muscle were recorded by the Delsys EMG system during the task. Figure 1 showed two prototype computer mice with different slanted angles. The Wilcoxon signed-rank test was used to determine whether there was a significant difference between the slanted mouse and the non-slanted mouse. The statistical significance level was set at $\alpha = 0.05$.

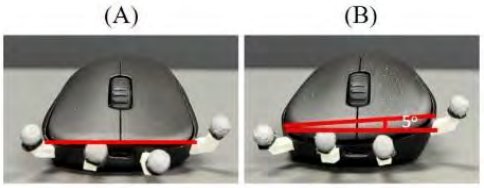

Figure 1 The computer mice with 0° (A) and 5° (B) slanted angles.

RESULTS AND DISCUSSION

The results revealed that when participants used the computer mouse with slanted angle of 5°, the index finger MCP joint angle was significantly greater. However, the click velocities and activation levels of all the muscles did not differ significantly between the two slanted angles of the computer mouse (Table 1). A previous study found that the slanted angles (0°-30°) of computer mice influenced forearm muscle activation [2]. The reason for this disparity could be that the slanted angle in this study was only 5°. Future studies are needed to determine whether greater slanted angles can affect gamers' performances.

CONCLUSIONS

In conclusion, the computer mouse with a 5° slanted angle had no effect on the muscles or performance in the quick click task.

INTRODUCTION

The gaming mouse is crucial to professional gamers' performances. It comes in different designs, contributing to various effects on maneuvering the mouse. Some studies have investigated the effects of slanted angles during general computer tasks. A prior study discovered that performances in pointing and dragging tasks worsened as the slanted angle increased [1]. Another study found that slanted angles would affect surface electromyography (EMG) levels in a text-editing task [2]. However, the effects of slanted angles in esports have not been explored. Thus, this study examined the upper limb muscle fatigue difference between slanted and non-slanted gaming mice in an intensive shooting task.

METHODS

Eight right-handed male esports gamers participated in this study. Their ages ranged from 19 to 27 years old, and the average age was 24.3 (SD: 2.9). The shooting task required the gamers to kill 200 enemies as fast as possible in the Counter-Strike: Global Offensive "Aim Botz - Training" Workshop. The enemies appeared in random positions within a designated range. Gaming mice with slanted angles of 0° and 5° were tested (Figure 1). Six upper limb muscles were assessed: the first dorsal interosseous (1st DI), the fourth dorsal interosseous (4th DI), extensor indicis (EI), abductor digiti minimi (ADM), extensor carpi ulnaris (ECU), and extensor carpi radialis (ECR) muscles. EMG signals were collected from the start to the end of the shooting task using the Delsys Trigno system. The raw EMG signals were bandpass-filtered between 20 and 450 Hz and then divided at 3-second intervals. In each interval, the median frequency was calculated with fast Fourier transforms using Matlab. Finally, linear regression analyses were conducted on the calculated median frequencies as a function of time, and the median frequency slopes in the six muscles were determined as the slopes of the regression lines. The Wilcoxon signed-rank test was used to determine whether there was a significant difference between the slanted and non-slanted gaming mice. The statistical significance level was set at $\alpha = 0.05$.

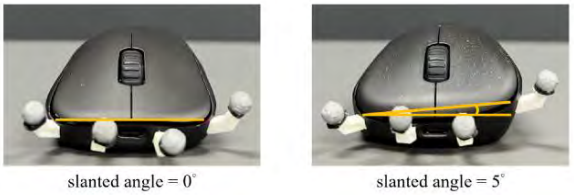

Figure 1 Gaming mice tested in the experiment.

RESULTS AND DISCUSSION

The median frequency slopes of the two gaming mice were not significantly different from each other in all six upper limb muscles (Table 1). However, there was a relatively larger difference in the ADM muscle. The median frequency when using the non-slanted mouse dropped more compared to that when using the slanted mouse, indicating that non-slanted mice might be more prone to fatigue in this muscle when performing an intensive shooting task.

Table 1: Median frequency slopes in the six upper limb muscles.

	slanted angle = 0°	slanted angle = 5°	*p-value*
1st DI	-0.051 ± 0.039	-0.032 ± 0.042	0.742
4th DI	-0.022 ± 0.087	-0.030 ± 0.051	1.000
EI	-0.027 ± 0.031	-0.024 ± 0.095	0.148
ADM	-0.085 ± 0.151	-0.025 ± 0.132	0.078
ECU	-0.015 ± 0.041	-0.023 ± 0.034	0.313
ECR	-0.001 ± 0.020	-0.009 ± 0.033	0.547

A previous study found that an increase in slanted angle (30° vs. 0°) caused lower muscle activity in the ECU muscle in a 30-minute task of highlighting, copying, and pasting text [2]. This suggests the fatigue of the ECU muscle may also be different. In this study, however, there was no significant difference between the two mice in this muscle. Possible reasons may be the smaller angle difference (5°) and the shorter task time (around 2 minutes). Therefore, it is recommended that future studies should: (1) include more slanted angles that cover a larger range; and (2) lengthen the task time. That way, the effects of slanted angles in esports might become more prominent, which could help design new gaming mice that benefit gamers.

CONCLUSIONS

This study shows that a five-degree difference in the gaming mouse slanted angle does not significantly affect fatigue during the shooting task in the 1st DI, 4th DI, EI, ADM, ECU, and ECR muscles. The fatigue difference between the slanted and non-slanted mice was relatively larger for the ADM muscle.

INTRODUCTION

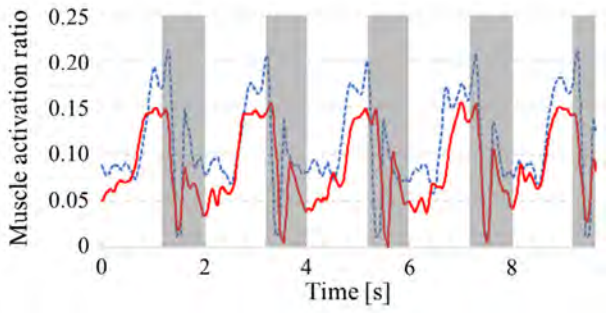
From the viewpoint of occupational safety and health, it is important to manage worker fatigue. Muscle fatigue can cause work-related musculoskeletal disorders [1]. In other words, some method to assess muscle fatigue in working conditions is important. One of the strategy of such methods is perforimg musculoskeletal simulation of work motions measured in actual work environment. It is expected that the measurement of work motions in the actual work environment will become easier in the future. This is because the method of estimating the 3D posture of the human body from moving images, which has been actively developed in recent years [2], can be applied to the moving images of surveillance cameras installed in the work environment. On the other hand, few studies have discussed on the changes of work motion and physical fatigue during repetitive task. Therefore, as a preliminary step to the discussion, this study aims to confirm whether changes in work motions in repetitive tasks are related to changes in muscle activity.

METHODS

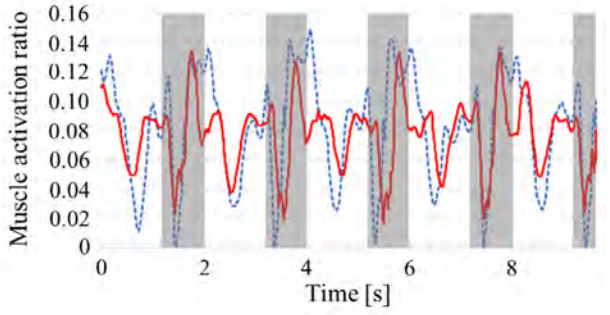
By the IMU-based motion capture system Perception Neuron Studio (Noitom Inc, Florida), three-dimensional human body motion was measured while a healthy male participant performed a simulated occupational task to lift a bottle (500 g) from elbow height to shoulder height. This task was repeated 100 times in a row at the frequency of once per 2 seconds. Both start and end points of the task were set at 80 % of the upper limb length in the midsagittal plane in the natural standing position. For muscle activity simulation, the measured motion data was applied to musculoskeletal model of human body using the commercial software Anybody (Anybody Technology, Aalborg, Denmark). The human body model was adjusted to the body height and weight of the participant.

RESULTS AND DISCUSSION

During the period when the participant was lifting a bottle, the flexion and abduction angles of the shoulder joint were about 70 degrees and 30 degrees in the first ten times, whereas were about 60 degrees and 20 degrees in the last ten times, respectively. In addition, the elbow flexion angle was about 50 degrees in the first ten times, whereas was about 70 degrees in the last ten times. In other words, in the last ten times, the participant performed work motion around a posture that kept their upper arms closer to his body with his elbow extending than in the first ten times. Results of musculoskeletal analysis show that the activity of the middle deltoid works on shoulder abduction decreased in the last ten times, whereas the activity of the biceps brachii works on elbow flexion was similar through the experiment (Figure 1). These results indicate that the participant changed work motion to reduce shoulder workload without increasing elbow workload.



(a) middle deltoid



(b) biceps brachii

Figure 1. Simulation results of muscle activation ratio. Blue dashed line and red solid line show results from the 5th to 9th and from 89th to 93rd times, respectively. Areas with a grey background indicate time periods when the participant did not have a bottle.

CONCLUSIONS

This study analysed time changes of body motion and muscle activity in a repetitive lifting task. Musculoskeletal simulation results indicate that body motion at the ends requires less activity of shoulder muscles with similar activity level of elbow muscles compared to that at the beginnings. This shows the applicability of the musculoskeletal simulation in quantitative evaluation of the muscle activity change along with the work motion change.

INTRODUCTION

Intramuscular heterogeneity exists in the shear modulus of the rectus femoris (RF) muscle [1]. However, the underlying heterogeneity mechanisms are not entirely understood. Previous research has reported that detachment of superficial tissues reduces the shear modulus by 50% [2]. However, the effect of superficial tissues on the shear modulus has only previously been examined at one site and its involvement in heterogeneity is unknown. Additionally, changes in shear modulus distribution have not been investigated when inter-tissue connections are disconnected so that fascial force transmission does not occur. The aim of this study was to examine the effects of the skin, deep fascia, and intermuscular connections on the shear modulus of the RF at multiple sites.

METHODS

Eleven donors were fixed using the Thiel method. The mean age at death was 84.8 years (ranging 60–98 years). Measurements were performed at 0°, 60°, and 120° knee flexion in a neutral hip position. Tissue processing was performed under four conditions: superficial tissue (CONT), skin off (SKIN), deep fascia detachment (FASC), and intermuscular connections detachment (ALL). The shear modulus of RF muscle was measured using ultrasound shear wave elastography (Aixplorer Ver. 12. MSK mode; Hologic, Marlborough, USA). The measurement sites were the proximal (25% of the length of the RF), central (50%), and distal (75%). The study was approved by the Sapporo Medical University Ethical Committee (approval number: 30-2-26).

RESULTS AND DISCUSSION

Three-way ANOVA revealed no significant interaction between treatment, site, and angle (P = .156), treatment and angle (P=.067), or site and angle (P=.441). There was a significant effect of treatment (P<.001), site (P=.010), and angle (P<.001) and interaction between treatment and site (P<.001). Figure 1 shows a graph of RF shear modulus measurements based on treatment and site interactions. Post-hoc test results showed that the shear modulus in the CONT and SKIN conditions were greater than those in the FASC (vs. CONT: p = .010, vs SKIN: p = .030) and ALL (vs. CONT: p < .001, vs SKIN: p < .001) conditions. Proximal region measurements in the FASC condition were greater than that in the ALL condition (p = .019). In the central region, the shear modulus in the CONT and SKIN conditions were greater than that of the ALL condition (vs. CONT: p = .023, vs SKIN: p = .003). There were no significant differences among the shear modulus of the distal region between any of the treatment conditions. The proximal shear modulus was greater than that of the central (p = .048) for the CONT condition. There were no significant differences between the SKIN condition measurement sites. The distal shear modulus was greater than that of the proximal (p = .004) in the FASC condition, and the distal shear modulus was greater than that of the proximal (p = .002) and central (p = .006) in the ALL condition.

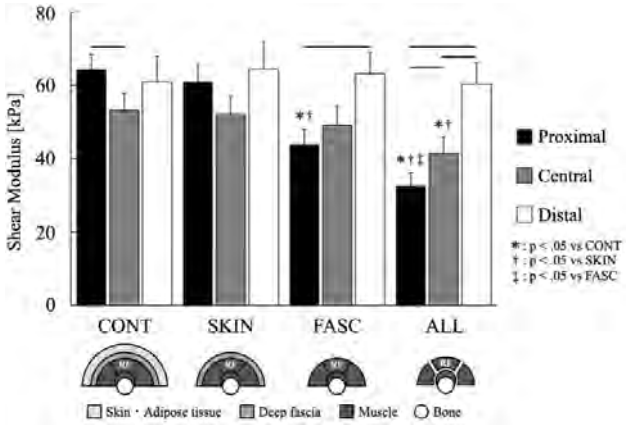

Figure 1 Rectus femoris shear modulus based on treatment at each site.

CONCLUSIONS

The shear modulus decreased in the RF's proximal and central regions due to the detachment of the deep fascia and inter-tissue connections. Regional dependence may exist in the effects of superficial tissues and interstitial connections on the shear modulus of the RF. These results suggest that the superficial fascia and inter-tissue connections should be considered during muscle evaluation and clinical treatment.

INTRODUCTION

Knee meniscus injury is common injuries on basketball with high surgery rate and long-term impact on knee cartilage health [1]. Dynamic extrusion of the meniscus was associated with meniscal injuries which could be used to examine the meniscal health [2]. While acute structural response of medial meniscus from non-weight bearing to weight bearing position are widely reported, how knee medial meniscus responses to specific sports workout are not well understood. The purpose of this study was to determine the degree of displacement on knee medial meniscus in response to 30 minutes of basketball-specific workout.

METHODS

Twenty division I high school male basketball athletes (1.77 ± 0.07 m, 73.4 ± 12.2 kg, 16.1 ± 0.9 yrs) without lower extremity injury within 6 months, previous knee surgery, or serious knee injury history were recruited. All participants underwent ultrasound imaging of the knee medial meniscus on both limbs during non-weight bearing, weight bearing position, immediately after, and one hour after a 30 minute basketball workout. The 30 minutes basketball workout included 8 minutes of dynamic warm-up exercise, 8 minutes various defense drills, 8 minutes interleaving layup and pull-up jumper. Meniscal extrusion was measured via ultrasound imaging which was defined as peripheral medial meniscal margin exceeding the tibiofemoral compartment of the knee. Two-way repeated measures ANOVA examined the differences in right and left knees meniscal extrusion during non-weight bearing, weight bearing position, immediately after, and one hour after a 30 minute basketball workout.

RESULTS AND DISCUSSION

There was no significant main effect of limb on knee medial meniscal extrusion ($F(1,19) = 0.242$, $p = .628$). The left knee meniscus extrusion was similar with right limb (2.5 ± 0.1 mm Vs 2.5 ± 0.1 mm). There was significant main effect of time points on knee meniscus extrusion ($F(3,17) = 8.772$, $p = .001$). Post hoc tests using the Bonferroni correction revealed that knee meniscus extrusion increased from non-weight bearing to weight bearing position (2.2 ± 0.1 mm Vs 2.5 ± 0.1 mm, $p = .022$) and was increased from weight bearing position to immediately post-workout (2.5 ± 0.1 mm Vs 2.6 ± 0.1 mm, $p = .049$). There was no significant difference between immediately post-workout and an hour post-workout (2.6 ± 0.1 mm Vs 2.6 ± 0.1 mm, $p = 1.000$). There was no interaction between limb and time points on knee meniscus extrusion ($F(3,17) = 0.690$, $p = .570$).

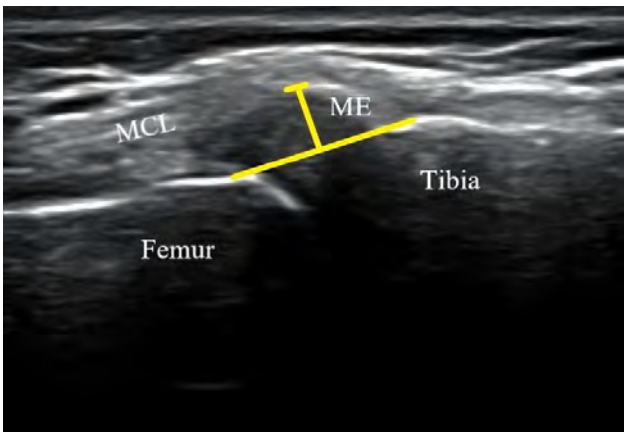

Figure 1. Ultrasound examination of medial meniscal extrusion. ME, meniscal extrusion; MCL, medial collateral ligament.

CONCLUSIONS

After 30 minutes basketball workout, the displacement of knee medial meniscus was higher than non-weight bearing and weight bearing position and was similar with an hour later after workout. This work suggests that basketball workout induced short-term structural displacement in knee medial meniscus and could not recover after an hour rest. Future research should focus on how knee meniscus responses to long-term sports activities and the association with meniscus injury.

INTRODUCTION

A recently developed image processing technique uses 2-D statistical shape and appearance modelling (SSAM), which analyzes the shape and density of the femur to predict hip fracture risk accurately [1,2]. A dual-energy X-ray absorptiometry (DXA) scanner has many imaging protocols clinicians may use, with a standard protocol typical for hip DXA scans. The IVA-HD imaging protocol provides a high-definition image typically used on the lateral spine, yet may provide a more accurate fracture risk prediction if applied to the hip. In addition, the present algorithms [1,2] were developed using JPGs, so theoretically, performance could be enhanced by using a file type with a higher resolution (e.g., DICOM). The main concern is JPG images are low-resolution images as this image type does not preserve each original pixel. DICOM images are considered high-performance images that can be converted to high-resolution images like PNG while maintaining the actual pixel values of the image [3]. The goal of this study was to quantify any differences in the SSAM fracture risk tool by comparing each DXA protocol (standard hip & IVA-HD) in JPG & DICOM format (i.e., four total image types).

METHODS

Cadavers and patients were used in this study to test further the sensitivity of the SSAM fracture risk algorithm (i.e., with femur and pelvis, and femur only). A device was designed and built to support cadaveric femurs in a DXA scanner. A 15 cm clear bucket filled with water simulated the attenuation of muscle and fat [4]. Seven isolated cadaveric femurs (5M/2F, age 59.9±11.9 years) were DXA scanned at a neutral position (parallel to the DXA table) using a Hologic Discover A system. Each femur was scanned using two main imaging protocols from the DXA scanner: a standard hip and an IVA-HD. Similarly, six patients (1M/5F, age 69.5±7.74 years) were also recruited from the Hamilton Osteoporosis Diagnostic Clinic to receive an additional scan using the IVA-HD imaging protocol, in addition to their regular scheduled hip DXA scan (standard hip) (Fig 1.). Each hip scan for all subjects (patients & cadavers) from each protocol was exported to two different file types: DICOM and JPG (52 total images). To use the SSAM algorithm and apply landmarks along the femur [2], the DICOM images were converted to PNG. Each image was assessed using the SSAM algorithm [1]. Briefly, the SSAM algorithm applies principal component analysis (PCA) to obtain the main modes of variation. Logistic regression is then used, applying the modes, age, and bone mineral density values to find the probability of sustaining a fracture [2]. The probability fracture was outputted for each image/file type. A two-way repeated measures ANOVA (α=0.05) with a Bonferroni post-hoc test was used to determine the effect of the protocols and file types on fracture probability and compare the impact on different subjects.

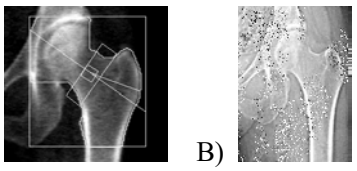

Figure 1 Hip DXA scan using (A) clinical standard (B) IVA-HD

RESULTS AND DISCUSSION

The degree of freedom was corrected using Greenhouse-Geisser (ε<0.75) due to violating the assumption of sphericity. When examining the four image types, no significant differences (p=0.254) were found in the probability of sustaining a fracture. This demonstrates that the fracture risk prediction tool's output was unaffected by the protocol or file type selection. This is important to assess because IVA-HD is not regularly used for a hip assessment. Since it provides a higher-quality image, this comparison ensured that the current hip protocol used clinically could remain utilized for diagnosis and fracture risk assessment. Also, using DICOM and JPG (regardless of DXA protocol) did not alter the results of the fracture risk prediction tool, which can enable this tool to be used in a clinical setting, irrespective of the file type used. Finally, the fracture probability while using the four image types was not significantly impacted (p=0.254) by the interaction between cadavers and patients. This further supports the sensitivity of the tool as regardless of the subjects (either cadaver or patient) and image types used, the tool's output remains unaffected.

CONCLUSIONS

Novel fracture prediction tools rely on high-quality images for accurate performance. This study's results indicate that the present tool performs equally well on DXA scans regardless of file type or scan protocol, showing potential for clinical integration.

INTRODUCTION

Scoliosis is an abnormal spine curvature mainly affecting children, progressing rapidly as they grow. If conservative treatment fails, surgery can prevent progression and improve spinal alignment. Implanting screws in a deformed spine can be challenging, risking spinal cord and nerve root injury, causing neurological issues. To address this, surgical planning tools can create patient specific guides. CT scans used to generate 3D models for surgical planning come with a high ionising radiation dose which is problematic for children, as it increases risk of radiation induced cancer, and it is not a clinical standard in the UK. Improvements in Magnetic Resonance (MR) imaging allow better bone-tissue delineation, with no radiation risk. It is safe for clinical pre-operative investigation and performed routinely in scoliosis surgery. This study aims to validate MR generated spine models compared with CT generated models.

METHODS

Porcine spine specimens (n=6) were acquired and imaged using a Somatom go.Sim CT scanner (Siemens) and a 3T Magnetom Prisma MR scanner (Siemens). A series of different sequences were performed to determine the best imaging parameters. Individual vertebrae were segmented in Simpleware Scan IP (Synopsys) using semiautomated threshold techniques from the two imaging modalities. 3D models were then exported and the MR and CT models were registered using an iterative closest point technique and then compared using a 3D deviation map (Artec Studio 13). Initial pilot was performed comparing MR derived model (T1 VIBE) with CT for one spine specimen.

RESULTS AND DISCUSSION

Visual differences between the two imaging modalities can be seen in Figure 1. 3D Deviation results can be seen in Table 1. Initial results show that the overall difference between MR derived bone models vs gold standard CT models is approximately a single voxel of the MRI (0.6mm^3). This suggests that MRI is a suitable and accurate alternative to CT imaging. The main limitation of MR imaging is the increased scan time and processing time required for generating models. Future work will quantify the difference between imaging modalities further, using 2D measurements such as pedicle width and height [1,2] and carrying out clinical MR imaging (1.5T) as an additional comparator.

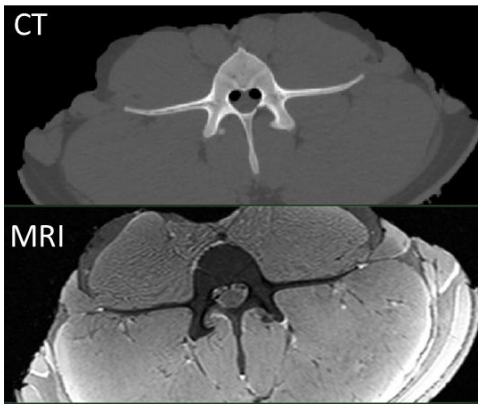

Figure 1 Representative axial slice of vertebra showing visual difference between CT and MR imaging

CONCLUSIONS

MR imaging is a viable and accurate alternative to CT imaging for the application of surgical planning of the spine. Future work will advise on which clinical MR sequence is most appropriate for incorporating into future surgical planning software.

INTRODUCTION

Biplanar Video radiography (BVR) is an essential approach for measuring *in vivo* bone motion during dynamic activities. It is well established for tracking larger joints, such as the knee; however, tracking complex joints such as the foot and the wrist, where there are many small, occluded bones, remains challenging. Autoscoper (Brown University) is an open-source software solution designed to facilitate bone tracking. Here, a 3D bone volume is projected as a digitally reconstructed radiograph (DRR) onto the two radiographs captured by BVR. The partial volume is rotated and translated until the DRRs best match the radiographs. This process is repeated for each bone across time, yielding 6dof bone and joint motion.

While manual or semi-manual tracking approaches can yield accuracies on the order of 1 mm and 1 degree in the foot [1], the process is time consuming. Optimization algorithms promise to automate tracking. Autoscoper uses a particle swarm optimization to minimize normalized cross-correlation values (NCCs) between the DRR and the radiographs. Bones with minimal occlusion from neighbouring bones have strong correlation between low NCCs and accurate pose estimation [2]. In multiarticular joints, the NCC values of a DRR representing a single bone may not be at a minimum when the pose is correct because a DRR derived from a single bone may not match well with radiographs containing multiple, occluding bones.

The purpose of this study was to determine whether the optimized NCCs yield accurate pose estimation for bones in the foot joint. We took advantage of a rare, *in vivo* dataset where the participant had tantalum beads implanted into their tibia, talus, and calcaneus.

METHODS

The partial volume talus was generated from a CT scan (0.39x0.39x0.625mm). The pose of the partial volume was initialized by applying 6dof transformation matrices from the bead tracking (Figure 1A). The NCCs for the bead poses were evaluated before optimization. Then, the particle swarm optimizer altered the pose at each frame such that the NCCs were minimized. This process was repeated across 20 frames with three optimizer search limits of -0.1, -1, and 3 (+/- mm and degrees). Rotational errors were quantified using the angle swept by the rotation axis between the bead-based transforms and the optimized transforms. A repeated measures ANOVA and post-hoc t-tests evaluated whether the NCC values differed.

RESULTS AND DISCUSSION

The optimizer found NCC values between 9 and 11% lower than the correct bead-based pose ($p<0.05$). There were differences among the NCCs across the search limits ($p > 0.05$); however, the angular error differed by 0.8°, 1.1°, and 1.3° degrees for the 0.1, 1, and 3 search limits, respectively. The maximum error was 6° (Figure 1 C,D). This suggests the optimizer is indeed minimizing the NCC value but low NCC is not strongly correlated with correct pose.

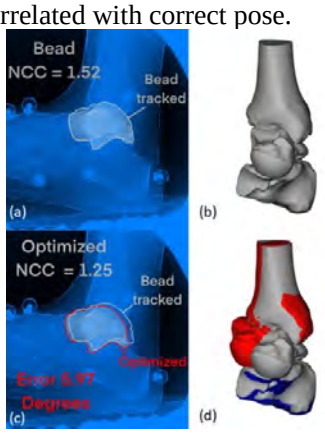

Figure 1 (a) The bead tracked talus (grey outline). (b) Bead tracked calcaneus, talus, and tibia. (c) Autoscoper image of the optimized (red) and bead tracked (grey) talus. (d) The bead tracked (grey) overlayed with the optimized (red) bones.

CONCLUSIONS

These results suggest that a semi-manual approach with manual rotoscoping is still the best-practice for tracking foot bones using Autoscoper, and the optimizer should be used with caution. Errors using a semi-manual method are on the order of 1 mm and 1 degree [1]. Multi-bone tracking, where the pose is optimized for all occluding bones at once may provide better correspondence between NCC and the correct pose. Collision detection may also yield more accurate automated tracking. These limitations are planned to be addressed in the next iteration of Autoscoper, which will also entail porting it into the 3D Slicer computing environment (SlicerAutoscoper[M]).

INTRODUCTION

Jaw functions such as biting, chewing, swallowing, and speech are facilitated by the temporomandibular joint (TMJ). Disoders that impact TMJ function can hence cause social dysfunction and discomfort to patents[1].

The aim of this experimental phantom study was therefore to investigate the feasibility of using dynamic CT scans to evaluate TMJ motion. We established a scanning protocol and a realistic mock-up phantom with detailed mandibular anatomical representation.

In addition, the complete image processing workflow was set in place and the radiation dose to the patient was simulated using a humanoid virtual phantom. Preliminary results of mandibular motion in a patient that had undergone joint replacement surgery was evaluated.

METHODS

A 3D printed phantom (created by segmenting DICOM files of CT data of a male jaw) mounted on a six degrees of freedom stewart platform was developed to simulate mandibular movements with variable speeds.

Dynamic CT acquisition was achieved using a clinical 256-slice Apex Revolution CT (GE Healthcare, Waukesha, Wisconsin, USA). Continuous volume scans were obtained without table motion during the movement of the phantom. A series of rigid transformation matrices were estimated using a pairwise volume-based image registration workflow. This allowed to describe motion of the phantom for each time point from the computation of Cardan angles.

RESULTS AND DISCUSSION

From the phantom experiments, the 3D trajectory of the condyles could be successfully traced and represented in 3D plots (figure 1). Average 95% confidence interval for the displacement was 0.41mm, 0.61mm and 0.20mm for the X, Y and Z axis respectively. In terms of rotations, results were 1.39°, 0.31° and 1.29° for the X, Y and Z axis respectively. CTDIvol was 63.95mGy and a DLP of 1023mGycm corresponding to an effective dose of 1.3mSv.

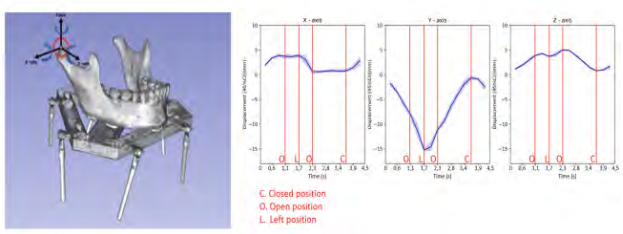

Figure 1 Plots showing the displacement of a point of interest on the mandibular phantom along X,Y and Z axis. Markings on the plot indicate the different motion of the mandibular phantom

CONCLUSIONS

This preliminary study showed reproducible results. Future applications could be in pre-operative planning or potential patient follow-up from combining the visual and 3D graphical mandibular motion kinematics.

INTRODUCTION

Regular physical exercise increases hippocampal volume and has beneficial effects on brain function such as memory function in the older adults [1]. However, it remains unclear to what extent physical activity level (PAL) and/or motor function is linked with hippocampal volume in the older adults. The purpose of this study was to examine whether hippocampal volume is associated with PAL and/or motor function in the older adults. Based on previous studies, we predicted that both PAL and motor function affect hippocampal volume.

METHODS

We analyzed data from thirty-nine older adults (27 females) (age: 70.9 ± 7.1 yr.). Structural MRI was collected on a 3.0 Tesla scanner (Magnetom Skyra, Siemens). Gray matter volume of the hippocampus and total intracranial volume were assessed using voxel-based morphometry, and hippocampal volume was divided by total intracranial volume. Total energy expenditure for 16 days was measured using the doubly labelled water method [2]. Basal metabolic rate was predicted using the Ganpule equations for adult men and women [3]. Then, PAL was calculated by dividing the total energy expenditure by basal metabolic rate. Total metabolic equivalents (METs) were calculated from accelerometers data. Timed-Up and Go test (TUG) and one-leg standing time test with eyes open were performed to evaluate motor function. Multiple regression analyses were conducted to analyze the relationship between hippocampal volume and independent variables (age, sex, PAL, METs, TUG, and one-leg standing time). Data are expressed mean ± SD.

RESULTS AND DISCUSSION

Hippocampal volume was 7,322 ± 824 mm^3, and normalized value was 0.56 ± 0.06 %. Normalized hippocampal volume was greater in the female older adults as compared with male older adults ($p < 0.001$). Female older adults also exhibited greater total METs ($p < 0.01$) and PAL ($p < 0.001$) than male older adults. Multiple regression analysis revealed that hippocampal volume was associated with sex ($p = 0.001$) and tended to be associated with TUG ($p = 0.099$) (adjusted $R^2 = 0.445$, $p < 0.001$). PAL and METs reflect temporal trends in, but not regular, physical activity level. In the current cohort, regular physical activity was presumably greater in females than males. Hence, we can assume that sex, but not PAL and METS, was associated with hippocampal volume in the present study.

CONCLUSIONS

The present study suggests that regular physical activity and, to a lesser extent, motor function are associated with hippocampal volume in the older adults.

TASK-ORIENTED WHOLE BODY REACHING IMPROVES POSTURAL PERFORMANCE IN HEMIPARESIS PATIENTS AFTER STROKE

INTRODUCTION

Stroke is the primary cause of disability globally. Postural control deficits following stroke increase risk of fall and functional dependence [1]. Bean-bag activity (BBA) is a frequent used task-oriented whole body reaching activity uses in rehabilitation clinics routinly to improve stroke patients' postural control performance. Changes in postural control performance was reflected in functional mobility, stability limit, balance, and center of pressure sway total path length [2]. The purpose of this study is to investigate the effects of BBA on postural control performance in hemiparesis patients after stroke.

METHODS

This is an experimental-control, pre-posttest experimental design study. 21 hemiparesis patients, 11 in experimental (A) and 10 in control (B) group, who fulfilled the inclusion and exclusion participated in this study. Participarnts in group A underwent BBA training for twelve weeks, twice a week for 60 minutes each time, while those in group B underwent routine occupational therapy which was comprised mainly sedentary activities. Participants in both group underwent similar physical theray programs at the same time. Postural control performance was measured by Timed-Up and Go Test (TUG) , Functional Reach Test (FRT), center of pressure travel path (COPTPL) in three stance postures (bilateral feet shoulder width v.s. close together v.s. heel-toe stance) and two vision conditions (eyes open v.s. close). All the variable was measured at one week before and 6 and 12 weeks after training. Descriptive and repeated measure two-way analysis of variance were used and effect sized was calculated. SPSS 23.0 statistical soft-ware package was used.

RESULTS AND DISCUSSION

The results showed no significants difference ($p > 0.05$) between groups in demographic characteristics. The interaction of group and test times was significant ($p < 0.05$) indicating the difference between groups was affected by the measurement time points. The simple main effects of group showed that the group A performed significantly better than the group B in TUG ($p = 0.022$), FRT ($p = 0.010$) and BBS ($p = 0.034$). The calculated effect size showed that the training in group A improved the postural control performance mediumly to largely in terms TUG ($\eta p^2 = 0.182$), FRT ($\eta p^2 = 0.252$), and BBS ($\eta p^2 = 0.206$). The improvement of COPTPL during stance was not signivicant, while the effect size showed that BBA training induced COPTPL change mediumly to largely($\eta p^2 = 0.69$-0.109) in stance posture demanding high control effort, such as stance in eyes closed condition. Finally, 6 weeks of training in group A with BBA was able to improve the postural control performance and another 6 weeks of training was able to improve those performance further. The training in group B was not able to improve but deteriorate the postural control performance of the participants. It is necessary to monitor the risk of fall of after BBA training.

Table 1: Summery of repeated measure two-way ANOVA.

	Time	Group A (n = 11)	Group B (n=10)	Effect size	*p-value*
TUG	T1	22.13±14.91	39.00±40.67	0.182#	0.022*
	T2	19.99±14.05	37.89±41.395		
	T3	17.06±10.50	38.10±40.34		
FRT	T1	27.36 ±6.87	29.60± 2.72	0.252#	0.010*
	T2	29.82± 7.01	30.40 ±4.93		
	T3	33.18 ±6.19	31.10 ±5.15		
BBS	T1	43.09± 8.13	38.80 ±12.86	0.206#	0.034*
	T2	47.18 ±7.52	40.80±12.94		
	T3	48.00 ±7.24	41.00 ±23.23		

CONCLUSIONS

Task-oriented whole body reaching activity required the performer to control their posture according to the goal of the task and was efficient in improving the postural control performance not only during dynamic but also static context. Interventions focus on sedentary activities might deteriorate patients postural control This effects of BBA on lowering the risk of fall in hemiparesis patients after stroke should be further investigated.

INTRODUCTION

Parkinson disease (PD) is a progressive neurodegenerative disorder of the central nervous system. The most critical disability as disease progression is postural instability, which is a main motor deficit associated with balance ability and fall risks. Falling is very common in PD, which occurs in sixty-eight percent of patients with PD each year. However, not all of the patients with PD are at risk of falls, some of them only have some functional declines or minimal impairment in balance. Thus, it is critical to distinguish the fallers (PD-F) from non-fallers (PD-NF) of PD and provide fall prevention program as soon as possible.

Patients with PD could be distinguished from normal individuals under the visual deprivation and dual task condition by using static posturography [1][2]. However, whether using visual deprivation and dual task paradigm can distinguish PD-F from PD-NF is unclear. As a result, this study aimed to compare the performance of postural control under different internal perturbation conditions between PD-F and PD-NF by using static posturography.

METHODS

The participants were allocated to PD-F and PD-NF according to their previous fall history. The participants were allocated to PD-F if the falls history greater than or equal to one time in past one year [1]. All participants were tested during the on-medication state [2] The participants were instructed to stand barefoot on the force plate (Qoppa, Taiwan). They were asked to perform three balance tasks randomly, including eye open (EO), eye closed (EC) and performing dual task, color judgement task (DT) while standing [2]. The sampling rate for force plate was set at 120 Hz for seventy seconds. The participants were performed two times in each condition and the means was be calculated.

RESULTS AND DISCUSSION

All participants increased the path length, velocity, and instability ratio in EC and DT as compared with EO, except for PD-NF in DT. The PD-F had longer path length and higher velocity in DT compared with EC, but the opposite was found in PD-NF. In contrast, all participants showed less instability ratio in DT as compared to EC (Figure 1). The executive and sensory function deficits might affect the postural control. The increasing mediolateral (ML) range and decreasing anteroposterior (AP) range were observed in PD-NF, it might be due to the axial rigidity, and their balance was compensated by ML sway. The PD-F increased the sway in both directions in order to maintan the posture stability [2] [3].

For group difference, there were diffrences for velocity and length in DT, and for instability ratio in EC and DT (Figure 1). The postural control deficits was detected in EC because their condition might induce inhibition on the visual adaptive strategy. In addtion, the invisible posture control deficits could be detected by inhibiting attention strategy to compensate the basal ganglia circuit deficits [1] [2] [3]. Using internal perturbations might be suitable to distinguish PD-F from PD-NF.

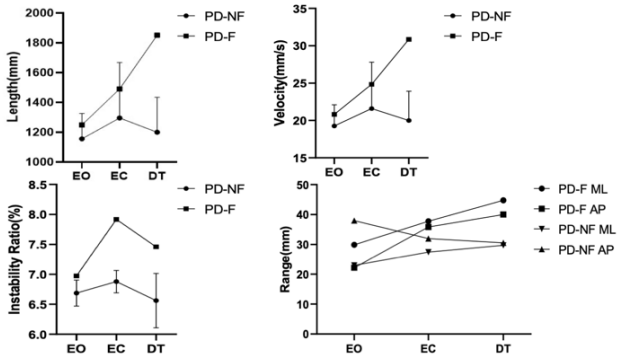

Figure 1 Comparison of the postural control parameters between groups and among conditions

CONCLUSIONS

Using internal perturbations, especially DT might be suitable to distinguish PD-F from PD-NF. Early identifying faller and providing preventive intervention is crucial for PD. All questions about the conference should be addressed to isb-jsb2023-ab@congre.co.jp.

INTRODUCTION

Overweight individuals often report gait imbalance issues, which can further impair mobility and increase the risk of falls. [1]. Becauase the foot is the first body part to interacts with the external surroundings during walking, assessing plantar pressure can provide important information regarding gait balance control. Therefore, this study aimed to investigate the difference in plantar pressure between overweight and non-overweight during walking at different speeds.

METHODS

Eleven overweight individuals (Female 4/Male 7; 27.2±8.1 years; BMI: 29.4±2.8kg/m^2) and 13 non-overweight individuals (Female 7/Male 5; 23.3±7.9 years; BMI: 22 kg/m^2) walked on a 10-meter walkway at three controlled speeds (80%-120% of preferred). The degree of gait imbalance was quantified by calculating the extent of the mediolateral whole-body center of mass (COM). Wireless pressure sensing insoles (Xsensor®) was used to measure plantar pressure data. All participants wore the same traditional running shoes (New Balance, prototype). An analysis of variance model was conducted to investigate the effect of body size, gait speeds, or their interactions on the peak mediolateral COM (including displacement (m), velocity (m/s), and acceleration (m/s^2) and peak plantar pressure (kPa) from hallux (T1), second-fifth toes (T2-5), metatarsal 1-2 (M1-2), metatarsals 3-5 (M3-5), lateral midfoot (LM), medial midfoot (MM), lateral heel (LH), and medial heel (MH) during walking.

RESULTS AND DISCUSSION

Significant group effects of peak plantar pressure under the later forefoot (P = 0.03), lateral midfoot (P = 0.02), and medial heel (P = 0.02) were observed (Table 1). The peak pressure was transmitted from the medial heel during the mid-stance phase to the lateral forefoot during the pre-swing, which was more prominent in overweight gait (Fig 1). However, only mediolateral COM displacement (P = 0.02) and acceleration (P = 0.04) revealed significant speed effects. At a slower walking speed, both groups seem to have a greater range of COM displacement, indicating a slower walking speed may induce gait imbalance.

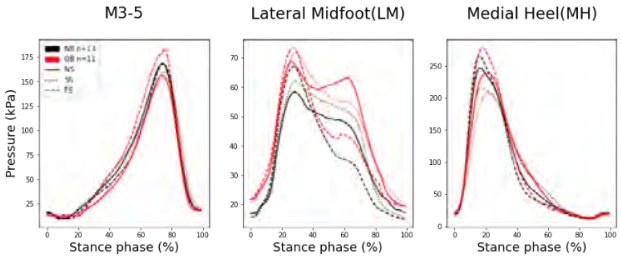

Figure 1 Plantar pressure under the M3-5, LH, and MH during the stance phase of the gait cycle. This figure reports only three anatomical regions that revealed significant group effects.

CONCLUSIONS

This study was the first to document the effect of body size and gait speeds on plantar pressure distribution and COM during walking. Different gait speeds altered mediolateral COM motion during walking. Only the plantar pressure distribution responded differently across the body size group during walking. Based on the current results, overweight individuals appear to have increased pressure on the lateral side of the foot for stable walking.

Department of Health, Kinesiology and Applied Physiology, Concordia University, Montréal, Canada.
Email: emma.chen@outlook.com

INTRODUCTION

Falls cause 85% of injury-related hosptializations and 95% of hip fractures among Canadian older adults [1]. These injuries disporportionately affect women across all age classifications of older adults [2]. Postural stability decreases with age due to deterioration of sensory systems, muscular strength and mobility [3]. It is well-known that physical activty can improve postural stability [3], however traditional exercise programs lack adherence for older women and can be difficult to access for those living in remote areas or affected by social distancing guidelines [4]. The aim of this study was to determine if 12-weeks of online dance classes could provide an engaging and accessible method for older women to improve their postural stability.

METHODS

22 women (74.7 years ± 5.8) completed two, 1-hour long integrative ballet-modern dance classes per week, for 12-weeks over Zoom. Postural stability, dynamic balance and functional strength were assessed at pre (week 0), mid (week 6) and post (week 12). Postural sway was analysed during 30-seconds of quiet standing on force plates, dynamic balance was assessed using a modified Star Excursion Balance Test and knee and ankle strength were assessed using the 30-Second Sit-to-Stand test and the Calf Raise Senior test. Significance was evaluated using one-way repeated measures ANOVA and nonparametric Friedman test ($p<.05$).

RESULTS AND DISCUSSION

17 participants completed the 12 weeks of online dance classes, with a strong adherence rate of 80.4%. Significant improvements were found in knee and ankle strength through the intervention (Figure 1). Participants performed a higher number of repetitions on the 30-second Sit-to-Stand from pre to mid ($p=.015$) and pre to post ($p=0.011$), while they performed an increased number of calf-raises from mid-post ($p=.012$) and pre-post ($p=.005$). Clinical significance was also demonstrated during the Calf Raise Senior test from mid-post and pre-post. Significant improvements in dynamic balance were found in the distanced reached during the Star Excursion Balance Test from pre-post in lateral ($p=.010$) and posterior-lateral directions ($p=.004$). A lack of findings regarding postural sway may be due to the insufficient intensity of online dance classes, as the online medium necessitates lower intensity to ensure the participants' safety.

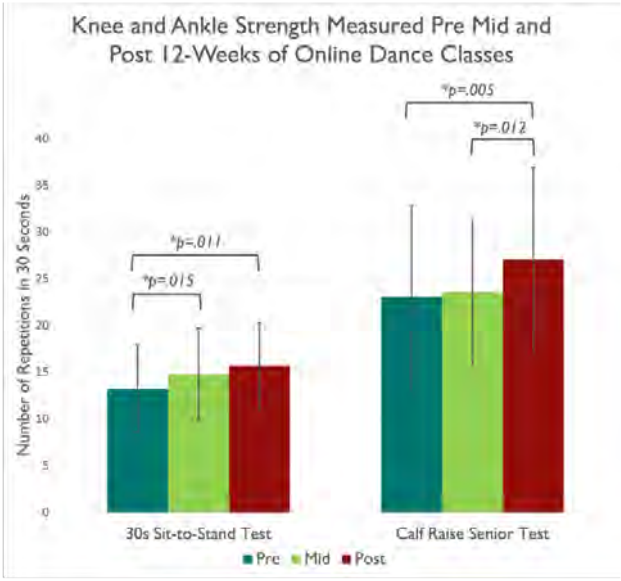

Figure 1. Increases in strength over 12-weeks of online dance classes with error bars illustrating standard deviation

CONCLUSIONS

Our findings demonstrate that 12-weeks of online dance classes may serve as a fun and engaging way for older women to improve their strength and dynamic balance, thereby reducing their fall risk. As the online medium was shown to be safe while lacking in sufficient intensity to induce improvements in postural sway, current studies are exploring the addition of blood flow restriction. Online dance classes demonstrate great potential as fall prevention programming for older women who may otherwise face barriers to participate in exercise. With the increased accessibility of online classes, more women may have opportunities increase their independence and quality of life as they age.

DEVELOPMENT OF THE TWO-DIMENSIONAL MECHANICAL MODEL OF HUMAN STABILITY

INTRODUCTION

Human movement analysis is an increasingly popular topic. However, there is still a need to develop knowledge about estimating the forces and moments of forces acting in the joints, since they cannot be measured unequivocally. Another difficulty is the appearance of an external force acting on a human in the model of motion. For this reason, the authors propose a model of human motion treated as a semi-closed chain, defined by the Euler-Newton equations [1]. This model was tested on the example of a fall caused by an external force, i.e. a fall that may occur during a sudden braking of a public transport vehicle. The input data were obtained with the use of an optoelectronic motion capture system, dynamometric plates and a dynamometer. The proposed model can be later on applied in devices for monitoring and assessing human movement.

METHODS

In this study, participants were asked to backward fall. The movement was captured with the use of the optoelectronic motion capture system (sampling frequency of 250 Hz and spatial measurement resolution of 0.001 m) complemented by two AMTI force plates with a sampling frequency of 500 Hz and measurement resolution of 0.001 N. With the use of platforms, the ground reaction forces (GRF) and the centre of pressure (COP) trajectory were captured. Additionally, the external random force was applied to the participants' body to cause a backward fall. The time course of the external force was registered with the use of a dynamometer (sampling frequency and measurement resolution are equal to 500 Hz and 0.5 N, respectively). The participants were standing with each leg on a separate platform.

The mechanical model of human was described as a semi-closed chain of symmetrical non-deformable rigid bodies connected by rotational joints. Because the inertial and mass parameters of segments were taken from David Winter's description, the placement of markers on the subjects' body was determined [2].

To make the collected data applicable to Newton-Euler equations the necessary accelerations were calculated and smoothed using the Taylor series.

The input variables on the model are inertial and mass parameters of the body, accelerations of centres of masses and angular accelerations of segments, GRF and COP of the right lower limb. The output of the model are COP and GRF given by the left lower limb on its force plate. The output variable allows for the assessment of the accuracy of the model.

RESULTS AND DISCUSSION

The presented method allowed for acquisition of a mechanical model of human motion in two-dimensional space. The comparison of vertical and horizontal GRF during the performance of external force-caused fall, obtained with the use of the model and measured by the platform is shown in Figure 1. One can notice, that the waveform representations of the GRF in time are less accurate when the system is perturbated by an external disturbance – while accelerations and inertial parameters have a more significant impact on the performance of the model.

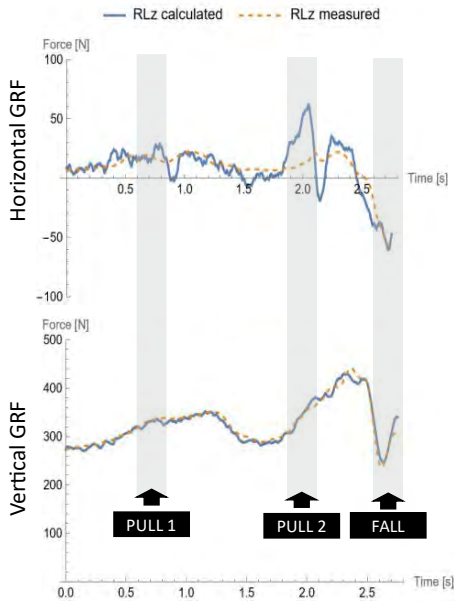

Figure 1 Comparison of the vertical ground reaction force measured by force plate and obtained by the model.

CONCLUSIONS

The proposed model can be considered sufficient for biomechanical studies. The inertial parameters of segments of the body have a crucial impact on the performance of the model, especially when studying fast-changing movements.

INTRODUCTION

Postural stability during standing could be an important index for elderly people. Especially, postural stability on a single leg stance (SLS) may reveal the overal and general systematic information of the central nervous system failure, atheletes injury, and other motor control abilities [1]. It may also be used as a good index to evaluate sports injury and performance, stroke, etc. To date, single leg stance is usually assessed by the total time not by quantitative physiological measurement such as surface electromyography (sEMG). In this study, authors recorded multi- channel sEMG from six muscles of each leg during SLS and evaluated the muscle activity patterns.

METHODS

All subjects signed consent forms before participation (IRB no. DHCIRB-2022-06-0008). Total of 20 neurologically intact subjects (3 males, 17 females, and average age=68.9±4 years) were asked to follow the standard protocol for SLS made by the Korean Balance Ability Data Center. Total of 12 surface EMG (sEMG) electrodes were attached to both legs for SLS test. sEMG recording was made from rectus femoris, tibialis anterior, peroneus, biceps femoris, gastrocnemius, and soleus for right and left leg. We made prototype sEMG profile using sEMG data from 18 subjects as the control group and later sEMG data from two subjects who were chosen arbitrarily among 20 subjects were compared as the test group. sEMG recording system was (Ultium, Noraxon, USA) with a bandwidth of 10-500 Hz and 2000 s/s/channel. A root mean square (RMS) algorithm was used and then total data were integrated for the test window. The sEMG was recorded up to 30 seconds for SLS for each subject. We normalized the integrated sEMG data using the sampling rate. Multi-channel sEMG patterns were compared during SLS. The whole process for EMG assessment followed the Brain Motor Control Assessment Protocol (BMCA) [2]. In short, a prototype vector was made using 18 subjects using six response elements of one side. Finally, similarity index and total EMG activity were calculated

RESULTS AND DISCUSSION

Average EMG amplitude was 114.7±25.5 μV for right SLS (range 50.4~152 μV) and 119.4±18.5 μV for left SLS (range 86.5~151.8 μV). Similarity index was 0.96±0.04 for right side (range 0.8~1.0), and 0.98±0.02 for left side (range 0.9~1.0) (Fig. 1). Time duration could give us only one dimensional information regardless of various motor control patterns of elderly people. In this point, similarity index and EMG total activity during SLS could give us new additional information because neurologically intact subjects showed the similar motor control pattern during SLS. It may be an useful index to screen elderly people who possibly have motor control difficulties on a single leg stance even though they could stand on one leg for acceptable amount of time comparing to people who has no difficulties for SLS.

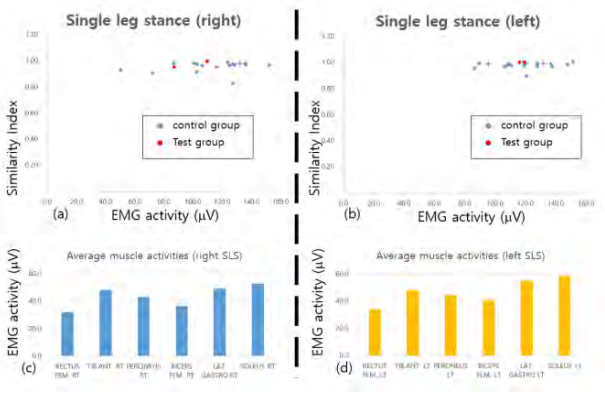

Figure 1 Similarity index and EMG activities during single leg stance for right (a) and left side (b). Multi- channel sEMG are showing the similar activities during SLS for right (c) and left side (d).

CONCLUSIONS

In this study, we applied BMCA protocol to see whether multi-channel sEMG among subjects are showing consistent and similar activities during SLS test. Results showed similarity index and total magnitude of sEMG may be a good screening tool for elderly people who may have difficulties in maintaining for SLS.

Alteration of Inter-joint Interaction during Standing due to Spinal Cord Injury

Kimiya Fujio[1], Kenta Takeda[1], and Noritaka Kawashima[1]
[1] Department of Rehabilitation for movement function, Research Institute of National Rehabilitation Center for Person with Disabilities, Saitama, Japan.
Email: fujiokimiya@yahoo.co.jp

INTRODUCTION

Inter-joint interaction in lower limb is one of the essential mechanisms for human standing. There are, at least, two types of interactions: for whole body center of mass (COM) kinematics and for local joint kinematics [1]. Those interactions work for counteracting to decrease the objective (COM and joint angular) acceleration. Our previous research indicated that aging deteriorates the former interaction, but it does not affect the later. It implies that control mechanisms are separated for each interaction, and if the central nervous system (CNS) contributes to the later, the inter-joint interactions for local joint kimematics could be impared in patiants who have a disfunction of the CNS. Thus, we focused on the inter-joint interaction in patients with spinal cord injury (SCI). The purpose of this study was to clarify whether inter-joint interaction, especially that for local joint kinematics, would be impared in SCI patients.

METHODS

We utilized database in our laboratory for the analysis. Sixteen healthy and Sixteen people with SCI were allocated into 2 groups respectively (desired power: 0.85, effect size: 0.25, alpha: 0.05). The dataset included kinematic signals recorded by a motion capture system (8 infrared cameras on Mac3D system, Helen Hayes-marker set, 200Hz) during standing without any aid. Every trial was measured for 30 seconds. In order to analyse inter-joint interaction, standing posture was modelled by a double inverted pendrum with lower and head-and-trunk segments. After calculating hip/ankle joint angular accelerations, COM acceleration and gravitational/muscle/velocity-dependent torques, we applied induced-acceleration analysis [2] to separate contribution of each torque for the net angular acceleration in ankle/hip joint. In this method, the components of joint angular acceleration were distinguished by origin that from homonymous and that from remote joints (e.g. ankle joint angular acceleration was composed with not only component from ankle but also that from hip joint). Finally, uncontrolled manifold (UCM) approach was applied to quantify the above 2 types of inter-joint interactions (joint angular acceleration for COM, and the components of angular acceleration for local joint kineamtics; $UCM_{ankle/hip}$). Statistical test (Mann-Whitney test) was applied at α=0.05.

RESULTS AND DISCUSSION

We found that both COM acceleration and angular acceleration in ankle/hip joints were significantly increased in SCI patients. It indicated postural sway and joint kinematics during standing were larger and faster in SCI. Nevertheless, UCM_{ankle} was higher in SCI group ($p=0.016$, $r=0.596$), while UCM_{hip} was not different between healthy and SCI groups, indicating not deteriorated inter-joint interaction in SCI. Statistical test further showed that both components of ankle and hip angular accelerations were significantly larger in SCI patients (Figure1, lower). Those results suggested that inter-joint interaction for local joint kinematics was preserved even when the CNS (spinal cord) was damaged. Instead, we suspect that larger accelerations of all components from homonymous and remote joints cause the increased joint angular acceleration.

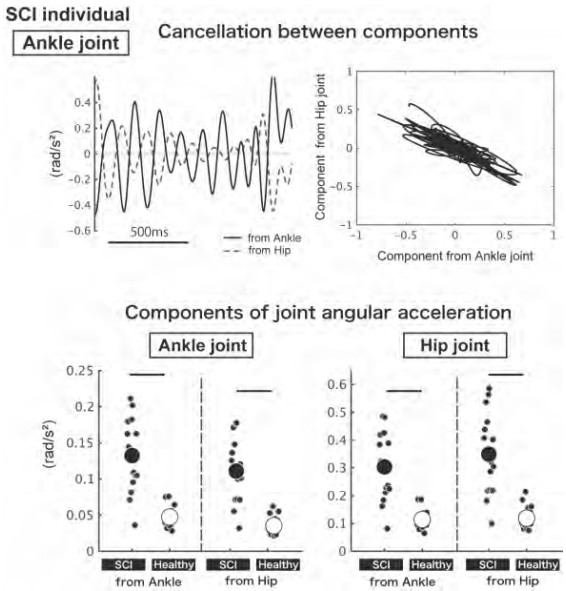

Figure 1 Inter-joint interaction for local joint kinematics.

CONCLUSIONS

Our results demonstrated that inter-joint interaction for local joint kinematics is not always impaired in people with SCI. It could rather be caused by a larger acceleration effect of each component from homonymous and remote joints. Further studies are expected to clarify the details of mechanisms for inter-joint interaction by using a multi-link pendrum model.

INTRODUCTION

To explore the relationship between specific frequency band EEG and balance performance of freestyle skiers aerial skills during balance control tasks with different difficulty.

METHODS

Select 17 freestyle skiers of the national team as the research object. The subjects used the HUMAC portable balance instrument to perform the standing continuous balance test (CBT) of the dominant leg and the non-dominant leg on the soft and hard support surfaces respectively, and recorded the center of pressure (COP) of the body during the subject's standing balance process.

The 64-lead EEG recorder (ANT Neuro) was used to simultaneously collect the EEG signals of the subjects during the balance task. Each test is performed for 30s, with an interval of 1min. After the collected signals are processed by segmentation, downsampling, and artifact removal, frontal lobe (F3, Fz, F4), frontal lobe-central (FC1, FCz, FC2, C3) are selected. , C1, Cz, C2, C4), central-parietal lobe (CP1, CPz, CP2, P3, Pz, P4) and other three regions to the θ (4-8Hz) frequency band Fast Fourier transform (FFT) and then After natural logarithmic transformation, the average value of electrode power was taken for each region.A 2 × 2 × 3 three-way repeated measures analysis of variance (ANOVA) was designed, and the independent variables were: support surface (2 levels: hard and soft support surface) × standing leg (2 levels: dominant leg, non-dominant leg) × brain Sensory cortical areas (3 levels: frontal, frontal-central, central-parietal).

RESULTS AND DISCUSSION

(1) Compared with both feet, the average amplitude of Cop on one foot was significantly higher than that on both feet , and there was no significant difference in the average amplitude of Cop in the dominant leg and the non-dominant leg ; (2) In unstable surface, during the balancing process of standing on the support surface, the swing degree of the COP of the left leg standing and the right leg standing was significantly greater than that of the subjects with a hard support surfaceswing ($P<0.001$);(3) The energy values of theta waves in the three sensory cortex areas were significantly higher than those in the hard support condition ($P<0.05$), and the non-dominant leg was higher than the dominant leg ($p<0.05$). (4) The ANOVA results of cortical activity in the theta frequency region showed that different support legs had significant effects in frontal ($p<0.001$), frontal-central ($p<0.01$) and centro-parietal ($p<0.001$) regions .

CONCLUSIONS

(1) Freestyle skiing aerial skills athletes' balance control ability on the soft support plane is weaker than the hard support surface balance ability; (2) The left and right balance ability of freestyle skiing aerial skills athletes is stronger than the front and rear balance ability; (3) Balance task As the difficulty increased, theta activity in the frontal, fronto-central, and central-parietal regions of the cerebral cortex increased. In addition, frontal-central and central-parietal Theta power was associated with balance performance.

A STATIC MODEL PREDICTS ROOF-TO-LADDER TRANSITION FRICTION REQUIREMENTS

Sarah C. Griffin[1] and Kurt E. Beschorner[1]
[1] Bioengineering, University of Pittsburgh, Pittsburgh, USA
Email: scg57@pitt.edu

INTRODUCTION

Ladder-related injuries create a severe burden on the working population. Specifically, transitioning across support surfaces and lateral leaning lead to more than 20% of fatal ladder-related incidents [1]. Previously, a relationship has been found between the lateral lean angle (defined by the relationship between the center of mass and the base of support in the frontal plane) and the medial/lateral (ML) directed required coefficient of friction (RCOF) in walking [2]. An inclined beam model is often used to determine friction and normal reaction forces. The goal of this work is to determine the predictive ability of a simple static model on friction requirements in the ML direction.

METHODS

Seventeen healthy participants who regularly climb ladders completed six trial replicates for two ladder conditions: a traditional extension ladder that requires climbers to step around the ladder when transitioning to a roof and a modified extension ladder that allows the user to step through the top. Kinetics were collected from the rung and passive reflective markers quantified body kinematics. ML RCOF was calculated as the ratio of ML shear force to the normal force in a coordinate system relative to the shoe's contact plane. The ML body angle was the angle between vertical and the frontal plane projection of a vector from the toe to the trunk center of mass.

A static model based on an inclined beam was utilized to predict the ML RCOF. The model was based on a point mass (i.e., the climber's trunk) located at the top of a massless beam (the segment connecting the trunk to the foot). The beam's orientation was defined by the body angle (θ) measured from vertical. The predicted ratio of the friction and normal force at the ground was found to be: $ML\ RCOF = \tan(\theta)$.

Model fit was determined via the root mean squared error (RMSE) and a bivariate correlation analysis with the experimental values as the outcome variable and predicted values as the regressor. Better models would correspond to a linear fit with a slope nearer to one, a y-intercept of zero, and low variance around the fit line.

RESULTS AND DISCUSSION

Acceptable agreement was found between the predictions and experimental data (**Figure 1**). The regression analysis resulted in a significant linear relationship ($t = 12.49$, $p < 0.001$) with a slope of 0.758 and an R^2 value of 0.722, indicating that the model explained most of the variance in the data. The low RMSE (0.046) also supports the strength of this model.

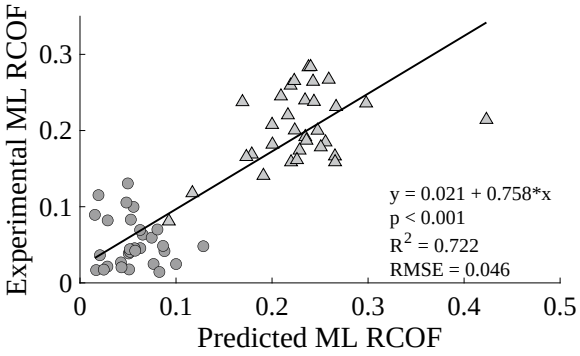

Figure 1: Bivariate relationship between the predicted ML RCOF and the experimental ML RCOF where circles correspond to a walk-through ladder and triangles correspond to a traditional ladder top.

These results demonstrate that the relationship between the ML friction requirements and frontal plane body angle is well explained by a static model. This simple relationship between kinetics and kinematics is advantageous for applications of ladder safety research. Kinetic data is difficult to collect and requires modifying a ladder structure and using expensive and non-portable force plates. Kinematic data, on the other hand, can be collected in the field through use of wearable technology or camera-based methods. Results of this model suggest that individuals should attempt to minimize their ML body angle during roof-to-ladder transitions, keeping their center as closely aligned with their foot as possible. Researchers can use this to develop both individual- and context-specific feedback which can be delivered to ladder users in real time, thus minimizing the number of lateral slips that occur during roof-to-ladder transitions.

CONCLUSIONS

The predicted values correlated with the experimental ML friction requirements during roof-to-ladder transitions. The existence of a mechanistic model to explain previous experimental work strengthens safety recommendations and allows researchers to provide subject- and context-specific feedback to improve ladder safety.

EVIDENCE FOR MODIFYING EXTENSION LADDER DESIGN TO REDUCE SLIPPING RISK

Violet Williams[1], Sarah Griffin[1], and Kurt Beschorner[1]
[1] Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, USA.
Email: Violet.Williams@pitt.edu

INTRODUCTION

Falls threaten safety in both occupational and non-occupational settings. Ladder falls are the second most common cause of falls, accounting for 8% of all occupational falls [1]. A quarter of falls resulting in an emergency department visit involved extension ladders [2]. One challenge in extension ladder climbing is the transition between the fly or upper section and the base or lower section. The fly is stacked on top of the base but minimal justification exists for this design choice. This study examined the effect of the extension ladder fly configuration on an individual's slip risk quantified by required coefficient of friction (RCOF).

METHODS

The testing apparatus consisted of two extension ladders, each oriented at 75° from horizontal. One configuration was a traditional fly ladder. The other configuration was a reversed extension ladder with the fly section underneath the base section (Figure 1). The transition between the fly and base sections occurred at the 3rd and 4th ladder rungs where anterior/posterior foot placement must change. Participants were asked to ascend and descend the ladder to the 5th rung at a comfortable but urgent pace for three trials of each configuration. The 3rd rung of each configuration was attached to a force plate and 12 motion tracking cameras (Vicon) collected kinematic data. Only descent trials were included in this analysis. RCOF was calculated as the ratio of the resultant shear and normal forces on the shoe in its local coordinate system. The RCOF values were split into two halves of stance with the bounds of initial foot contact, toe off, and the midpoint between these times. The root mean squared (RMS) values were found for each half of stance and averaged between the replicates of a participant's descents in each configuration. 16 participants (10 male, 6 female; 34.50 ± 15.37 years) were analysed. Paired t-tests were conducted with ladder configuration as the independent variable and RMS RCOF as the dependent variable.

RESULTS AND DISCUSSION

There was no significant difference found between the traditional and reversed configurations for RMS RCOF ($t_{15} = 0.798$; $p = 0.438$) in the 1st half of stance. In the 2nd half of stance higher RMS RCOF values occurred in the traditional fly configuration than the reverse ($t_{15} = 3.008$; $p = 0.009$) (Figure 1). These values indicate an increased risk of backwards slip in the traditional fly ladder as the individual prepares for toe off. This difference is likely because while transitioning from the fly to the base section of the traditional configuration, the plane of the rungs moves forward. One possibility is that the shift results in a more anterior foot placement, and the increased horizontal distance between the participant's foot and center of mass could increase the friction force required. The relationship between this lateral distance and force direction is commonly explained by an articulated strut model. Another possibility is that climbers unaware of the forward shift contact the rung closer to their toes as they don't fully shift their foot forwards. This difference in position could increase the moment arm from the ankle, rotating the foot and increasing RCOF [3].

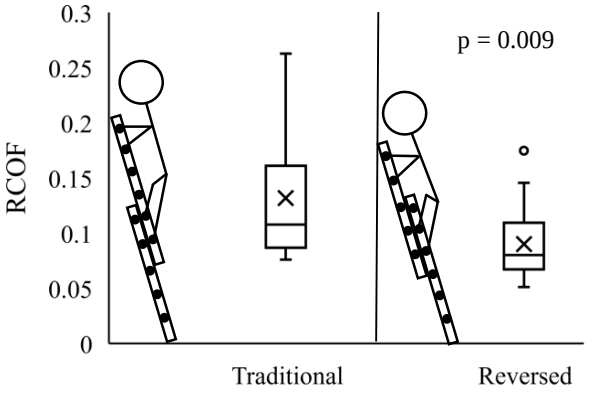

Figure 1: RMS RCOF values for traditional and reversed fly configurations in the 2nd half of stance where X signifies the mean, and the lines signify the median and interquartile range.

CONCLUSIONS

The reversed fly configuration was found to have significantly lower values of RCOF during ladder descent. These results indicate that there may be a higher slip risk during late stance for traditional fly ladders. An opportunity may exist to improve extension ladder safety by reversing the fly configuration.

INTRODUCTION

In human bipedal standing, centre of mass (COM) is the controlled variable and centre of pressure (COP), representative point of the ground reaction force, is controlling variable. Several studies found COM acceleration (COMacc) is regulated to be minimum in quiet standing and sensitive to age-related changes in the postural control [1,2]. Since COMacc is equal to the horizontal ground reaction force, it is expected to be related to the behavior of the COP. A few studies revealed COP velocity reflects whole body COMacc [3], but the relationship between them is not clear. We divided the COP into low and high frequency components and analysed which COP behavior leads to COM acceleration.

METHODS

The subjects were 18 young adults and 9 health elderly. They held a static standing on a force platform (Type9281B, Kistler, Switzerland) for 30s with their eyes open or eyes closed. Four trials were performed for each visual condition. COP position and horizontal ground reaction force were obtained from a force plate, sampled at 1000 Hz. COP was decomposed into low frequency components (rambling) and high frequency components (trembling) [4]. COP velocity was calculated differentiated by COP displacement.

RESULTS AND DISCUSSION

Trembling had a larger coefficient of determination with COMacc than rambling (Fig.1). Multiple regression analysis showed that rambling had the largest coefficient(β) to COMacc in the anterior-posterior (AP) direction, while COPvel had the largest coefficient in the medio-lateral (ML) direction (Table.1).

Rambling reflect migration of the reference point from one instant equilibrium point and trembling is oscillation respect to the moving equilibrium reference [4]. The latter is related to the intrinsic mechanical properties of postural muscle. Human standing is unstable in AP direction, approximated by an inverted pendulum. The COMacc in AP direction is related mainly to the fast and small oscillation generated by muscle. In the ML direction, on the other hand, no relationship between trembling was observed. We presume load/unload mechanism in the ML direction led to these results. These trends were observed regardless of age, suggesting that the increase in COMacc, especially elderly, is influenced by the increase in oscillation around the equilibrium reference rather than by the migration of the reference point.

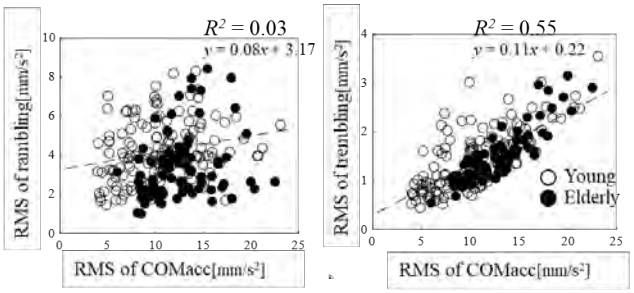

Figure 1 Linear regression for COM acceleration and rambling/trembling in anterior-posterior direction

CONCLUSIONS

COM acceleration is influenced by trembling in the AP direction and not rambling. This relationship may be a factor in the increase in COM acceleration due to aging and disease.

THE EFFECTIVENESS OF ARTIFICIAL INTELLIGENCESPORT TRAINING MIRROR COMBINE WITH CHINESE MARTIAL ARTS FOR LOWER EXTREMITIES BALANCE

Cheng-Wei Chen, Ching-Ting Hsu*, Wei-Hua Ho and Pao-Hung Chung
Institute of Sports Equipment Technology, University of Taipei
*E-mail: jingting@utaipei.edu.tw

INTRODUCTION

Chinese martial arts is an exercise that improves the balance and lower limbs stability, but not restricted by all age groups thus very suit for the general public. Human balance ability can be separated to static balance and dynamic balance [1]. Chinese martial arts movements mainly depend on hand shape, step shape, body shape, strength coordination, clear movement and stillness. Mirror image training is one of the main methods of martial arts training. The mirror is a very important tool in sports training, because the mirror reflects learners image for learners to observe and adjust own movements.In this paper, we improve the traditional mirror training to artificial intelligence sports training mirror which not only provide reflection image but also both real time and play back video with skelet combined with Chinese martial arts training to observe the balance ability improvement.

METHODS

Exercise procedure:In this study, we recruit10 young female participants for a 6-week balance training. In this paper, we arrange a set of basic lower limbs actions from Chinese martial arts to improve lower limbs stability. These actions are horse step, lunge, single step, frontal kick and side kick. Participants do each action for 30 seconds, 5 sets in each exercise and 2 times exercises for a week. Balance ability evaluation:In this study, we utilize Y-balance to evaluate participants' balance ability [2]. Statistical method:SPSS Statistics 20.0 is utilized to test statistical data. And, paired sample *t* test evaluates the balance ability difference between before and after our balance exercise. The level of statistically significant difference is set as $p < 0.05$.

RESULTS AND DISCUSSION

Table 1 and Table 2 shows the results of 6-week balance exercise for artificial intelligence sport training mirror and traditional mirror, respectively. From these tables,we can observe that after 6-week exercise, the dynamic balance ability of the expermental group has significantly improvement. However, from Table 1, we can observer that AT of the experimental group also improves after our artificial intelligence sport mirror balance exercise. On the other hand, there is no significant difference in the dynamic balance ability between the pre-test and post-test in the control group (Table 2). These results denotes that after 6-week of artificial intelligence sports training mirror combined with step exercises can improve the dynamic balance ability of young females.

CONCLUSIONS

This study shows the effect of dynamic balance ability and lower limbs stability improvement by utilizing artificial intelligence sports training mirror combined with Chinese martial arts. The results show that the artificial intelligence sports training mirror can efficiently and significantly improve the balance ability and the lower limbs stability.

GAIT STABILITY RESTRICTIONS DID NOT ELICIT COMPENSATION FROM REMAINING STRATEGIES

INTRODUCTION

Healthy humans are proficient at overcoming everyday perturbations to avoid falls, but the underlying mechanisms that allow for stable gait are still unclear. Humans primarily utilize three stability strategies: corrective stepping (stepping strategy), centre of pressure (CoP) modulation (ankle strategy), and upper body momentum modulation (trunk strategy) [1]. Previous studies found that stepping is the predominant strategy for maintaining stability [1]. However, it is unclear if the strategies will compensate for one another when one is restricted. Focused on mediolateral behaviour, we aimed to investigate strategy restrictions, hypothesizing that when one strategy is limited, the remaining strategies will provide compensation.

METHODS

Ten healthy subjects (2F/8M, 27.9 ± 3.8 years, 173.4 ± 11.2 cm, 70.4 ± 10.3 kg) walked on a treadmill with randomized mediolateral perturbations applied to the pelvis at right toe-off. Subjects walked in four different randomized conditions – three restricted and one unrestricted. The ankle strategy was restricted using shoes with a narrow strip of rubber (2 cm) on the bottom, limiting mediolateral CoP modulation [2]. The trunk strategy was restricted using a brace that restrained spine bending. The stepping strategy restriction was imposed by laser lines projected onto the ground at a fixed step width.

Trunk strategy was assessed by changes in trunk angular acceleration, ankle strategy by CoP changes during single support, and stepping strategy by step width changes. For the former two measures, the deviation area between the mean trajectory of the unperturbed strides and a perturbed stride was calculated, and then linear fits were created between the deviation area and perturbation magnitude (Figure 1). For step width, the percent change in step width between an unperturbed stride and a perturbed stride was calculated. Similar linear fits were created between the percent change in step width and the perturbation magnitudes. The slopes and intercepts of the linear fits were compared to the no restriction condition using repeated-measures ANOVA and post-hoc t-tests with a Holm-Sidak correction ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The restrictions were successful in reducing the effectiveness of the intended strategy, with reduced slopes for trunk angular acceleration and stance CoP, and reduced intercept for step width change for the respective restriction conditions (Table 1). Contrary to our hypothesis, the investigated measures did not suggest compensatory behaviour. However, the rate at which swing time decreased as a function of perturbation magnitude was 22% greater for the stepping restriction compared to the no restriction (p = 0.007), suggesting other gait changes may have allowed for stability to be maintained.

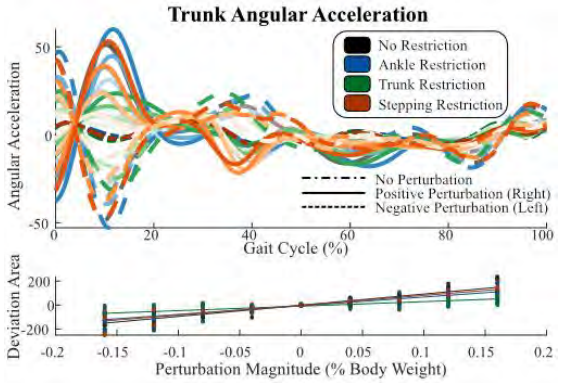

Figure 1: Exemplar analysis to compare restriction conditions. Darker shading indicates a stronger perturbation.

CONCLUSIONS

Despite restrictions, healthy humans overcame perturbations without exhibiting compensation. Stricter restrictions may elicit compensatory behaviour.

INTRODUCTION

Parkinson's disease (PD) is a neurodegenerative disorder that impairs postural and balance control. Postural and balance disabilities during functional transitional activities, such as rising from a chair, are highly correlated to falls. The sit-to-stand (STS) movement is a complex transitional activity that requires sufficient propulsive force to accelerate the body forward and then upward. Deep brain stimulation (DBS) has been shown to be an effective surgical procedure to improve the motor performance of PD. However, the influence of subthalamic DBS on STS remains unclear. The study aims to investigate the dynamic balance in patients with advanced PD during STS before and following bilateral subthalamic DBS.

METHODS

Five patients with advanced PD (63±8y/o, 63±17kg, 1.6±0.7m) (Hoehn and Yahr stage III to IV when off medication) participated in the current study with written informed consent. All patients had undergone medication and received bilateral subthalamic DBS surgery. All PD participants were recruited from the Movement Disorders Outpatient Clinic at the Department of Neurologists, Taichung Tzu Chi Hospital. An 8-camera motion capture system with a sampling rate of 120Hz (Vicon Vantage System, Oxford Metrics Ltd., UK) and two force plates (AMTI, USA) were used. Each subject performed sit-to-stand (STS) with knee flexion of 80 degrees (STS-80) and 110 degrees (STS-110) at a self-selected pace. All PD subjects were tested under two conditions: (1) medication on before DBS surgery (pre-DBS) and (2) medication on and 3-4 months after DBS surgery (post-DBS). Three successful trials for each condition were collected and analyzed. A chair was placed on one force plate, and two feet stepped on another force plate. A 13-body-segment model of the whole body was used to calculate the position of the body's center of mass (COM) as the weighted sum of the segmental COMs of all body segments [1]. The segmental inertial properties were determined using Dempster coefficients. The center of pressure (COP) positions were calculated from the force plate. The anterior and posterior (A/P) positions and medial and lateral (M/L) positions of the COM and COP were analyzed. The STS was composed of three phases: phase I (flexion-momentum phase), phase II (momentum-transfer phase), and phase III (extension phase) [2]. The balance control capability is represented by the peak displacement distances of COM and COP in the A/P and M/L directions. Parameters before and after DBS were compared using the Mann-Whitney U test, with statistical significance set at 0.05.

RESULTS AND DISCUSSION

Comparing pre- and post-DBS, the results showed that the peak displacement distance of A/P and M/L of the COM and COP become smaller during phases II and III of STS-80 and STS-110 (Table 1).

Table 1. Mean values of peak displacement (mm) of the COM and COP at phase I, II, and III during STS with knee of 80 and 110 degrees.

		STS-80			STS -110		
		Pre-DBS	Post- DBS	P value	Pre-DBS	Post- DBS	P value
COM A/P	Phase I	35.60 (20.39)	72.77 (13.56)	0.67	31.04 (19.76)	64.12 (18.88)	0.41
	Phase II	138.07 (38.65)	83.40 (0.26)	0.06	132.69 (34.71)	67.81 (27.62)	0.06
	Phase III	143.87(12.89)	123.78 (7.51)	0.08	130.15 (7.73)	111.06 (12.28)	0.08
COM M/L	Phase I	4.33 (2.95)	2.48 (0.87)	0.25	1.63 (0.57)	2.47 (0.33)	0.51
	Phase II	18.71 (2.50)	3.38 (1.96)	0.06	20.36 (11.38)	3.21 (2.48)	0.06
	Phase III	22.27(3.60)	22.39 (5.14)	0.27	20.03 (3.10)	22.32 (1.01)	0.40
COP A/P	Phase I	2.25 (0.55)	1.19 (0.18)	0.39	1.77 (0.34)	1.24 (0.09)	0.44
	Phase II	14.76 (10.95)	2.90 (3.03)	0.05*	5.36 (2.864)	2.95 (3.14)	0.05*
	Phase III	17.44 (5.50)	10.18 (12.26)	0.00*	16.75 (2.22)	10.90 (11.53)	0.05*
COP M/L	Phase I	1.05 (0.11)	0.63 (0.16)	0.74	0.66 (0.29)	0.64 (0.13)	1.00
	Phase II	4.20 (1.81)	1.31 (1.47)	0.03*	3.71 (1.64)	1.32 (1.49)	0.03*
	Phase III	7.89 (3.35)	1.69 (0.67)	0.05*	4.92 (2.71)	1.79 (0.81)	0.01*

*Significant difference between pre-DBS and post-DBS

CONCLUSIONS

After DBS surgery, it is helpful for PD patients to achieve balanced control during sit-to-stand standing. From sitting to standing, phase II and phase III are the most challenging to maintaining balance control. Because Phase II is at the largest angle of the knee joint, sufficient muscle strength of the lower extremity is required to stand up. Phase III needs the trunk to erect again and sufficient muscle strength. For PD patients after DBS, it is recommended to strengthen and maintain lower limb strength training and exercise.

INTRODUCTION

Reactive postural control is important for fall prevention. Perturbation-based balance training using medical device is effective for fall prevention. However, this training requires large therapeutic instruments or medical expert guidance. Recently, we developed wearable balance training device (WBTD : Figure 1), which is allowed users to perform perturbation-based balance training at home. Although the WBTD improve static postural control [1], the effect of WBTD on reactive postural control is still unclear. The purpose of this study was to investigate the effect of WBTD on muscles activity related to reactive postural control.

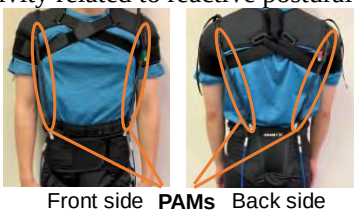

Figure 1 Wearable balance training device (WBTD) which can generate unexpected small perturbation by pneumatic artificial muscles (PAMs).

METHODS

Twelve healthy adult males participated in this study (age: 23 ± 0.9 years; dominant leg: right). Subjects were separated into a device group and a sham group equally. At the training session, all subjects were asked to perform a tandem stance with wearing the WBTD (in total 16 times of 1 minute trial). In device group, WBTD perturbated subjects laterally in random timing and direction for a minute, while WBTD didn't perturb subjects in the sham group. Before and after training session, pre-test and post-test session were conducted using air cylinders as assessment for reactive postural control. The air cylinders were placed on each side of the subjects and perturbed the subjects' pelvis laterally at random timing and direction. During test session, subjects were evaluated their reactive balance function by center of pressure (COP) and electromyography (EMG). EMGs were obtained from both side gluteus medius (GM) and adductor longus (LM). After the perturbation occurred (0 ms), time series COP data of the test session was separated into epochs as follows: 100 to 250 ms (epoch c1), 250 to 400 ms (epoch c2), and 400 to 550 (epoch c3) ms. While EMG data was separated as follows: 50 to 200 ms (epoch e1), 200 to 350 ms (epoch e2), and 350 to 500 (epoch e3) ms. Lateral maximum displacement (LMD) and sway area (SA) were calculated in each epoch. Co-contraction index (CCI) was calculated in each epoch. CCI combination was right-leg (right-GM and right-LM). The amount of change obtained by subtracting the pre-test from the post-test in each index was conducted at a t-test in the device group and the sham group. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Showing some of the results. Figures 2A and 2B show the device group significantly decreased, compared to those in the sham group of the LMD in epoch c1, c2 and SA in epoch c2 ($p < 0.05$). This result suggests the training by WBTD was effective in the improvement of reactive balance function. Figure 2C shows the device group significantly decreased, compared to those in the sham group of right-leg CCI in epoch e3 ($p < 0.05$). Higher rates of CCI are associated with a higher risk of falls [2]. Right-leg CCI in epoch e3 was decreased, possibly improving the balance of using GM and LM to maintain posture. Training with WBTD may contribute to fall prevention.

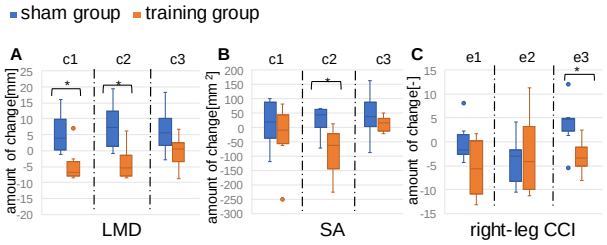

Figure 2 A-C : Amount of change obtained by subtracted pre-test from post-test in each time interval of evaluation index of COP and EMG (c1 means epoch c1, e1 means epoch e1).

CONCLUSIONS

Training with WBTD seemly improvement reactive balance function immediately. To find out the mechanism of improvement in more detail, we should investigate older adults with a larger sample size.

The Effect of suspensory Strategy on Postural Control under Lateral Perturbations: A Study on COM Height and Balance Performance

Linjing Jiang[1], Satoshi Kasahara[1], Tomoya Ishida[2], Yuta Koshino[1], Mina Samukawa[1], and Harukazu Tohyama[1]

Email: jlinjing@eis.hokudai.ac.jp

INTRODUCTION

Postural control under lateral perturbations is essential for maintaining balance and stability during various daily activities. At the same time, the suspensory strategy of bending the knees or squatting is a recognized strategy for stabilizing and maintaining balance by lowering the center of mass (COM) [1]. Although this study investigated the contribution of the suspensory strategy to voluntary postural stability in the anterior-posterior direction, it is unclear whether the suspensory strategy affects postural stability under lateral perturbations. This study aims to investigate whether the suspensory strategy (lowering the COM height) affects balance performance when subjected to unpredictable lateral perturbation.

METHODS

Eighteen healthy young adults (10 males, 8 females; mean age 24.4 ± 2.2 years; weight 62.0 ± 13.9 kg; height 168.8 ± 5.3 cm) participated in this study. This study was to adjust the COM height by having participants assume three different postures: standing, semi-squatting, and squatting. External lateral perturbation was produced with the platform moved in the rectilinear direction, and participants did not know its onset and motion direction. The displacement of the participants' center of mass (COM) and the perturbation generator were measured using a 3D motion capture system. We calculated the initial time and reversal times of the COM movement, as well as the minimum margin of stability (mini-MOS), which is the distance between the predicted displacement of the COM and the edge of the base of support in the frontal plane (Figure 1). We used one-way repeated ANOVA to analyze the data for initial time, reversal time, and mini-MOS, and post-hoc Bonferroni tests to compare differences between postures. The significance level was set at $p < 0.05$.

RESULTS AND DISCUSSION

From one-way repeated ANOVA, there were significant differences in reversal time and mini-MOS at different COM heights, but no significant differences in initial time (Table 1). Post-hoc analyses showed that reversal time was longer in the standing posture compared to both the semi-squatting and squatting postures ($p < .05$). This supports that the suspensory strategy benefits the temporal parameters of postural stability response to unpredictable lateral perturbation. Post-hoc analyses revealed that the mini-MOS was significantly shorter in the squatting posture compared to both the semi-squatting and standing postures ($p < .05$). This indicates that excessive knee flexion or deeper squat decreases postural stability in external lateral perturbation.

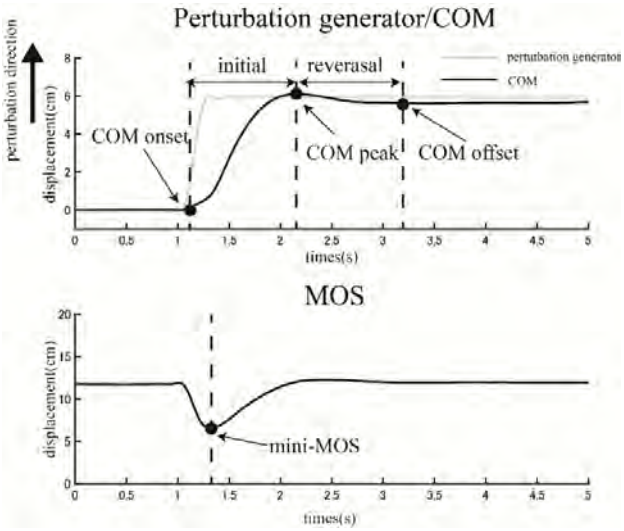

Figure 1 Raw data sample from an experiment.

CONCLUSIONS

These findings suggest that while lowering the COM height through the suspensory strategy may improve balance ability, caution should be exercised to avoid lowering it too much, as this could indicate potential risks for postural control, as shown in the case of the squatting posture.

INTRODUCTION

Postural control plays an essential role in daily activities throughout lifespan. Muscles acting around the ankle, knee and hip joint are of great relevance for maintaining posture [1]. Dynapenia (poverty of strength) is often associated with reduced performance in daily living activities, decreased mobility, impaired standing balance, expanded hospitalization and less protection from falling in old age [2]. The age-related deterioration in strength is not uniform between lower extremity muscles as the rate of decline in plantar flexors force is the largest compared with other muscle groups [3] and the relation between muscle strength and postural control is age-dependent [4]. Recently, it was demonstrated that the most consistent explanatory variable for the variance in sway-area rate was force control of the hip abductors and ankle dorsiflexors as indicated by the magnitude of the normalized force fluctuations (force steadiness) during a submaximal (5% and 15%) isometric contraction [5]. Therefore, the aim of this study is to examine the postural control across life span, associated with force steadiness of the plantar flexors and dorsiflexors.

METHODS

All participants (range of age: 7 – 70 years) were physically active, healthy and free from any disease or impairment. The postural sway was evaluated by employing the NIH Toolbox test of standing balance (Kistler, 1000 Hz), which requires individuals to stand on a rigid or foam surface with eyes open or closed for 60 s. The average CoP velocity, the peak-to-peak amplitude, the standard deviation of CoP displacement, the root mean square (mm) of CoP in anterior-posterior (A/P) and medio-lateral (M/L) axis were used.

The force steadiness during plantar flexion and dorsiflexion at 5% and 15% MVC was evaluated in an isometric dynamometer. Visual feedback of the applied force was provided. The force fluctuations were expressed as the coefficient of variation (CoV: standard deviation/mean*100) during the 5 steadiest seconds of the submaximal contraction (average of 3 trials).

RESULTS AND DISCUSSION

All CoP variables had a U-shaped distribution by age, with those who are very young or very old having the highest values. Similarly, the CoV for force during plantar flexion and dorsiflexion was high for the participants before puberty, it decreases in adolescent and then increases again with age. Pearson's test showed strong positive correlation between CoV for force during plantar flexion at 5% and 15% and CoP velocity in M/L axis during standing on a rigid surface with eyes closed (Figure 1). However, the correlations did not reach always the significance, especially for the dorsiflexors and the standing task on a foam surface.

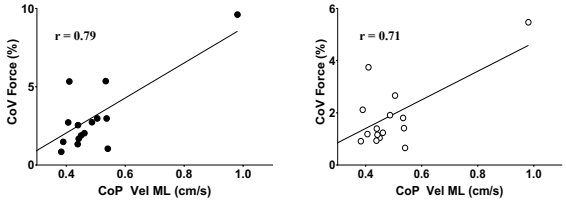

Figure 1 Correlation between the Coefficient of Variance for force during plantar flexion at 5 and 15% MVC and Centre of Pressure velocity in medio-lateral axis during standing on a rigid surface with eyes closed.

CONCLUSIONS

Children and older adults presented poorer postural control during standing and poorer force steadiness with the ankle muscles compared to young and middle-aged adults. The postural control was correlated with the force fluctuations depending on the standing task and the muscles involved.

INTRODUCTION

Vision plays a significant role in the maintenance of stability. The laterality of the eye, so-called "eye dominance", have shown to be related to visual acuity, speed of information processing and even postural control [1]. With compromised vestibular and proprioceptive systems, the importance of visual information in gait are further highlighted in older people, while visual field deficits caused by ageing lead to an inability to recover balance with subsequent increased risk of falls. Therefore, the study aimed to identify the effects of eye dominance on whole-body balance control during level walking in the elderly.

METHODS

Thirteen older adults without neuromusculoskeletal and ocular disorders participated in this study. Each subject walked at a self-selected pace on an 8-m walkway with three visual field conditions, namely dominant vision (DV), non-dominant vision (N-DV) and full vision (FV), while the balance control was quantified by inclination angles (IA) of the line joining the body's centre of mass (COM) and centre of pressure (COP), and the rate of change of IA (RCIA) [2]. Spatial-temporal parameters, namely walking speed, cadence, step length, stride length and stride width, were also calculated. Comparisons of all the calculated variables between test conditions were performed using paired t-tests with a significance level of 0.05.

RESULTS AND DISCUSSION

Compared to the FV condition, the elderly walked with increased step length, step width and cadence for the DV condition (Table 1). Similar gait patterns were found for the N-DV condition, except for increased walking speed but decreased stride length (Table 1).

Table 1: Means (standard deviations) of the temporal-spatial parameters in the elderly for all vision conditions. P_{DV} = DV vs. Control; $P_{N\text{-}DV}$ = N-DV vs. Control; P_S = DV vs. N-DV; *: $p < 0.05$.

Parameters (unit)	Conditions			P-Value
	DV	N-DV	Control	P_{DV}, $P_{N\text{-}DV}$, P_S
Walking Speed (mm/s)	1071.4 (62.0)	987.1 (103.6)	958.8 (106.4)	0.29, 0.01*, 0.01*
Stride Length (mm)	1090.6 (30.0)	1033.0 (34.3)	1047.4 (39.3)	0.09, 0.01*, 0.01*
Step Length (mm)	545.5 (15.5)	543.8 (16.1)	526.6 (20.7)	0.01*, 0.01*, 0.36
Step Width (mm)	95.0 (25.8)	92.7 (25.3)	77.8 (27.6)	0.01*, 0.02*, 0.33
Cadence (step/min)	117.2 (5.2)	117.2 (5.1)	109.8 (10.0)	0.01*, 0.01*, 0.95

For the IA-related and RCIA-related variables, differences in between-condition comparisons were found in the sagittal plane but not in the frontal plane (Fig. 1). The elderly showed increased sagittal IA during single limb support (SLS) but decreased sagittal RCIA at contralateral heel-strike (CHS) and the first peak value during terminal double limb support (tDLS) for the N-DV condition when compared to the FV condition (Fig. 1A and B). Compared to the DV condition, the elderly increased sagittal RCIA during tDLS for the N-DV condition (Fig. 1A and B).

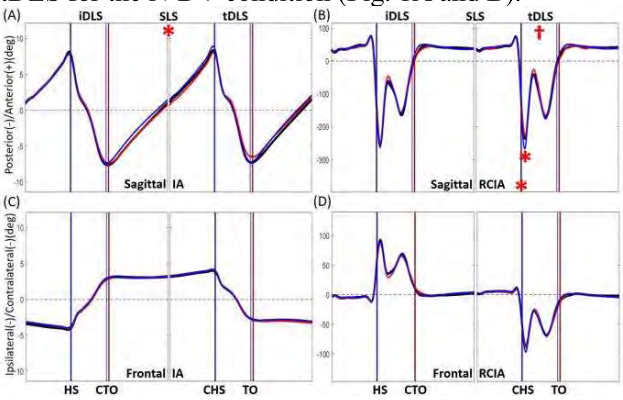

Fig. 1 Ensemble-averaged curves of COM-COP inclination angle (IA) and rate of change of IA (RCIA) in the sagittal plane and the frontal plane. TO: toe-off; HS: heel-strike; CTO: contralateral toe-off; CHS: contralateral heel-strike; iDLS: initial double limb support; SLS: single limb support; tDLS: terminal double limb support. Black line: Control; Red line: DV; Blue line: N-DV. *: N-DV significantly different from the Control; †: N-DV significantly different from DV.

CONCLUSIONS

The current study was the first in the literature to identify the effects of eye dominance on balance control in the elderly during walking. The results suggested that the elderly with non-dominant vision showed significantly compromised whole-body balance control strategies with altered COM-COP control – especially in the sagittal plane – that may lead to an increased risk of falling [2].

INTRODUCTION

Scoliosis affects physiological functions and appearance perception, which can cause pain and further deterioration in adolescent patients with severe deformities. Although it is common for the adult population to have some form of spinal deformity, only less than 10% of them are symptomatic [1]. This study aimed to identify the dynamic pattern of trunk and pelvis kinematics during obstacle-crossing in the asymptomatic scoliosis middle-aged population to further our understanding of the potential biomechanical changes which may assist in their clinical management to avoid surgery in later life.

METHODS

Eight middle-aged patients with asymptomatic scoliosis (SBC group) and eight healthy age-matched controls (Control group) participated in the current study with informed written consent as approved by the Institutional Research Board. Each subject walked at their preferred walking speed and crossed a height-adjustable obstacle (i.e., 10%, 20% and 30% of the subject's leg length). A counterbalanced measures design was used, while the sequence of the obstacle conditions was decided by a random number table. Three-dimensional marker trajectories were measured using an eight-camera motion capture system (Vicon 512, Oxford Metrics Group, UK) at 120 Hz, and the ground reaction forces (GRF) and the center of pressure (COP) were measured at 1080 Hz using two forceplates (AMTI, USA) placed on either side of the obstacle [2]. Angular motions of the trunk and pelvis during obstacle crossing were calculated. The crossing speed, cadence, stride length, and angular position of the trunk and pelvis were analyzed using a two-way mixed-design analysis of variance (ANOVA) with one between-subject factor (group) and one within-subject factor (obstacle height). Whenever a height effect was found, a polynomial test was used to determine the trend. All statistical analyses were performed using SPSS version 20 (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Compared to the Control group, the SBC group showed significantly slower crossing speed, shorter stride length, and lower cadence during obstacle-crossing (Table 1). In addition, the SBC group showed significantly increased pelvic and trunk posterior tilt during obstacle-crossing. With increasing obstacle height, both SBC and Control groups linearly increased their upper-body posterior tilt (Figure 1).

Table 1: Means (standard deviations, SD) of the crossing speed, stride length, and toe-obstacle and heel-obstacle distances in the patients with asymptomatic scoliosis (SBC) and healthy adults (Control) when crossing obstacles of 20% leg length (LL).

	SBC	Control	Group effect
Crossing speed (m/s)	1.03 (0.16)	1.33 (0.11)	p = 0.01*
Stride length (m)	1.27 (0.07)	1.41 (0.04)	p = 0.01*
Cadence (step/min)	76.38 (8.9)	93.21 (5.9)	p = 0.01*

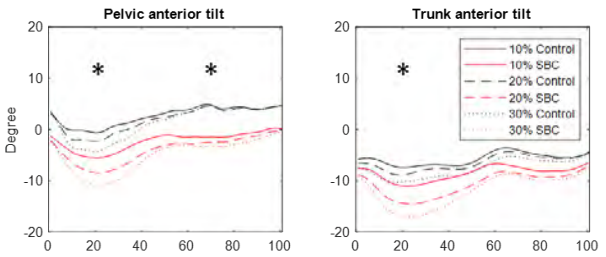

Figure 1: The mean curves of the angles of the pelvic and trunk in the sagittal plane in the SBC (red) and Control (black) groups when crossing obstacles of 10%, 20% and 30% of the leg length. * Significant linearly increasing trend.

CONCLUSIONS

Patients with asymptomatic scoliosis were found to develop a more conservative obstacle-crossing technique, i.e., with significantly greater posteriorly tilted upper body position. Further studies on the joint kinematics and kinetics of the locomotor system will be helpful for a better understanding of the different adopted mechanisms between the groups.

INTRODUCTION

In cerebral palsy (CP), neuromuscular function is abnormally developed, causing gait and postural impairments [1]. Reduced postural control and the resulting increased risk of falling might be caused by the inadequate interaction between sensory feedback and motor command when standing upright. The significance of sensory feedback can be tested by manipulating sensory sources and assessing their consequences on motor responses. [2]. A correlation between these responses and the extent of motor capacities, depicted from field tests, might give an insight into the causes of the impairment. This might refine diagnostic tests and treatments. Therefore, the purpose of this study was to investigate the neuromuscular responses while standing with sensory restrictions and to test if these responses are correlated with performance in field tests in children with CP and typically developed (TD) children.

METHODS

Nine children with CP (12.5±1.7 yrs, 147.3±0.5 cm, 46.1±0.8 kg) and 16 TD children (14.0±3.8 yrs, 161.2±1.2 cm, 54.8±0.9 kg) were evaluated in the field tests of 10 m walking at comfortable and maximum speed, 2- or 6-minutes walking (for CP or TD, respectively), and the time up and go test. Children with CP had 1.73±0.98 [mean±standard deviation (SD)] level of ankle spasticity, as evaluated using the average of the plantar and dorsiflexors score, based on the modified Ashworth's scale. All participants were asked to stand comfortably on a force platform, in four different sensory conditions: eyes open (EO) or eyes closed (EC), on a rigid (R) or foam (F) surface. The SD and velocity of the center of pressure (CoP) on the anterior-posterior and mediolateral direction, the trunk acceleration (TrA), as well as the root mean square of the soleus (SOL), gastrocnemius medialis (MG) and tibialis anterior (TA) muscles electromyogram (EMG), were recorded in three, 60-s trials, in each balance condition. The rate of change for ECR, EOF and ECF was expressed as the $\log_2$ ratio relative to EOR. A linear mixed model was used to compare the differences between conditions, groups, and interaction. The correlation between the variables was examined with the Pearson's r, whereas Spearman's rho was calculated when normal distribution was not granted.

RESULTS AND DISCUSSION

Children with CP demonstrated overall lower performance in all field tests compared to TD children. Both SD and velocity of CoP and TrA demonstrated greater values for the children with CP than TD children, in all four conditions. However, the rate of change was greater in TD children, indicating a ceiling effect for the values of children with CP, probably because they demonstrated great values even at EOR condition. However, no variable regarding CoP and TrA or the rate of changed compared to EOR was correlated to any of the field tests. Regarding the EMG, although GM and SOL increased in ECR, EOF and ECF conditions compared to EOR in both groups, the extent of these changes did not correlate with the performance in any of the field tests.

CONCLUSIONS

The current findings indicate that the adaptations during sensory restrictions from visual (i.e., eyes closed) and proprioceptive (i.e., foam) sources may not reflect motor capacity of children with CP and TD children in complex balance tasks, characterized by changes in sensory flow during the completion of the task. Accordingly, changing the input from other sensory sources (e.g., vestibular) or in a different manner than in the current study (e.g., changing the proprioceptive input by means of local tendon vibration), may highlight possible links between physical performance and sensory feedback in CP.

INTRODUCTION

Duchenne muscular dystrophy (DMD) is a genetically defective and lethal neuromuscular disorder characterized by severe and progressive muscular weakness. Muscular weakness in the lower limbs contributes to altered kinematic patterns and with ~~unstable~~ balance disturbances during gait ~~in patients with DMthatD~~ subsequently leading to increased risk of falls ~~, increasing the risk of falls~~ [1]. However, difficulties still exist in synthesizing this kinematic and kinetic information to reveal the underlying dynamic stability control in patients with DMD during gait. Therefore, this study aimed to develop a novel balance evaluation method based on a bi-planar inverted pendulum model with measured gait data to quantify the dynamic stability in patients with DMD during the single limb support (SLS) phase.

METHODS

Fifteen patients with DMD and fifteen healthy controls were recruited in this study. Each subject walked at a self-selected pace on an 8-m walkway while the kinematic and kinetic data were measured. A bi-planar inverted pendulum model based on Pai and Patton [2] was used to determine the feasible stability region on the phase portrait between the joint angle and angular velocity of the stance ankle. The magnitude of the stability margin index (SMI) was defined as the Euclidean distance between the measured gait data and the edge of the corresponding feasible stability region. The negative sign of SMI signified that the feasible stability region was violated, meaning that the subject was dynamically unstable at the corresponding instant. A segmented least squares regression fitted between the joint angle of the stance ankle and SMI during SLS was used to estimate the joint angle of the stance ankle and corresponding SMI at the initial instant, the intersection instant and the terminal instant, and the change in SMI between each two instant (Figure 1). Comparisons of all the calculated variables between patients with DMD and healthy controls were performed using independent t-tests with a significance level of 0.05.

RESULTS AND DISCUSSION

For all calculated variables, differences in between-group comparisons were found in the frontal plane but not in the sagittal plane (Figure 1). Compared to the healthy controls, patients with DMD walked with significantly decreased frontal SMI at the initial and intersection instant (Figure 1B) but similarly at the terminal instant. These results suggested that patients with DMD showed significantly compromised whole-body balance control strategies with altered COM-ankle control in the frontal plane which may ~~lead to an~~partially contribute to increased risk of falling.

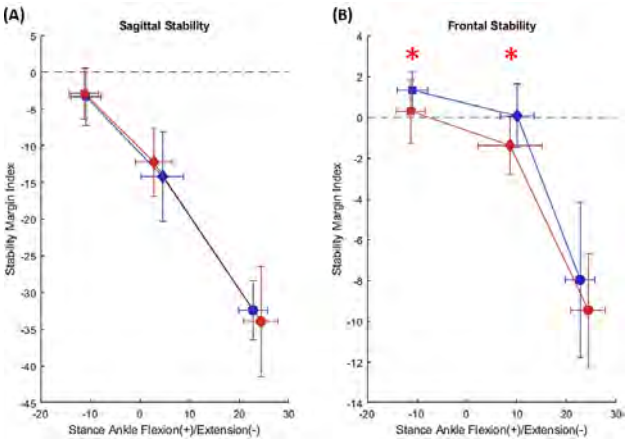

Figure 1 Comparisons of the joint angle of the stance ankle and corresponding SMI at the initial instant, the intersection instant and the terminal instant in (A) the sagittal plane and (B) the frontal plane during level walking with the corresponding standard deviations shown as error bars. ■: initial instant; ◆: intersection instant; ●: terminal instant (red: DMD; blue: Control). *: DMD significantly different from Control.

CONCLUSIONS

This study was the first in the literature to develop a quantifiable~~ied~~ balance evaluation method based on an inverted pendulum model to evaluate the dynamic stability control in patients with DMD during SLS. The current results showed that patients with DMD have a higher risk of falling in the medial-lateral direction during the early stage of SLS due to altered COM-ankle control in the frontal plane.

MUSCLE-TENDON BIOMECHANICS AND DAILY STEPS IN PATIENTS RECOVERING FROM ACHILLES TENDON RUPTURE

Taija Finni, Maria Sukanen, Iida Laatikainen-Raussi and Raad Khair
[1] Faculty of Sport and Health Sciences University of Jyväskylä, Finland.
Email:taija.finni@jyu.fi

INTRODUCTION

Achilles tendon rupture (ATR) results in long term functional deficits characterized by longer and thicker tendon, muscle atrophy and weakness, and decreased heel-rise performance in the injured limb [1]. Rehabilitation exercises are important for recovery, but in addition to spesific rehabilitative measures also daily physical activity may be relevant for the time course of recovery. We examined and expected to find associations between the daily steps at 2, 6 and 12 months, and biomechanical factors at 12 months post rupture.

METHODS

Data was extracted from a clinical cohort study "non-operative treatment of Achilles tendon Rupture in Central Finland: a prospective cohort study – NoARC" (trail registration: NCT03704532) Recruitment and treatments are described in detail in [2]. The number of patients measured at 12 months (m) was 45, but due to missing data, 15 is the minimum number of participants in some correlations.

At 12m, bilateral measures of isometric plantarflexion strength (MVC), medial gastrocnemius (MG), lateral gastrocnemius (LG) and soleus (SOL) subtendon lengths, MG fascicle length, MG and LG muscle cross-sectional area, tendon stiffness and ankle joint resting angle were assessed as described in [2]. MG fascicle operating range during heel rise was assessed. From all variables, limb asymmetry was calculated as ((healthy-injured)/healthy)*100 and used in analysis.

At 2m (N=24), 6m (N=22) and 12m (N=35), the patients were given 3D accelerometers (RM42, UKK Institute, Finland) that were to be worn on hip on 7 consecutive days. Wear time was to be marked on a diary. Step counts were analyzed based on algorithms of Actilife-software. Recordings with at least 3 days and 10 hours of good data were included in the analysis. Mean daily steps from the recording period and daily minimum and maximum step counts were extracted.

Repeated measures ANOVA was used to check the differences in daily steps across time and two-tailed Pearson's correlations were calculated between step variables and biomechanical variables at 12m.

RESULTS AND DISCUSSION

Mean daily step count (N=15) increased ($p<0.001$) from 4824±1331 at 2m to 8389±2706 at 6m and remained similar at 12m being 8240±2902. Maximum step count at 2m correlated with average step count at 6m ($r=0.651$, $p=0.006$) and maximum step count at 6m correlated with average step count at 12m ($r=0.507$, $p=0.022$).

Associations between step data and biomechanical variables at 12m were found only between LG subtendon length asymmetry and mean daily steps at 2m ($r=-0.529$, $p=0.024$, N=18, Figure 1).

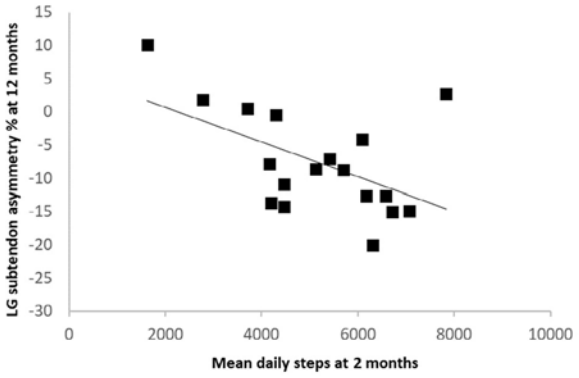

Figure 1 The only significant association found between daily steps and biomechanical variables examined at 12m.

CONCLUSIONS

Maximum daily step count associates with average step count at a later time point suggesting that step count of the most active day may reflect future potential for increased physical activity. The one association found between biomechanical variables and step counts should be interpreted carefully since it may be a chance finding. However, the observation warrants for further studies whether too much daily steps in the early rehabilitation phase could have negative influence on tendon elongation.

INTRODUCTION

Knee osteoarthritis (KOA), one of the most common degenerative knee diseases, is related to the fibrosis of the infrapatellar fat pad (IFP) in its pathomechanism [1]. Recently, it has been suggested that the IFP fibrosis involves HIF-1α activation induced by hypoxia [2]. In young healthy subjects, the IFP stiffness changes occurred during the isometric quadriceps exercise (IQE) and the close relationships between this change and the oxygenation in the IFP was suggested [3]. However, it is unclear whether similar results can be obtained in the KOA. This study aimed to elucidate the characteristics of KOA patients with respect to IQE-induced changes in IFP stiffness and hemoglobin concentration.

METHODS

Eighteen knees of 9 patients with a bilateral KOA were included in the KOA group (mean age, 70.3±7.6 years; 9 females). The control group consisted of 18 knees of 9 healthy volunteers without a history of surgical treatment, trauma, or neurological disorder (mean age, 31.1±7.1 years; 4 males, 5 females). The IFP stiffness was measured during the IQE and then hemoglobin concentration in the IFP before, during, and after the IQE. The measurement limb position is the long sitting position, and the IQE is performed by pressing the manchette of the sphygmomanometer pressurized to 100 mmHg placed in the popliteal space. Exercise intensity was set at 10% of the maximum IQE. The IFP stiffness was measured based on the shear wave velocity at using ultrasound scanner with a 18 MHz linear transducer. The region of interest was set within the IFP, and measured at rest and 10% IQE. The hemoglobin concentration was measured using near-infrared spectroscopy. The modified Beer-Lambert method was used to calculate oxygenated hemoglobin (O2Hb) and deoxygenated hemoglobin (HHb), and the sum of the two, total hemoglobin (cHb). The exercise task was performed 10 times with one set of 10% IQE for 10 seconds and a 3-second rest. Measurement value before the IQE (Pre) was recorded as the mean resting value at 1 min before the IQE, those during, the mean minimum value of 10 times, and those after the IQE (Post), the mean resting value 3–4 min after the IQE. Two-way ANOVA was performed for the IFP stiffness in Group (KOA, control) and exercise task (rest, IQE), and repeated measure ANOVA for hemoglobin concentration in Group (KOA, control) and timing of measurement (pre, IQE-t, post). Multiple comparison procedures were used for post hoc comparisons. All significance level was set at $p<0.05$.

RESULTS AND DISCUSSION

The IFP stiffness significantly increased during the IQE in control (Table 1, Pre vs IQE; 1.3±0.2 m/s vs 3.4±0.5 m/s, $p<0.001$), but did not significantly change in the KOA (Table 1, Pre vs IQE; 2.3±0.6 m/s vs 2.9±1.1 m/s, $p=0.23$). With regard to the hemoglobin concentration in IFP, the O2Hb significantly increased after the IQE compared to pre-IQE in both group, but the O2Hb after the IQE was significantly higher in the control than in the KOA (Table 1, Control vs KOA; 3.4±1.6 mol/dl vs 0.8±1.6 mol/dl, $p<0.001$). Repeated changes in the IFP stiffness by the IQE may improve the IFP hypoxia through capillary compression and release. Therefore, it was suggested that the KOA obtained oxygenation by the IQE, but to a lesser degree than the control due to the insufficient increase of the IFP stiffness by the IQE.

CONCLUSIONS

The KOA showed less change in IFP stiffness and hemoglobin concentration during IQE than the control .

INTRODUCTION

Prolonged lumbar flexion is thought to cause creep of the passive tissues of the spine [1]. As a result, spinal stability is reduced, which may make the lumbar region more vulnerable to external stress when high exertion is required immediately after prolonged bending postures such as lifting loads. However, it is unclear whether the creep of spinal passive tissues due to prolonged lumbar flexion affects lifting.

Previous studies have suggested that the upper and lower lumbar spine move differently, and understanding spinal kinematics requires analysis of multiple segments [2]. Additionally, increased flexion angles lead to increased shear forces [3]. Therefore, understanding the spinal flexion angle changes due to spinal passive tissue creep during lifting in multiple segments is important for low back pain (LBP) prevention.

Therefore, this study, the effect of twenty minutes of full lumbar flexion on lifting was examined in multiple segments.

METHODS

The subjects were 10 healthy men with no history of LBP and a body mass index below 25.

The creep protocol consisted of sitting on a platform and performing lumbar forward bending for twenty minutes. Lifting movements were performed in knee joint extension (Stoop method), and the weight of the box to be lifted was 10% of the body weight. Measurements were taken from the time the box was grasped until the patient stood completely upright.

The data measurement method used was a 3D motion capture system and a force plate to obtain kinetics and kinematics data. Spinal markers were affixed 4 cm lateral to Th7 and L1, and L4, and on the spinous processes of Th3, L3, and L5 to define segments. The flexion angle was defined based on the position of the upper segment relative to the lower segment (Figure 1). The distributions of all continuous variables were examined using the Shapiro-Wilk test. Paired t-tests were performed for continuous values following a normal distribution and Wilcoxon rank sum tests for non-normally distributed data variables. The null hypothesis was rejected at $p < 0.05$.

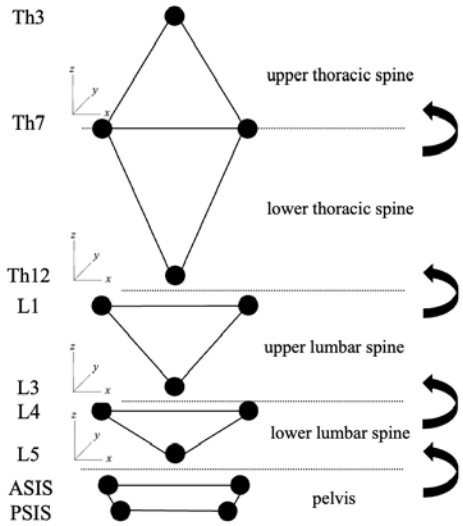

Figure 1 The position of the spinal marker position and the definition of the segment

RESULTS AND DISCUSSION

The spinal flexion angle during lifting after creep was found to increase predominantly in the lower lumbar spine and upper lumbar spine (before creep protocol: 15.87 ± 6.27°, after creep protocol: 16.76 ± 6.32, $p < 0.05$) and upper lumbar spine and lower thoracic spine (before creep: 18.39 ± 7.16°, after creep: 19.04 ± 7.19 °, $p < 0.05$). Spinal passive tissue creep from twenty minutes of lumbar flexion was found to increase the maximum flexion angles of the lower lumbar spine and upper lumbar spine and upper lumbar spine and lower thoracic spine during lifting.

CONCLUSIONS

Attention should this indicates that attention should be paid to the movements between the lower lumbar spine and upper lumbar spine and between the upper lumbar spine and lower thoracic spine when considering the prevention of LBD by creep.

INTRODUCTION

Velopharyngeal closure plays a crucial role in oral and maxillofacial functions including speech and swallowing. It is known to be a complicated coordination of the muscles in the soft palate and pharynx. Although velopharyngeal closure patterns varied based on individuals, it was reported that normal velopharyngeal closure for speech can be classified into four distinct patterns. The reported typical 4 patterns are coronal, circular, circular closure with the Passavant ridge, and sagittal closure. However, it is not clearly reported whether one of the patterns can be changed into other patterns when the anatomic or physiologic changes occurs through practice or prosthetic treatment, although it was suggested that several factors such as learning capability and anatomical variations can have influence on that.

As velopharyngeal closure is three-dimensional mechanism and occurs in the area that is hard to be observed, current methods evaluating velopharyngeal closure can have limitations. Using three-dimensional computer simulation, the whole velopharyngeal mechanism can be easily observed and it is possible to investigate exact muscle coordination for normal swallowing. In addition, it can be found that the necessary change of muscle activation after morphologic alteration, the influence of different levels of muscle activation with same anatomical structures, and the possibility of changing closure patterns.

The purpose of the study was to analyse the action of muscles related to velopharyngeal closure and the influence of the muscle activation during velopharyngeal closure.

METHODS

A three-dimensional model for computer simulation was developed. The images from Visible Korean Human Project were used for the development of the model. The data were made of a Korean male in his sixties. The segmentation for the model was done using a segmentation software. The mandible, masticatory muscles, hyoid bone, soft palate and pharynx were included. After segmentation, the morphological data were sent to ArtiSynth which is a three-dimensional biomechanical modelling platform.

In Artisynth model, bones were regarded as rigid bodies and soft tissues were made of finite element materials. The directions of muscles based on the anatomy were defined and set in the artisynth model.

Data on muscle activations and material properties of the structures from the previous studies were used. After normal velopharyngeal closure was performed by muscle activations, alterations of velopharyngeal pattern were tried by changing activation level of muscles without morphological change in the muscles.

The changes in the muscle activation were as follow.

Table1: muscle activation changes during simulation

Situation\muscle activation	Levator Veli Palatatini muslce	Uvular muscle	Superior pharyngeal constrictor muscle	Palatoglossus muscle	Palatopharyngeal muscle
Normal closure	0.3 N	0.3	0.3	0.3	0.3
Soft Palate Defect	0	0	0.3	0.3	0.3
Soft palate defect muscle control	0	0	0.6	0.3	0.3

RESULTS AND DISCUSSION

With computer models velophayngeal closure could be performed. When there is a soft palate defect situation, by increasing force of superior pharyngeal constrictor muscle, the velophagyngeal closure was enhanced.

Continuation of the use of obturator prosthesis would strengthen the muscles of pharyngeal muscles including superior pharyngeal constrictor and it would contribute the velopharyngeal closure.

CONCLUSIONS

The impact of muscle activation on velopharyngeal closure was analyzed using computer simulation. It was revealed that enhancing the force of the superior pharyngeal constrictor muscle can improve velopharyngeal closure, and that continue use of obturator prosthesis may further improve the defect situation.

INTRODUCTION

Maxillary defects are very common in clinical practice due to the surgical management of oral and maxillofacial lesions, trauma, and congenital malformations. Prosthetic rehabilitation can enhance the quality of life of maxillary defect patients with the fulfillment of their functional, speech, and aesthetic needs as well. However, partially edentulous maxillectomy dental arches are quite different from normal partially edentulous dental arches in terms of support and stabilization [1]. Moreover, massive maxillary defects have a negative impact on both the biomechanics of the obturator prostheses and the biomechanical response of the supporting tissues [2]. Aramany class VI defect is a defect that lies anterior to the remaining abutment teeth, and the prosthetic management of this kind of defect is quite difficult. To the best of our knowledge, there are no studies about the biomechanical analysis of obturator prostheses in class VI maxillary defects. The purpose of the study was to evaluate the biomechanical effects of an Aramany Class VI obturator prosthesis in comparison to a removable partial denture (RPD) prosthesis.

METHODS

A basic 3D geometric skull model, including the maxilla and teeth, was developed based on the CBCT data of a female volunteer using modeling software. An Aramany class VI defect extending from the right first premolar to the left first premolar was created with this basic model. A partially edentulous maxillary model with the same missing teeth but without a bone defect was also created as a control model. For the virtual fabrication of splinted surveyed crowns, remaining abutment teeth were prepared after 3D printing. A maxillary obturator prosthesis and a RPD prosthesis were virtually constructed for respective models in a similar framework design. Tetrahedral meshes of all the components in each model were generated using the Visual-mesh program. A static load of 100 N was applied to the marginal ridges of incisors and canines as well as the triangular ridges of the buccal and palatal cusps of the premolars of the prosthesis in a 45° oblique direction to stimulate masticatory forces. The analysis was processed using the Visual-Crash software. The maximum von-Mises stress and displacement values were analyzed and compared for each component of the models.

RESULTS AND DISCUSSION

Concerning biomechanical stresses on the prostheses, the metal framework of the obturator prosthesis did not exhibit greater maximum von-Mises stress values than that of the RPD prosthesis, showing the values of 216.3 MPa for the obturator model and 315.9 MPa for the RPD model. The maximum stress values of the PMMA resin surface were presented at 4.3 MPa, similarly, for both models. Moreover, the maximum stresses on the surveyed crowns of each model were almost the same (149.4 MPa on the right side and 93 MPa on the left side in the obturator model, and 154.2 MPa and 99.4 MPa, respectively, in the RPD model). Regarding the biomechanical response of the supporting tissues, the maximum von-Mises stresses on the periodontal ligament of the remaining teeth were significantly greater in the obturator model (about 20 times) compared to the RPD model. In addition, the obturator model showed greater maximum displacement values of the remaining abutment teeth than that of the RPD model. Moreover, the prosthesis displacement distribution pattern of each model was also significantly different (Figure 1). However, the stresses on the remaining bone were not greater in the obturator model than in the RPD model.

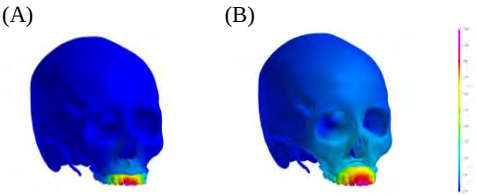

Figure 1: Prosthesis displacement distribution pattern of (A) RPD model (control model); (B) obturator model (experimental model).

CONCLUSIONS

Within the limitations of the study, it can be concluded that the Aramany Class VI obturator prosthesis had a significant biomechanical impact on the remaining abutment teeth rather than on the bone or the prosthesis itself. Therefore, special attention should be paid to the prosthesis framework design and the maintenance of the supporting dental tissues for the long-term prognosis of the obturator prostheses in the prosthetic rehabilitation of maxillary defect patients.

INTRODUCTION

Many patients who come to dental hospital has short clinical crown due to physical trauma or severe attrition. Even the clinical crown length of targeted tooth is short, dentist have to make the definitive prosthesis as its original state for esthetic and functional reason. Therefore, after finishing the endodontic treatment, clinician has to decide whether to do the post & crown before the definitive prosthesis, or not. The aim of this study is to evaluate the effect of post and core in maxillary lateral incisor with short clinical crown. The null hypothesis is that the post and core treatment will increase the physical strength and retention of the definitive prosthesis.

METHODS

Two three-dimensional finite element models of maxilla, lateral incisor and the adjacent teeth were developed. RCT(root canal treatment) model was composed of the maxillary bone, endo-treated maxillary lateral incisor with definitive prosthesis. Post & crown model was composed of the maxillary bone, endo-treated maxillary lateral incisor with post & core and definitive prosthesis. PDL spaces, and cement spaces were also developed.

Figure 1. configuration of RCT model(left), and Post & core model (right)

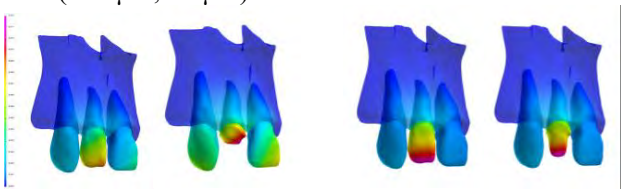
Oblique loading of 50N that simulated occlusal force was applied to the definitive prosthesis of each model. The stress distribution patterns and the maximum von-Mises stress value(MPa), maximum displacement values(μm) of the individual components were compared.

RESULTS AND DISCUSSION

In the supporting alveolar bones, stress was concentrated in the cortical bone at the labial of cervical area of #12. The highest von-Mises stress in the cortical bone for RCT model was 14.1, MPa and 7.2 MPa for post & core model.

In tooth #12, the highest von-Mises stress in ceramic crown turned out to be 8.4 MPa in RCT model, and 8.2 MPa in post & core model, and both at the mesial of the marginal ridge of incisors. The highest von-Mises stress for dentin were 5.2 MPa for RCT model, and 3.6 MPa for post & core model, and both at the labial cervical area. In the PDL space around tooth #12, the highest von-Mises stress turned out to be 0.1 MPa for RCT model at the apex, and 0.2 MPa for post & core model at the palatal or cervical area. Additionally, for ceramic cement layer, the highest von-Mises stress was 5.7 MPa for RCT model, and 4.3 for post & core model at the labial of cervical area. The highest von-Mises stress of resin part of tooth #12 for RCT model was 2.2 MPa at the bottom. The highest von-Mises stress of post cement layer and post & core of tooth #12 for post & core model were 2.2 at the middle of the post, and 0.9 at the palatal of middle of the post, retrospectively.

Displacement value of ceramic crown for RCT model (11.9μm) was higher than that of post & core model (6.7μm), also for cortical bone(3.2μm, 1.6μm) and GP cone(10.3μm, 0.6μm).



(A) (B)

Figure 2. Displacement pattern of RCT model(A), and post & core model(B)

CONCLUSIONS

This study evaluated the effect of post & core in short clinical crown on the maximum von-Mises stress value and maximum displacement value. Generally, both value was higher in RCT model.

INTRODUCTION

The number of edentulous patients have been continuously increasing. This is due to a globally upward trend in the elderly population, likewise resulting to considerably increasing demands for prosthodontic treatments [1]. Dental clinics have commonly used complete and partial denture prostheses in order to restore patients' oral health, mastication, and improve their quality of life. In mastication, these complete dentures play a critical role in distributing occlusal loads to the underlying mucosa and residual ridge over a large denture-tissue supporting interface [2]. The purpose of this study was to analyse the stresses generated in the mandible of complete denture prosthesis wearers and their corresponding effects.

METHODS

Three-dimensional finite element models were made of the mandible, mucosa, denture base and denture teeth using CT, DICOM and STL data. The models were fabricated via a mesh generation software (Visual-Mesh; ESI Group). Six models were developed with differing load directions [vertical and oblique (45°)] and static loads (50 N, 100 N and 150 N) respectively. The loads were distributed to the posterior teeth: the buccal slope of the buccal cusp, the lingual slope of the buccal cusp, and the buccal slope of the lingual cusp, respectively [1]. Maximum von Mises stress and displacement values were then compared and analyzed. All materials used were assumed to be linear, homogeneous, and isotropic. Finite element analysis was done with a modelling software (Visual-Crash for PAM, Visual-Viewer; ESI Group) (Figure 1). In order to prevent dislodgement of models during simulation, all nodes of bone surfaces in the models were bounded in all directions: condylar head, insertions of temporalis, masseter, and medial pterygoid muscles.

RESULTS AND DISCUSSION

The maximum von Mises stress (mPa) results of the six models are summarized at Table 1. It can be observed that stress load towards the residual ridge is directly proportional to the maximum stress values (MPa) received. Conversely, no significant differences were found in the mucosa, denture teeth and denture base respectively, except for 50 N with vertical loading at 1.30 MPa. These positive stress values can be correlated to alveolar bone resorption based on several previous studies. In addition, the maximum displacement values (μm) on mucosa at vertical - 100 N and 150 N were 20.10 and 36.90; oblique - 100N and 150 N were 37.6, 41.7 respectively. The results showed that stress load is directly proportional to the extent of mucosal displacement. These values are significant for further assessment of denture stability and pain perception.

Table 1: Maximum von Mises stress values (MPa) of different components of the models.

Part	Load Direction	50 N Load (MPa)	100 N Load (MPa)	150 N Load (MPa)
Cortical bone	Vertical	0.40	3.80	8.10
	45°	0.10	4.40	4.50
Mucosa	Vertical	0.05	0.05	0.05
	45°	0.05	0.05	0.05
Denture teeth	Vertical	4.20	4.30	4.30
	45°	4.30	4.30	4.30
Denture base	Vertical	1.30	4.19	4.30
	45°	3.70	4.30	4.30

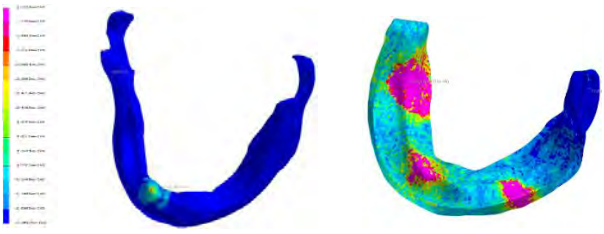

Figure 1 Stress concentration areas on the mandibular cortical bone and mucosa with 150 N vertical load.

CONCLUSIONS

The present study demonstrated that complete denture prostheses may translate mucosal displacement and induce stresses to the bone which may lead to resorption. This represents the first phase of research to evaluate the stress loading in the mandible that can help further studies to expand and consider anisotropic properties of tissues, and accuracy of denture teeth models and masticatory behaviors.

INTRODUCTION

Anterior cruciate ligament (ACL) deficiency (ACLD) is a common injury in the sports crowd. The ACL plays an important role in maintaining the stability of the knee joint. The clinical diagnosis of ACLD is complex and expensive, and the diagnostic process requires the subjective judgment of clinicians. For auxiliary diagnosis, many studies have used statistics to study the gait in ACLD [1]. Regardless of the statistical method used, feature selection is the most important variable. With the help of musculoskeletal models, the kinematics and dynamics in ACLD-affected knees can be used as statistical features [2]. This study was performed to identify patients with ACLD through a composite index that combined kinematics and muscle forces.

METHODS

Twenty-five male patients with unilateral chronic ACLD (the contralateral side was intact) were recruited before ACL reconstruction (ACLD group). A control group comprising nine healthy male volunteers with no history of musculoskeletal injury or surgery in the lower extremities was selected (Control group). The experimental 3D data were collected while the patient was jogging using an optical motion capture system. For each participant, five successful jogging trials were recorded, and these results were imported into multi-body dynamics software, AnyBody Modeling System. A composite index containing the data of the knee flexion and muscle forces' characteristic points, which were the time points in the gait cycle when the most significant difference was observed between the two groups, was used in this study. The selection method of the characteristic points is shown in Figure 1 (using the vastus as an example). Comparing the ACLD and Control groups based on knee flexion and muscle force data for all participants, t-tests were performed at each point during a 0–100% gait cycle. The data of the characteristic points ($p < 0.05$ and p values were minimal) were finally filtered out as a matrix to calculate the composite index. Finally, the matrix was processed using principal component analysis to select features.

RESULTS AND DISCUSSION

A multivariable linear regression model using the composite index was developed to predict, with 79.1% accuracy, whether participants had ACLD. The positivity determined the grouping. Both of the features were significant at the $p = 0.001$ level by the t-test. The

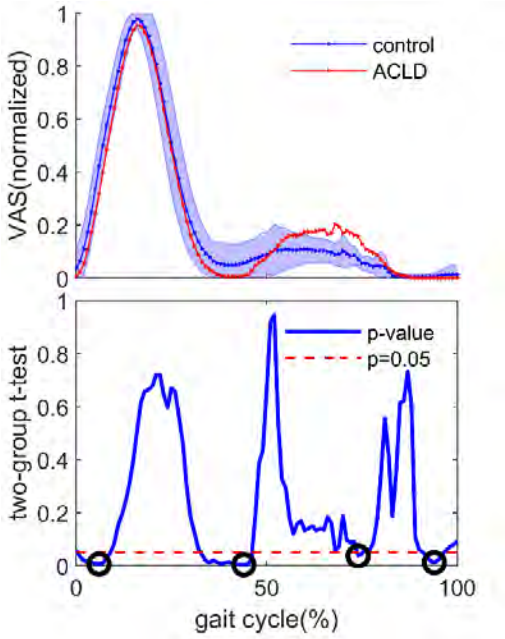

Figure 1 Extraction method of characteristic points (taking the muscle force of vastus as an example). Average force and error band of muscles are shown on the top. P values are shown on the bottom. The black circle is the selected characteristic point.

coefficients for the two features were −1.5504 and −1.6218, respectively. Two hypothetical subjects from the ACLD and Control groups had feature values close to the mean of their respective groups. Their expected final regression results were 0.5458 and −0.3690, which were clearly classified into the two groups. The subject values from the features generated by the composite index were −0.1490, −0.0937 for the ACLD group and 0.2069, 0.1301 for the Control group. It was noteworthy that the subject values of the two groups also differed in the positivity and negativity, verifying the validity of the composite index in the regression model and proving that using only the composite index is also a successful evaluation index.

CONCLUSIONS

The composite index and characteristic points can be used to extract effective information more quickly and conveniently for diagnosis.

INTRODUCTION

Degenerative musculoskeletal disorders account for large proportion of the adult population with several cases of work inability, temporary disability and probable early retirement. OA is a degenerative joint disease that leads to chronic pain and disability thus restricting physical functioning and their ability to perform activities of daily life[1]. Among the activities of daily life, walking is considered to the most important one[2]. This study, thus attempts to quantify the degree of association between the knee joint health and the kinematics of pelvis and plantarpressure variables.

METHODS

The Study includes 3 healthy subjects and 3 OA subjects. The healthy subjects have mean age of 27 and the OA patients are of a mean age of 66.33. All three subjects are suffering from bilateral advanced knee OA and are of grade 2 or higher as per the Kellgren-Lawrence (K/L) system. The healthy subjects have no history of musculoskeletal disorders. The study is approved by the Institute Human Ethical Committee (IHEC), IIT Guwahati. Gait of the subjects is recorded using a wearable sensor and a Pressure Mat in Gait & Motion Analysis Lab, IITG as shown in Figure 1(a).

Figure 1 Data collection in (a) Gait & Motion Analysis Lab using (a)Wearable Sensor (b) Pressure Mat.

The wearable sensor captures the right and left pelvis angles in three directions during normal walking as shown in Figure 1 (b) and the trunk flexion extension angle during Timed Up and Go (TUG) experiment. In addition, the plantar pressure of the subject while walking has been captured using the Pressure Mat as shown in Figure 1(c). The parameters obtained from the experiment includes the time from TUG test, pelvis angle in three planes and the trunk flexion extension as kinematic variables and gait line length, plantar pressure data of the foot divided in three sections namely forefoot, midfoot and heel as kinetic variables.

RESULTS AND DISCUSSION

The pelvis and trunk angles were recorded with respect to the gait cycle percentage. Thus, mean, and standard deviation (SD) of the pelvis angle and trunk angle were used for comparative analysis along with the kinetic variables for the distinction between healthy subjects and subjects with knee OA. The degree of correlation between the knee health and the kinematic and kinetic variables are quantified using the Point biserial correlation (r_{pb}) as shown in Table 1. It can be observed that except for mean values of Pelvis Obliquity left and Pelvis rotation right, all the mean and SD parameters have negative r_{pb}. The negative r_{pb} for the SD parameters indicates the reduced mobility in all the directions. The kinetic variables also have negative correlation which is supported by the negative r_{pb} value of Gait line, thus indicating reduced foot contact time.

Table 1: r_{pb} relating health status and gait variables.

Variables		r_{pb}	
		Left	Right
Pelvis Tilt	Mean	-0.66	-0.66
	SD	-0.62	-0.61
Pelvis Obliquity	Mean	0.87	-0.67
	SD	-0.46	-0.54
Pelvis Rotation	Mean	-0.43	0.16
	SD	-0.82	-0.87
Gait Line		-0.49	-0.4
TUG		0.78	
Forefoot	Force	-0.73	-0.59
	Pressure	-0.37	-0.42
Mid Foot	Force	-0.44	-0.52
	Pressure	-0.56	-0.53
Heel	Force	-0.81	-0.53
	Pressure	-0.59	0.09

CONCLUSIONS

The negative r_{pb} of the SD of kinematic variables is a direct indication of the reduced mobility in the pelvis due to degradation in the knee health. This has also reduced the load taken by the foot as evident by the negative r_{pb} for both the force variables and gait line. Thus, it can be inferred that knee health greatly affects the kinematic of the pelvis and the plantar pressure parameters and thus have a high degree of association. Thus, these parameters can act as biomarkers of assessing knee health.

Knee Joint Moments Calculated Using Markerless Motion Capture Can Distinguish Osteoarthritis Severity During Walking Gait

Jereme Outerleys[1], Anastasija Mihic[1], Jacob Calderone[1], Vajra Keller[1], Elise Laende[1] and Kevin Deluzio [1]

Email: Jereme.Outerleys@Queensu.ca

INTRODUCTION

Joint loading patterns of the knee in the frontal and sagittal planes can discriminate knee osteoarthritis (OA) severity[1,2], have been linked to disease progression[3], and are targets for treatment. Joint moments are typically calculated using inverse dynamics with kinematic inputs from marker-based motion capture. Recent advances in markerless motion capture technology can measure kinematics that show high agreement with marker-based data with improved inter-session repeatabilty[4]. Reduced clothing constraints and shorter collection times associated with markerless methods are clear advantages for large-scale and longitudinal clinical investigations. The objective of this study was to investigate whether knee joint moments calculated using kinematic inputs from markerless motion capture can distinguish knee OA severity.

METHODS

Subjects were recruited from an orthopaedic clinic. Knee OA severity was determined clinically by advanced practice physiotherapists. Subjects with severe and moderate medial knee OA were included, yand a group of asymptomatic controls. Subjects walked back and forth across a 10m-walkway embedded with 4 force plates (AMTI, 1200 Hz) for 60s at self-selected walking speed in their own clothing and footwear. Video data were captured by 8 cameras (OptiTrack, 1080p, 60 Hz) digitally synchronized with force data. A calibration chessboard placed in a known location relative to each force plate aligned video and force coordinate systems. Video data were processed using Theia3D (Theia Markerless, v2021.3.02047) to obtain 3D kinematics from an inverse kinematics model with 3 degrees of freedom at the ankle, knee, and hip. The data were lowpass filtered at 8 Hz for kinematics and 50 Hz for force. Inverse dynamics was used (Visual3D, v2023.02.1) to obtain internal knee flexion and adduction moments resolved in the joint coordinate system and normalized by body mass. Moments were time normalized to stance phase and ensemble averaged over at least 3 strides. Principal component analysis extracted the first two modes of waveform variability[1] (PCs), and ANOVAs with post-hoc comparisons (Tukey HSD) were used to test for differences across severity in PCs and gait speed ($\alpha < 0.05$).

RESULTS AND DISCUSSION

Forty-two subjects were included in the analysis (24 severe, 10 moderate, 8 control). Groups were well matched in age (Table 1). PC1 captured overall waveform magnitudes while PC2 captured the difference between early and late stance. A severity effect was detected in PC2 for both the knee flexion and adduction moments (Table 1). The severe and moderate groups had stiffer flexion moment patterns compared to controls (Figure 1). The severe group also displayed a more sustained adduction moment pattern compared to moderates and controls. Gait speed decreased with severity and contributes to differences in kinetic outcomes in these populations. These data agree with previous work[1,2] that report decreased sagittal moments and more sustained loading patterns in the frontal plane, with increasing levels of knee OA severity.

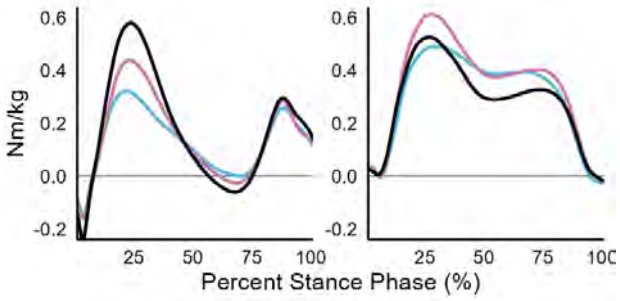

Figure 1 Group mean knee flexion (left) and adduction (right) moments of controls (black), moderate (purple), severe (blue).

CONCLUSIONS

Kinematics from markerless motion capture produce joint loading outcomes that can distinguish between knee OA severities. This demonstrates the clinical utility of markerless motion capture by replicating clinical findings reported in the literature and more globally provides additional validity of the technology.

INTRODUCTION

Total ankle arthroplasty (TAA) is one of the surgical treatments for end-stage ankle osteoarthritis. The two-component type implant models that replaced the upper surface of the talus (standard TAA) are commonly used. On the other hand, the standard TAA has problems like talar component subsidence. Another model that uses talar body prosthesis (combined TAA) is expected as an effective strategy for the problems and was reported to improve objective foot scores, subjective pain assessments, and range of motion [1]. However, little is known about in vivo kinematics of the talar prosthesis and the differences between standard TAA and combined TAA. The purpose of this study is to measure in vivo three-dimensional kinematics of the standard TAA and the combined TAA during ankle dorsiflexion-plantarflexion and investigate differences in kinematics due to different shapes of the talar implants.

METHODS

The study included 19 participants (9 standard TAA, 10 combined TAA) who underwent total ankle arthroplasty. First, the 3D implant models of ankle dorsiflexion and plantarflexion were created from Computed Tomography (CT) images by using ITK-SNAP. To define the standard position of the implants, a global coordinate system was made on the model data of the tibial implants. Then, tibial implants of dorsiflexion and plantarflexion were aligned with it by Go-ICP [2,3] algorithm. Next, the middle position of talar implants was defined with the model data of aligned tibia implants and talar implants of standard TAA, and a talar reference system was created on the model data of talar implants. In the case of standard TAA, talar implants of dorsiflexion and plantarflexion were aligned with the referent system by Go-ICP algorithm. In the case of combined TAA, the underside of the talar implants was cut off and the remaining upper side was aligned with the model data of the talar implant by the same method as the standard TAA. The combined TAA implants were designed to have the same diameter of the talar surface as the standard TAA implants. The cutting process was done manually ten times per each subject's implant data. For the evaluation of 3D kinematics during dorsiflexion and plantarflexion, the rotation angles and the displacements for the alignment are calculated by using the Go-ICP results. In the case of combined TAA, the averages of ten times were used as the results. Both reference systems in this study are defined in the same way as in previous research [4].

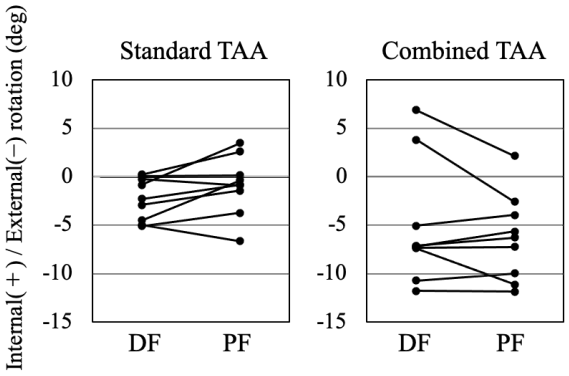

Figure 1 Internal/external rotation angle of standard TAA and combined TAA during dorsiflexion and plantarflexion.
DF: dorsiflexion; PF: plantarflexion.

RESULTS AND DISCUSSION

The internal/external rotation angles of implants during dorsiflexion and plantarflexion are shown in Figure 1. From dorsiflexion to plantarflexion, the implants of the standard TAA group rotated internally. This is a similar movement to a normal ankle joint [5]. On the other hand, some of the implants of the combined TAA group rotated externally. There was a significant difference between them in external rotation in plantarflexion. The rotation angle of the combined TAA group varied greatly among individuals. From dorsiflexion to plantarflexion, the implants of the combined TAA group translated medially and posteriorly. These implant translation patterns were not seen with the standard TAA group, and they tend to translate only posteriorly.

CONCLUSIONS

There were differences in the internal/external rotation angle and the direction of implant movement between the standard TAA group and the combined TAA group. The results may provide useful data for selecting the optimal implant shape.

INTRODUCTION

Asymmetric symptoms of bradykinesia is one of the representative moto symptoms in Parkinson's disease (PD). Recently, 4%–14.7% of patients diagnosed with PD have been showed normal dopamine transporter imaging and they have been referred to as having scans without evidence of dopaminergic deficit (SWEDD) [1]. The clinical characteristics of SWEDD is similar to that of PD. Also, SWEDD is difficut to describe its phenomenology. It is important to understand clinical characteritics of SWEDD and to distinguish patients with SWEDD from patients with PD for accurate and effective interventions. Therefore, the aim of this study was to investigate motor symptom asymmetry on forearm rotation performance using gyro sensor in patients with PD and SWEDD.

METHODS

Twenty-three patients with SWEDD, 23 patients with PD and 23 controls participated in our study. Patients with normal dopamine transporter imaging and normal brain MRI among patients diagnosed with PD were determined as the SWEDD patients [2]. For quantitative measures of forearm rotation movement, a custom-made angular velocity measurement system based on gyro sensor (CG-L53, NEC/Tokin, Japan) was used. In our study, forearm rotation categories were selected as the same tasks for investigation from the UPDRS part III (motor examination). All participants were asked to perform forearm rotation task for 15 s as rapidly as possible and with as large an amplitude as possible. The sensor signals were recorded in both right and left forearms at 250 Hz sampling frequency. Butterworth digital low pass filter with 50 Hz cutoff frequency was used. To evaluate asymmetry of forearm rotation performance, ratio of root mean squared (RMS) angular velocity between both forearms was calculated. Analysis of variance (ANOVA) and post-hoc (Tukey) test were performed to compare control, PD and SWED groups.

RESULTS AND DISCUSSION

Figure 1 shows results of asymmetry on forearm rotation speed among control, PD and SWEDD groups. There were significant group differences ($P<0.001$). Asymmetry of PD patients was significantly greater than that of SWEDD patients ($P < 0.001$). Expectedly, PD patients exhibited greater asymmetry compared to control group. In contrast, no significant difference was observed between SWEDD and control group ($P >0.05$) These results indicate that PD patients show asymmetric bradykinesia in forearm rotation movement, whereas SWEDD patients have less asymmetric forearm speed.

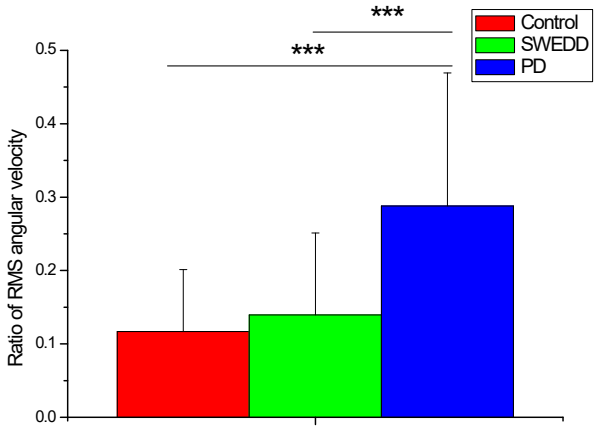

Figure 1 Comparison of asymmetry of forearm rotation in control, PD and SWEDD groups.

CONCLUSIONS

This study investigated asymmetry of forearm rotation speed in PD and SWEDD patients. PD patients had asymmetric bradykinesia while SWEDD patients had normal ratio of forearm speed. These findings could aid clinicians in identifying potential SWEDD patients among PD patients.

IMU-instrumented Timed-Up and Go test identified task-specific mobility declines in older adults

Yu-Pin Liang, Gregory Welk and Li-Shan Chou
Department of Kinesiology, Iowa State University, Ames, Iowa, USA.
Email: yupinl@iastate.edu

INTRODUCTION

Each year, in the US, one out of four older people falls, and one out of five falls results in a severe injury, such as hip fractures or traumatic brain injuries [1,2]. Declined gait balance control has been identified as a leading risk factor for falls [3]. Gait variability or altered center of mass (COM) motion may indicate gait imbalance [4]. The Timed-Up and Go test (TUG) is a commonly utilized clinical assessment for examining mobility, balance, and fall risk in older adults [5]. TUG measures the time taken by an individual to complete the tasks, which include rising from a chair, walking a distance of three meters, turning, walking back to the chair, and sitting down. An older adult who takes more than 12 seconds to complete the TUG is considered at risk for falling. While the TUG test has demonstrated utility for screening elderly with impaired gait balance [6] the overall time measure provides limited information for identifying the factors that contribute to an elevated risk of falling. The purpose of this study was to employ IMU-instrumented TUG to enhance our screening of individual task performance and quantification of body movement, which, taken together, could better guide clinicians in detecting mobility impairment and developing intervention plans.

METHODS

Seven male and five female older adults (>65y/o) were recruited for this ongoing study. All participants performed the TUG test with one IMU placed at the fifth lumbar vertebra (L5) as the proxy location of whole-body COM. Participants who took more than 12 seconds to complete the TUG test were classified as at-risk for falling (RF), and those who took less than 12 seconds were coded as non-risk for falling (NRF). TUG test was further divided into 6 task phases, including the sit-to-walk (STW), walking out (W1), turning around (TUA), walking back (W2), turning in place (TIP), and sitting down (SD) (Figure1). The time duration for each of the six TUG phases was identified with the IMU data and compared between two groups by independent t-test statistical approaches with $\alpha = 0.05$.

RESULTS AND DISCUSSION

Seven participants were classified as NRF and five participants as RF. Mean absolute time measured for each of the six task phases were 1.35, 2.38, 1.68, 2.29, 1.31 and 1.21 seconds for NRF, and 2.07, 3.04, 2.51, 2.94, 2.33, and 1.28 seconds for RF (Figure 2). Mean percentages of the overall time for the six phases were 13, 23, 16, 22, 13 and 18 percent for NRF, and 14, 21, 18, 21, 16, and 10 percent for RF. Participants in the RF group spent significantly more time in STW, TUA, and TIP ($p<0.05$). Individuals in the RF group allocated a significantly greater proportion of time to TIP ($p<0.05$) and a trend in a greater proportion of time to STW ($p=0.089$). There were no significant time-related differences between the two groups in W1, W2, and SD. The turning-related activities in the TUG were the major feature distinguishing the RF and NRF groups.

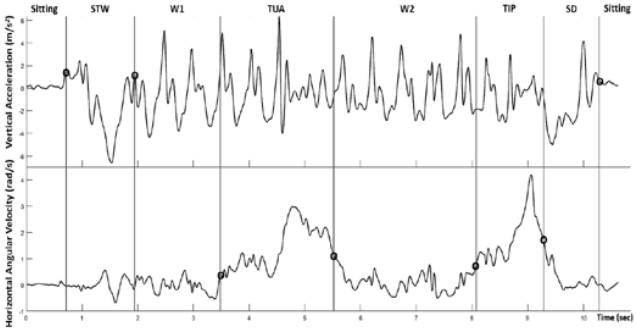

Figure 1 Representative data points to differentiate six phases of Timed Up & Go

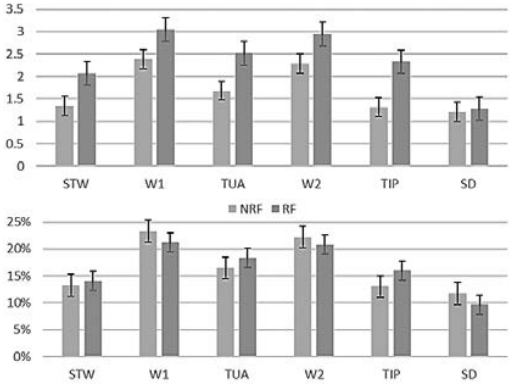

Figure 2 The raw (y-axis: seconds) and proportional (y-axis: 1=100%) time spending distribution in six phases of Timed Up & Go between NRF and RF groups.

CONCLUSIONS

Result of this study indicates that the IMU-instrumented TUG test could quantify each segment of the TUG and identify specific segments that contribute to risks or poor overall performance. Our next steps are to examine the kinematic data obtained from the IMU to better understand the mechanisms underlying the prolonged task performance. Such information would enhance the specificity in the clinician's screening of mobility impairment and the development of interventions for fall prevention.

INTRODUCTION

Understanding talar morphology is critical to the effective design and implantation of total ankle replacements. The success of an implant, however, is dependent not only on talar shape, but also on the local density of the underlying cancellous bone. Computed tomography (CT) can be used to extract the density of the cancellous bone for analysis and use in various applications. The purpose of this study is to observe and quantify the external shape and internal density of the talus. [1]

METHODS

Sixty non-pathological subjects were selected for this study. Weight-bearing CT scans of the leg were collected in bilateral standing posture. Three-dimensional models of the talus of each subject were generated, and local density values corresponding to the Hounsfield Unit of each CT voxel were extracted. A weighted spherical harmonic (SPHARM) analysis was performed to quantify talar external shape, and an average talus model was created. [2] One hundred seventy-nine volumes of interest were placed in the average talus and warped into the same relative positions in all other subjects using the thin plate spline interpolation function established using the output of the SPHARM analysis. [3] Separate principal component analyses (PCA) were run to summarize variation in both external shape and cancellous density respectively. Non-parametric statistics were run to test for significant differences between males and females and among different age brackets (young ≤35, middle 36-54, older ≥55) for both the shape and density data, as well as among different bone regions for density data.

RESULTS AND DISCUSSION

No significant differences in shape exist between males and females or among different age groups. In density, however, there are significant differences between males and females, as well as between the old group and both the young and middle groups. (Table 1).

The first PC (71% of variance) of density data corresponds to overall bone density, with high- and low-density specimens at the positive and negative extremes of PC1 (Figure 1).

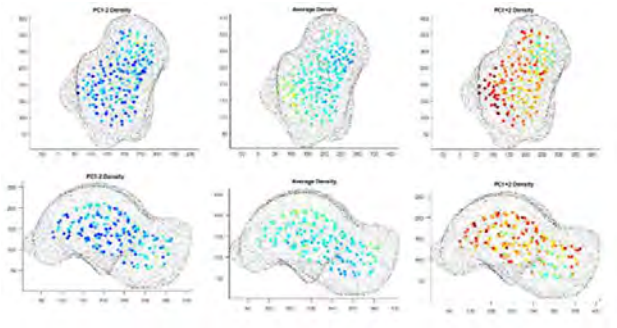

Figure 1 Axial (Top) and Medial (Bottom) Views of the First Principal Component of Density Variance, with Negative Extreme (Left), Average (Middle), and Positive Extreme (Right) (+/-2 sd)

The talar dome, head, and lateral process are significantly denser than the other regions of the talus. ($p<0.05$ for all three regions)

CONCLUSIONS

This study shows that while there is no significant difference in talar shape between male and female or among different age groups, there is significant variation in talar density both between and among these groups. Knowledge of variation in shape and internal density among humans is an important factor to consider for fixation at the bone-implant interface. This process can also be generalized to other bones, allowing for insights throughout the body.

INTRODUCTION

Habitual physical activity is attracting more important attention in the aging modern society.[1] Asians have emphasized habitual exercises such as Taichi and Yoga from ancient times to the present.

Baduanjin is one of the physical activities that Asians have performed. Baduanjin consists of eight movements and is known as a very simple, easy-to-learn, and effective exercise for preventing various diseases.

Focusing on two of Baduanjin's eight movements, the exercises lifting the upper extremity, we conducted kinetic and kinematic analysis by dividing the subjects into skilled and unskilled groups.

METHODS

We recruited six skilled people who regularly trained Baduanjin and six beginners who did not learn it. IRB (Investigational Review Board) deliberation was obtained (WKIRB 2019-3) and this study was registered to CRIS (KCT0003840).

Eight infrared cameras and six force plates were installed in the motion analysis room. After measuring the height and weight of the study subject, anthropometric measurement was performed. After that, the subject performed the first and third movements of Baudanjin on force plates installed in the center of the motion analysis room with 22 retroreflective markers attached to the body of the study subject.

The collected marker data were modeled with our model and preprocessed for analysis. Kinematic analysis was conducted on the right glenohumeral (GH) joint, the most movable joint in upper limb movement. Local coordinate systems representing the shoulder and upper arm each were created, and the angle between the two coordinate systems was calculated by quaternions. Finally, the GH joint angle was represented as the Euler angle.

As a statistical method to investigate the difference between the two groups, the Shapiro-Wilk test and F test were performed first. An unpaired two-sample t-test was performed when normality and homoscedasticity were satisfied, and the Mann-Whitney U test was performed when normality was not satisfied. All statistics were performed by Rstudio.

RESULTS AND DISCUSSION

The key point of Baduanjin's first movement "Two Hands Supporting the Sky – Regulates All Internal Organs" is holding both arms up. In this motion, the flexion angle of the GH joint was 144.37(±1.94)° for the unskilled and 128.47(±1.51)° for the skilled group. This result was contrary to the expectation that the flexion angle of the skilled group would be greater.

The difference in the left and right ground reaction forces (GRF) between the two groups was investigated to confirm whether the forces were distributed in a balance between both feet when performing the Baduanjin first and third movements.

When performing the first movement, the difference in GRF was 0.912(±0.675)% of the weight for the skilled and 2.743(±0.794)% of that for the unskilled group ($p=2.2e-16$, $W=9705$). When performing the third movent "Single Hand Pushing Up – Helps the Spleen and Stomach," the difference in GRF was 0.992(±0.763)% of the weight for the skilled and 2.638(±1.079)% for that of the unskilled group ($p=2.2-16$, $W=9050$).

These differences are noteworthy as an indicator of the proficiency of the skilled group because the weight of the body should be evenly distributed on both feet to secure stability when exercising to widen the upper extremity, which is a characteristic of the above two movements.

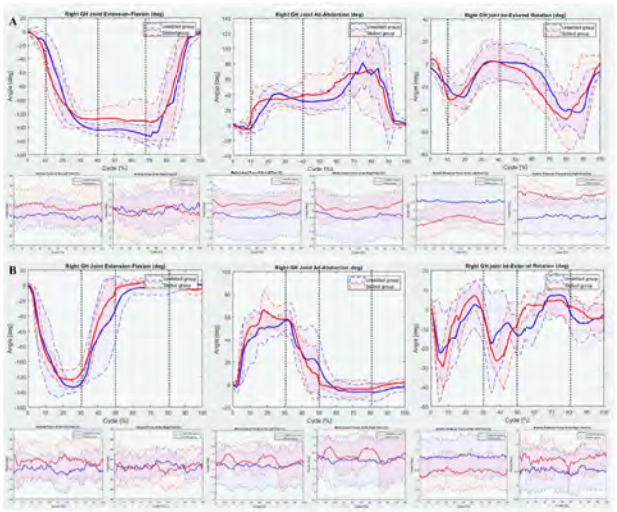

Figure 1 Kinematic and Kinetic Analysis Results of Baduanjin's first and third movements. A: "Two Hands Supporting the Sky – Regulates All Internal Organs"; B: "Single Hand Pushing Up – Helps the Spleen and Stomach"

CONCLUSIONS

The difference between the two groups could be confirmed when performing Baduanjin's upper limb elevation exercises. This difference is expected to be used as an indicator of proficiency evaluation of these exercises.

BIOMECHANICAL EFFECT OF FLOOR SIT-TO-STAND MOVEMENT ON THE OPTIMAL SURGICAL SITE IN ACLR SURGERY: A COMPUTATIONAL ANALYSIS

Jaewoong Han[1], Byeongchan Cho[1], Bowon Jeong[1], Tae Soo Bae[1]
[1] Department of Biomedical Engineering, Jungwon University, Chungbuk, Korea.
Email: bmebae@jwu.ac.kr

INTRODUCTION

ACL reconstruction (ACLR) surgery is performed for damaged ACL and the selection of an appropriate surgical site for the implanted graft is very important to determine the success of the ACLR surgery. However, there are insufficient studies on the selection of the optimal surgical site considering the floor sit-to-stand (FSTS) motion of Asians during ACL reconstruction, and the biomechanical evidence for improving the technique is insufficient. Therefore, the purpose of this study is to find a biomechanical basis for determining the optimal surgical site of the ACL allograft tendon considering the continuous FSTS movement during Outside-in ACLR surgery.

METHODS

A 3D knee joint was reconstructed through an image processing program (Mimics 20, Materialize Inc., Belgium) from CT images. To match the bone shape of the knee and the FSTS movement of the knee, motion analyses (Cortex 8, Motion analysis Inc., USA) were performed after attaching the reflective markers following Helen Hayes's markerset on the same position during knee FSTS motion to get the continuous kinematic data of the FSTS movement. A total of 24 cases were simulated at 24 surgical sites in at the starting point of the femoral tunnel at a radius of 5 mm, 10 mm, and 15 mm based on the femoral epicondyle. Through MFBD analyses, von-mises stresses on the implanted graft were calculated during continuous knee FSTS motions. The FSTS motion was divided into four phases, and we tried to find the optimal surgical site by calculating the stress applied to the implanted graft through MFBD analysis and then performing comparative analysis (Figure. 1).

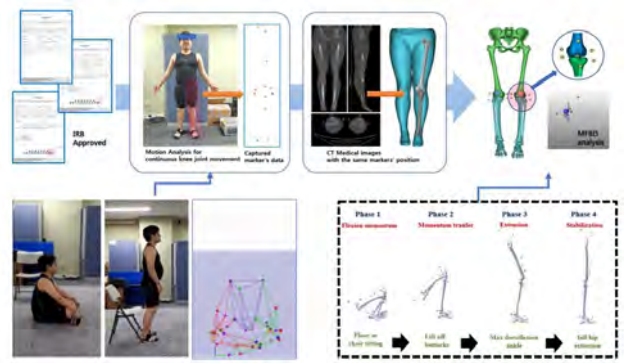

Figure 1 Flowchart of MFDB analysis for four phases of floor sit-to-stand using a three-dimensional knee joint model from CT images and knee joint movement from motion analysis with same reflective markers.

RESULTS AND DISCUSSION

In phases 1, 2, 3, and 4, the average stress for each surgical site was 47.52 MPa, 55.30 MPa, 52.25 MPa, and 12.41 MPa. The stress of the graft was the smallest at the proximo-posterior surgical site with a radius of 15 mm, and the stress of the graft was 23.30 MPa, 29.30 MPa, 27.28 MPa, and 7.09 MPa in phases 1, 2, 3, and 4 in order. Conversely, the stress of the graft was the greatest at the distal anterior surgical site with a radius of 15 mm, and the stress of the graft was 67.09 MPa, 72.78 MPa, 66.08 MPa, and 16.35 MPa in phases 1, 2, 3, and 4. In phase 2, the average stress of the graft at each surgical site was 55.36 MPa, which was larger than in other phases. When the surgical site was posterior or proximal, the stress of graft decreased as the radius increased, and when the surgical site was anterior or distal, the stress of graft decreased as the radius decreased.

In the floor sitting culture of Asians, it is common to maintain the Phase 1 posture for the longest time. At this time, the stress of the implanted ACL graft was higher than the yield stress (25.5 MPa) of ACL graft except for the proximal and posterior surgical site with a radius of 15 mm. Therefore, it is recommended that clinicians avoid setting the femoral tunnel start point towards the distal and anterior areas as much as possible during ACLR surgery. In this study, the finite element model was applied to the graft tendon, but femur and tibia were applied rigid bodies, it is expected that some errors will occur when comparing the results with the implanted graft in actual clinical practice.

CONCLUSIONS

Unlike the chair STS culture of Westerners, when outside-in ACLR surgery is performed on Asians exposed to FSTS culture, it will help to increase the success rate of ACLR surgery by not setting the starting point of the femoral tunnel near the anterior distal part.

OPTIMAL HINGE POSITIONS ON TIBIAL WEDGE IN BIPLANE OPEN-WEDGE HIGH TIBIAL OSTEOTOMY AS VARUS DEFORMITY ANGLE

Tae Soo Bae[1], Hyeongho Baek[1], Bowon Jeong[1], Jaewoong Han[1]
[1] Department of Biomedical Engineering, Jungwon University, Chungbuk, Korea.
Email: bmebae@jwu.ac.kr

INTRODUCTION

It is well known that biplane open wedge high tibial osteotomy is one of effective surgical techniques which relieve tibial varus and pain in patients with osteoarthritis. However, it is still difficult to determine an appropriate hinge position to prevent fracture in the lateral cortex of tibia in the process of making an open wedge or after applying a bone plate and body weight. Nevertheless, the optimal hinge position related to risk of fracture is still controversial. Therefore, in this study, we tried to present a biomechanical basis for determining the hinge position by using a heterogeneous model.

METHODS

Three-dimensional lower extremity models were constructed using Mimics (Figure 1a). The tibial wedge started at 40 mm distal to the medial tibial plateau, and osteotomy for three hinge positions was performed toward the head of the fibula (mid position), 5 mm proximal from the head of the fibula (proximal position), and 5 mm distal from the head of the fibula (distal position). Finally, tibial wedges were ended at 5mm far from tibial lateral cortex. The three tibial models for biplane open wedge high tibial osteotomy were made with varus deformity of 5, 10, 15 degrees with 3-matic software. The material properties of tibial bone in each model were set to heterogeneous material properties which converted from Hounsfield's unit to Young's modulus by applying empirical equation in existing studies. For a loading condition, displacement at the posterior cut plane was applied referring to Hernigou's table considering varus deformity angle. All computational analyses were performed by using FE commercial software (Figure 1b).

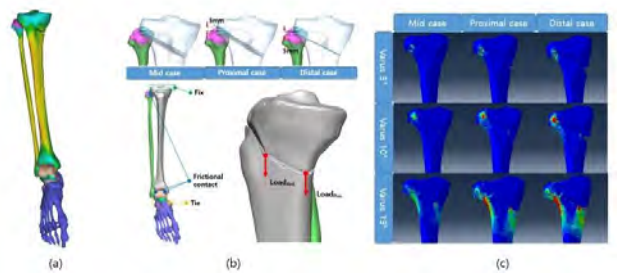

Figure 1 Computational analysis model for biplane OWHTO surgery (a)Heterogeneous tibia model, (b) Three hinge positions, loading & boundary condition in FE model, and (c)Von-mises stress contours as hinge positions and varus deformity angles.

RESULTS AND DISCUSSION

In To estimate the risk of fracture in the lateral cortex of tibia, von-mises stresses on the tibial wedge were calculated for three hinge positions considering varus deformity angles. The maximum stress increased to an average of 213±9% when the varus angle was 10 degrees compared to 5 degrees and increased to an average of 154±8.9% when the varus angle was 15 degrees compared to 10 degrees. In addition, the maximum stress of the distal position was 19 times higher than that of the mid position and 5 times higher than that of the proximal position on average (Figure 1c). For varus deformity angles, the maximum stress of the tibial wedge tended to increase as the varus deformity angle increased. For hinge position of tibial wedge, maximum stress was the lowest in the mid position, while the highest in the distal position.

CONCLUSIONS

These results suggest that the risk of fracture would be low in the order of mid, proximal, and distal hinge position and the distributed stress tends to increase as the varus angle increases.

INTRODUCTION

In recent years, the cost of force plates and similar devices for measuring vertical ground reaction force (GRF) has been reduced; thus, obtaining biofeedback on force information in golf practice has become feasible [1]. Therefore, the exertion of GRFs for achieving maximum shot distance by skilled golfers can be helpful information for recreational golfers. Nonetheless, the detailed GRFs changes during a full driver shot in skilled golfers have not been shown previously. The current study investigated the GRFs of Japanese male professional golfers during a full driver shot.

METHODS

Eight Japanese male professional golfers (age: 35.5 ± 1.7 years; height: 1.74 ± 7.7 m; body mass: 75.1 ± 9.4 kg) and 19 male collegiate golfers (age: 19.3 ± 1.2 years; height: 1.73 ± 4.7 m; body mass: 68.4 ± 7.4 kg) participated in this study. The experimental challenge involved a driver executing a full shot and achieving the greatest possible distance. The experiment was conducted in an indoor experimental facility. The GRFs of the front and rear legs were measured using two force plates (9287, Kistler; operated at 1000 Hz). Based on the address posture, the GRF was defined with the x-axis pointing forward (anteroposterior), the y-axis pointing from the tee to the target (mediolateral), and the z-axis pointing vertically upward (vertical). Time-series data for anteroposterior, mediolateral, and vertical GRFs were normalized to 100% for the downswing phase. A two-sample t-test using statistical parametric mapping (SPM) was used to compare groups of averaged GRFs [2].

RESULTS AND DISCUSSION

Compared to amateur golfers, professional golfers showed a trend toward greater maximum clubhead velocity during full driver shots (49.3 ± 2.1 vs. 51.7 ± 3.8 m/s, respectively, p = 0.13, n.s., effect size = 2.69). According to SPM, professional golfers produced a greater vertical GRF component in their front legs during 75%–91% of the downswing than amateur golfers (Figure 1). Other GRF components showed no differences between groups. In a research, it was found that the large vertical GRFs of the leading foot during downswing acceleration and 40 ms prior to impact were major predictors of driven ball velocity [3]. A greater vertical GRF of the front leg during the downswing may accelerate the body's center of mass vertically, increasing clubhead velocity. These results suggest that the push movement with the front leg during the downswing is crucial for the shot's quality.

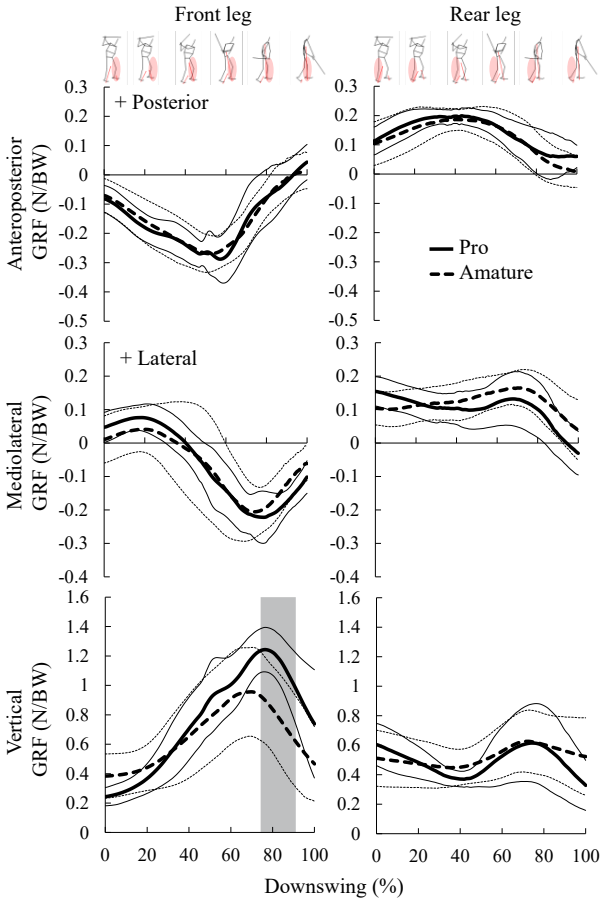

Figure 1 Waveforms of the GRF during the downswing of professional golfers, and amateur golfers. The mean and standard deviation are indicated by bold and thin lines, respectively. The shaded area indicates differences in curves between groups based on SPM results.

CONCLUSIONS

We examined the GRFs of Japanese professional and amateur golfers during full driver shots. The results showed that the front leg of the professional golfers had a greater vertical GRF during the late downswing. These results provide insights into the magnitude and timing of the forces required to increase the distance of driver shots during golf practice.

INTRODUCTION

It is well-known that keeping the swimmer's body position as high as possible is a crucial way of reducing drag and thus improving swimming performance. Coaches visually inspect the swimmer's vertical body position to evaluate the swimmer's ability or condition. Therefore, it is important for swimmers and their coaches to understand the factors determining a swimmer's vertical position. Swimming velocity is one of the factors associated with the vertical body position during swimming [1,2], and vertical body position increased linearly with swimming velocity over a wider velocity range during front crawl [2]. However, since this relationship was established for the average over a complete stroke cycle [2], coaches are required to observe the swimmers for the entire stroke cycle to evaluate their vertical body position fully. Focusing on specific phases within the stroke cycle rather than averages for a stroke cycle may provide practical information for swimmers and their coaches to easily detect changes in a swimmer's vertical body position. Despite this potential benefit, it remains uncertain whether a linear relationship between swimming velocity and vertical body position holds for each stroke phase (e.g., pull, recovery). This study aimed to investigate whether the linear relationship between swimming velocity and vertical body position establishes for each stroke phase in front crawl.

METHODS

Eleven college-level male swimmers (21.5 ± 2.3 y) performed a 15 m front crawl at various swimming velocities ranged from 0.8 to 1.6 m/s with sustained forced maximal inspiration to control for lung volume effects [3]. The three-dimensional positions of 36 reflective markers attached to the swimmer's body were captured at 100 Hz using an underwater motion-capture system (Qualisys). The body's center of mass (CoM) was estimated from individual digital human models with inertial parameters using inverse kinematics [2,3]. The horizontal CoM velocity and vertical CoM position relative to the water surface as an index of vertical body position were calculated for one stroke cycle and divided into five stroke phases (i.e., entry, pull, push, release, and recovery) [1]. We used a linear mixed-effects model with random intercepts and slopes to test whether there was a positive trend between mean swimming velocity and mean vertical CoM position for one stroke cycle and for each stroke phase. It was constructed with the swimmers as a random effect and swimming velocity as a fixed effect. Marginal R^2 (R^2m; variance explained by fixed effects) and the conditional R^2 (R^2c; variance explained by both fixed and random effects) of the linear mixed-effects models were calculated.

RESULTS AND DISCUSSION

There was a positive trend between mean swimming velocity and mean vertical CoM position for one stroke cycle (β = 0.037, p < 0.001, Figure 1). There was a positive trend between mean swimming velocity and mean vertical CoM position for the entry (β = 0.041, p < 0.001), pull (β = 0.055, p < 0.001), push (β = 0.048, p < 0.001), release (β = 0.030, p < 0.001), and recovery (β = 0.024, p < 0.001) phases, respectively (Figure 1). These results indicate that a linear relationship between swimming velocity and vertical body position during front crawl can be established for one stroke cycle as well as for any stroke phases.

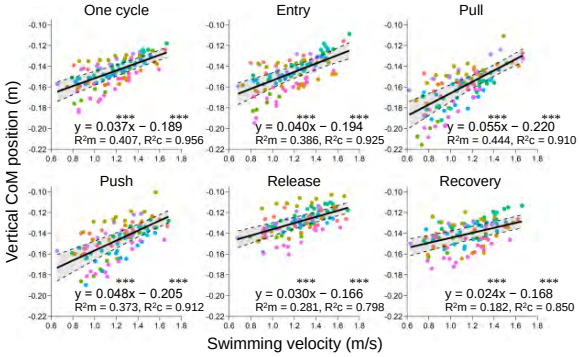

Figure 1 Swimming velocity plotted against the vertical CoM position across swimmers for one stroke cycle and for each stroke phase. Point colour corresponds to each swimmer of the data point.

CONCLUSIONS

The linear relationship between swimming velocity and vertical body position during front crawl was established for each phase of the stroke cycle. This finding provides practical information for swimmers and their coaches to easily detect changes in swimmer's vertical body position by focusing on specific stroke phases.

EVALUATION OF MUSCLE ACTIVATIONS OF UPPER ARM IN COLLEGIATE ATHLETE DURING 200-M FRONT CRAWL: A PILOT STUDY

Jia-Hao Chang*, Ying-Wei Lee, Chien Huang, Chia-Chuan Chang, I-Cheng Huang
Department of Physical Education and Sport Sciences, National Taiwan Normal University, Taipei, Taiwan.
*Email: jhchang@ntnu.edu.tw

INTRODUCTION

Muscle activations of upper arm during swimming could be measured and recorded by electromyography (EMG) to understand what the muscle did while swimmer swam. Monitoring the changes of the muscle activation in each stroke during swimming provided the information for the coach to know the muscle condition of the swimmer. Therefore, it is important to identify the stroke cycle of swimming correctly and quickly in the swimming poor. The wearable inertial measurement unit (IMU) is easy to be used for special event detecting to define the stroke cycle of swimming [1]. Using electromyography combined with wearable IMU to record the muscle activations during swimming could provide the exact information whether the muscle fatigue or not. The purpose of this study was to evaluate the muscle activations of the upper extremity in each stroke cycle during 200-m front crawl.

METHODS

Six front crawl male swimmer in college division I were recruited as participant in this study. No shoulder pain and any musculoskeletal injury in past 6 months were reported. The experimental procedure has been explained to swimmers and the participant gave informed consent. Three wearable IMU (Blue Trident, VICON), sampling @ 120 Hz, attached on the sternum and both forearm, and four water proof EMG electrodes (Mini Wave, COMETA), sampling @ 2400 Hz, placed on the muscle belly of pectoralis major, latissimus dorsi, triceps, and deltoid in dominant side, were used to collect and record the kinematics and muscle activities of swimmer, separately, in the 200-m front crawl. Each swimmer performed a 200-m front crawl trial at their maximal in a 50-m indoor swimming pool. Swimming stroke cycle was calculated from the IMU data based on the method modified from the report by James et al. [2] Raw EMG signal was filtered with a 4th order band-pass Butterworth filter with cut-off frequencies of 20 and 400 Hz. Then, linear envelope was found by full-wave rectified and smoothed with a 4th order low pass Butterworth filter of 10 Hz. Ten swimming stroke cycles from 15~45 meter in each swimming trip, totally 40 swimming stroke cycles, were used to understand the changes of muscle activation during 200-m front crawl. Mean values of the processed EMG amplitude relative to each respective maximal voluntary isometric contractions (MVIC) in each swimming stroke cycles were considered as outcomes for descriptive statistics.

RESULTS AND DISCUSSION

The muscle activations of pectoralis major, latissimus dorsi, triceps, and deltoid are showed in table 1 and on figure 1. The values of mean EMG were lower in the 2nd and 3rd 50-m trips. Using IMU to identify the swimming stroke cycle during front crawl is feasible, and the muscle activations could be calculated in each swimming stroke cycle to know the muscle condition.

Table 1: Muscle activations in each swimming trip during 200-m front crawl (Mean ± Standard deviation)

(%MVIC)	1st 50-m	2nd 50-m	3rd 50-m	4th 50-m
Pectoralis Major	28.8 ± 18.2	25.5 ± 15.1	24.9 ± 11.1	26.2 ± 10.1
Latissimus Dorsi	19.7 ± 8.0	21.9 ± 10.6	22.7 ± 11.1	25.8 ± 12.5
Triceps	62.4 ± 23.1	58.0 ± 24.8	64.6 ± 32.8	60.8 ± 30.2
Deltoid	30.5 ± 22.8	28.2 ± 18.9	29.9 ± 21.7	33.7 ± 25.9

CONCLUSIONS

The results supported using EMG device combined with wearable IMU to explain the muscle activation correctly and quickly is feasible in the indoor swimming poor.

The Effects of Two-Step Golf Swing Drills on Swing Rhythm and Clubhead Speed in Competitive Juniors

Kanji Mori[1], Taylor North[1], Kai-Jen Cheng[1], Seungho Baek[1], Hunter Alvis[1] and Young-Hoo Kwon[1]
[1] Biomechanics & Motor behavior Laboratory, Texas Woman's University, Denton, Texas, USA.
Email: kmori1@twu.edu

INTRODUCTION

The two-step swing drills (TSSD) are designed to promote a good swing rhythm by enhancing the golfer-ground interaction [1] through repeated rhythmic unloading/loading of each leg (i.e., stepping-like leg actions). The purpose of this study was to assess the effects of single TSSD session on swing rhythm and the clubhead speed. It was hypothesized that the TSSD would increase the clubhead speed, motion ranges, ground reaction force (GRF) peaks, and the angular velocity peaks of the axle-chain system [2].

METHODS

Ten competitive right-handed junior golfers (15-18 years old; mean age = 16.1 years; 9 males and 1 female) participated in this study and performed seven maximal effort drives with their own drivers before (pre-test) and after (post-test) a TSSD session each. The TSSD session (< 45 minutes) mainly consisted of 4 stages (Figure 1). Each stage started with a trigger motion either by swinging the club toward the target (club trigger) or by moving the body slightly (body trigger). Up to two steps (trail-side and lead-side) were taken in the stages. Correct timings of the steps along with rhythmic leg actions and speedy backswing were emphasized throughout the stages. The drill swings were repeated in each stage until the golfer exhibited correct step timing and/or reasonably fluent motion flow judged by the investigators.

Stage 1	Stage 2	Stage 3	Stage 4
Club trigger	Club trigger	Club trigger	Body trigger
Feet together	Narrow stance	Normal stance	Normal stance
Both steps	Lead-side step	No step	No step

Figure 1. Trigger type, stance, and steps used in the TSSD stages

A 10-camera optical motion capture system (500 Hz) and two force plates were used in acquiring the swing trials. The clubhead speed at impact, motion ranges of the body/pelvis, vertical GRF peaks (maximum and unweighting), and the angular velocity peaks of the axle-chain system were obtained. The pre- and post-test values were compared by using paired *t*-tests ($p < .05$).

RESULTS AND DISCUSSION

As a result of participation in single TSSD session, the clubhead speed increased significantly (Table 1) All participant revealed increases in the clubhead speed: +1.0 to +5.3%. Among the vertical GRF peaks, the unweighting peak significantly decreased, meaning more unweighting was induced by the stepping-like leg actions between the trail-side (right leg) push in the backswing and the lead-side (left leg) push in the downswing. The horizontal motion ranges (away from and toward the target) were characterized by consistent increases, while the vertical motion ranges (upward and downward) of the body CM partially increased significantly. Increases in the angular velocity peaks were observed across the board in both the backswing and the downswing with minor exceptions.

CONCLUSIONS

The findings show that the TSSD can be used as natural means to develop a rhythmic and dynamic golf swing. The stepping-like leg actions facilitate horizontal motions more than the vertical, and unweighting more than loading in terms of interaction with the ground.

CONSERVED BIOMECHANICAL STRATEGIES FOR STANDING AND WALKING BALANCE IN THE UPRIGHT AND INVERTED POSTURE

Charlotte Le Mouel[1,2]

[1] Department of Movement Science, Institute of Sport and Exercise Science, University of Münster, Germany.
[2] Centre Borelli, Université Paris Cité, Université Paris Saclay, ENS Paris Saclay, CNRS, Paris, France

INTRODUCTION

Balance during upright standing and walking requires controlling the ground reaction force (GRF, purple arrow in Figure 1) and center of pressure (CoP, red dot in Figure 1) according to the position of the whole body center of mass (CoM, green dot in Figure 1). This is achieved through a combination of muscle synergies and sensory feedback [1]. Maintaining balance in the inverted posture follows the same biomechanical requirements as in upright stance. This study shows that learning this novel skill allows the emergence of novel sensory feedback and muscle synergies which implement conserved biomechanical strategies.

METHODS

Sixteen gymnasts performed standing and walking both in the upright and inverted posture. GRF and CoP were recorded using force plates (Kistler). The positions of 38 markers placed on the body were recorded (Qualysis) and used to estimate the position of the CoM [2].

RESULTS AND DISCUSSION

During stance in both the upright (Figure 1, B) and inverted posture (Figure 1, C), subjects control the position of their CoP (Figure 1, A – C, red) according to delayed feedback control of the position and speed of the CoM [1] (Figure 1, B, C, prediction in black).
During walking in both the upright (Figure 1, E) and inverted posture (Figure 1, F), subjects maintain balance by aligning the GRF angle (Figure 1, D – F purple) with the angle of line connecting the CoM to the CoP (Figure 1, D – F, blue). This strategy minimises rotation around the CoM.

DISCUSSION

Although they must rely on different sensory information and muscle synergies, gymnasts nevertheless use conserved biomechanical strategies to maintain balance in the upright and inverted postures, both during standing and walking. Future work will address how this strategy emerges in gymnasts learning to walk on their hands.

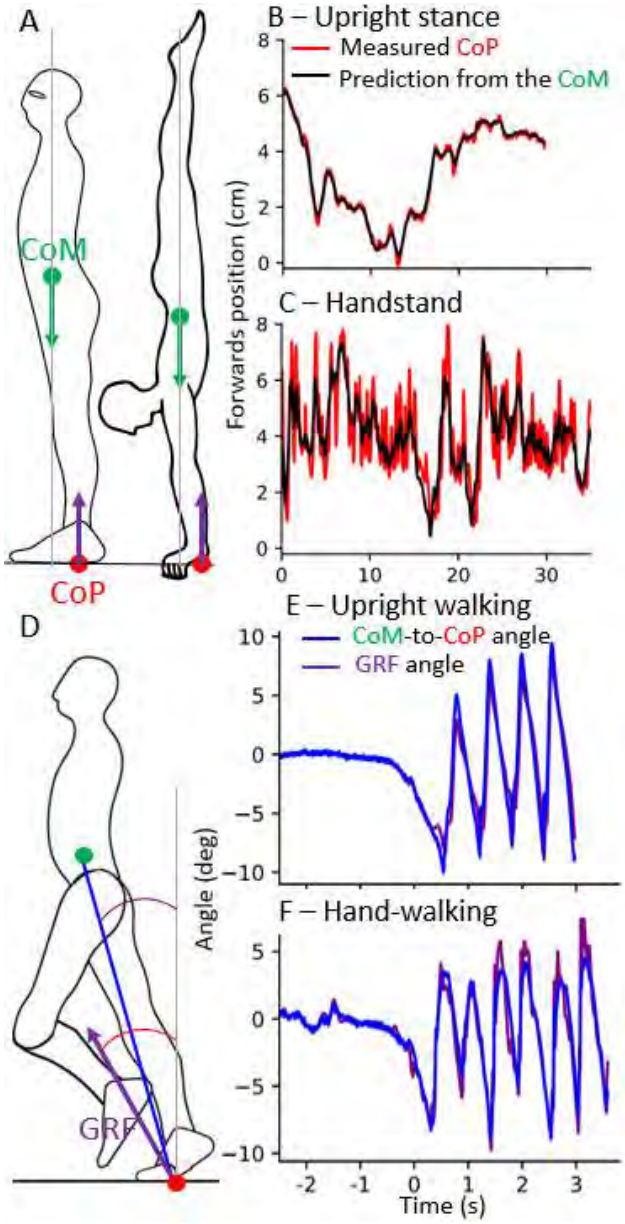

Figure 1 Standing and walking balance. During stance (A – C), the measured position of the CoP (red) can be predicted from the position and speed of the CoM (prediction in black) at previous timepoints, both in upright stance (B) and handstand (C). During walking (D – F), subjects control the angle of the GRF (purple) to keep it aligned with the line from the CoP to the CoM (blue) during both upright walking (B) and hand-walking (C).

INTRODUCTION

Wheelchair badminton players develop shoulder joint pain (Shoulder pain) more frequently than standing badminton players [1]. Shoulder pain occurs in the section from the shoulder joint in maximum external rotation (MER) to impact during the overhead swing motion. Shoulder joint movement is performed by interlocking movements of the scapulothoracic and glenohumeral joints. Therefore, it is necessary to analyze each to understand the mechanism of shoulder pain onset. However, no studies have investigated the movement of each joint during the swing motion in wheelchair badminton. This study aimed to compare the shoulder, scapulothoracic, and glenohumeral joint movements at the MER during overhead swing motion between standing (ST) and wheelchair sitting (WC) positions to elucidate the factors contributing to shoulder pain in wheelchair badminton players.

METHODS

Ten healthy male college students (Mean age, 22.3 ± 1.9 years) with at least 3 years of standing badminton experience participated in this study. Kinematic data were obtained using an electromagnetic tracking device (240 Hz, Liberty; Polhemus) from all participants during the overhead swing motion in ST and WC positions. Participants were instructed to perform the swing motion with maximum effort five times in each condition. The measurement items were shoulder joint angle in external rotation, scapulothoracic joint in posterior tilt, and glenohumeral joint in external rotation at the MER during the motion. For the statistical analysis, a paired t-test was used to compare items between the two conditions. Statistical significance was set at $p<0.05$.

RESULTS AND DISCUSSION

In the WC versus ST position, the shoulder joint angle in external rotation and the scapulothoracic joint angle in posterior tilt were significantly smaller by 3.6° and 2.2°, respectively. No significant difference was observed in the glenohumeral joint angle of external rotation in each condition (**Table 1**). The movement of the shoulder joint in external rotation involves a combination of the scapulothoracic joint in posterior tilt, glenohumeral joint in external rotation, and trunk extension movements. Among them, scapulothoracic joint movement contributes the most to the shoulder joint in external rotation movement [2]. However, sitting position in a wheelchair may limit the movement of the scapulothoracic joint in posterior tilt due to thoracic kyphosis, which may result in a smaller angle of the shoulder joint during external rotation. In contrast, a stronger swing motion requires a greater shoulder joint angle during external rotation [3]. Thus, in the WC position, which involves a smaller scapulothoracic joint angle in posterior tilt, an excessive glenohumeral joint in external rotation movement may have been induced to increase the shoulder joint angle in external rotation. This finding may be related to the occurrence of shoulder pain among wheelchair badminton players.

CONCLUSIONS

This study showed that the swing motion in the WC position involves less scapulothoracic joint movement than that in the ST position and may induce excessive compensatory glenohumeral joint movement. This may account for the predilection of shoulder pain among wheelchair badminton players.

Mass-spring characteristics explain the temporal step parameters but are not specific to individuals across phases in accelerated sprinting.

INTRODUCTION

Sprinting is a periodic motion in which the support phase and the flight phase are repeated. Numerous spatiotemporal patterns exist even at the same speed, and inter-individual variability has been observed [1]; however, its determinants have not been fully clarified. During sprinting, the lower limb behaves like a spring. Its properties can be evaluated by the mass-spring model with leg and vertical stiffness (k_{leg} and k_{vert}: the ratio of maximum force to leg compression and vertical displacement, respectively), which can be estimated as a function of spatiotemporal variables and body size parameters [2]. Thus, the stiffness properties might determine the inter-individual spatiotemporal variability. The trends of k_{leg} and k_{vert} for multiple sprinters were also reported to be constant over a range of phases in the 100 m sprint [2]. However, the joint stiffness, which determines overall spring-mass stiffness, is influenced by several factors, such as neuromuscular control and mechanical muscle-tendon properties [3]. Thus, it is unclear whether the stiffness is individual specific (i.e., whether the same individuals always exhibit stiff/compliant behaviour) across a range of phases.
We investigated the relationship of spring-mass behaviour to spatiotemporal variables, and its individual specificity across a wide range of phases within the acceleration phase of the 100 m race.

METHODS

Three high-speed cameras (480 fps) recorded the 0-45 m of sanctioned 100 m races. The toes of 19 male sprinters were digitized. Contact and flight duration and contact position were obtained. Sprint speed was calculated as the product of step length and frequency. We calculated k_{leg} and k_{vert} from these spatiotemporal variables [2].
We divided the 0-40 m into four sections of 10 m each, and the average values of each section were used in the analysis. We examined the relationship of k_{vert} and k_{leg} to the spatiotemporal variables by using a single regression analysis. Prior to regression, we excluded the outliers in the explanatory variables and in the residuals from the regression equation based on three times the median absolute deviation. To evaluate the individual specificity, the agreement in each variable among the four sections was assessed by the intraclass correlation coefficient (ICC).

RESULTS AND DISCUSSION

In all sections, both k_{vert} and k_{leg} were not significantly correlated with maximal sprint speed ($r \leq 0.28$), but were significantly correlated with the contact duration and to the ratio of contact duration to flight duration ($r \geq 0.52$), except for the 0-10 m for k_{vert}. The results suggest that spring-mass behaviour explains intra-individual temporal variability rather than sprint performance. Meanwhile, the agreement of each k_{vert} and k_{leg} between phases was fair (Figure 1, ICC $\leq$ 0.338), suggesting that the spring-like behaviour was not individually specific across a wide range of the phases in the acceleration. The spring-mass stiffness is determined by multiple factors, such as neuromuscular control and muscle-tendon mechanical properties [3]. Therefore, we suggest that the effects of these factors on the spring-mass behaviour differ from phase to phase within the acceleration phase of the 100 m race.

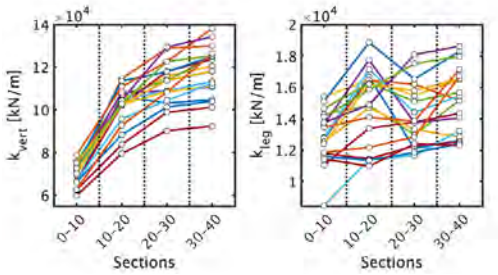

Figure 1: Intra-individual variation in k_{vert} and k_{leg}

CONCLUSIONS

We found that intra-individual variability in the spring-mass behaviour determined the temporal step parameters during each phase within the acceleration phase of the 100 m race. Meanwhile, the spring-mass behaviour was not individually specific throughout the entire acceleration phase. Therefore, we suggest that although the temporal step parameters for each phase are determined by the spring-mass behaviour, the determinants of this behaviour differ from phase to phase.

INTRODUCTION

Windsurfing hydrofoil is a lifting surface located horizontally at the tip of a board vertical fin submerged in water. As the windsurfing board gains speed, the foil lifts it above the water surface, reducing its drag and allowing the board to sail at higher speeds in less wind conditions. This change of sailing mode (board in the water vs. board in the air) creates completely new demands on the position of the athlete's body. Studying the body position in real iQFOiL sailing conditions is not easy due to the low availability and high cost of waterproof motion analysis systems. However, estimating the position of the center of mass (COM) of the body can be approximated on the basis of image analysis and basic anthropometric data of the competitor. The right position of the athlete's COM may be the key to better performance.

The aims of the study were as follows: (1) development of the algorithm that will calculate the location of the iQFOiL's athlete COM, based only on the two pictures taken in perpendicular planes and anthropometric data, (2) calculate the accuracy of the algorithm compared to the motion capture system, (3) development of the characteristics that describe the location of the COM regardless of the rake angle of the mast.

METHODS

Three athletes who trained in iQFOiL for at least one year participated in the study. Each of them performed five repetitions of three positions of the body: with high hips, low hips, and with one hand supported on an uphaul rope attached to the mast (Figure 1). Every repetition was recorded with the BTS Smart DX motion capture system and two mobile phone cameras. COM was estimated according to the method described in [1]. We developed the algorithm that calculates the location of the main joints based on photos and lengths of the body segments (*iQFOiL_photo*). The accuracy of the *iQFOiL_photo* algorithm was calculated as the absolute difference between the COM location calculated based on the motion capture system and with the use of *iQFOiL_photo*. COM was calculated separately for the upper limbs, lower limbs, and entire body and expressed as a perpendicular and parallel distance from the plane passing through the wrists and ankle joints (WA plane) of the athlete in the sagittal plane.

RESULTS AND DISCUSSION

The best accuracy of the COM estimate based on photos was observed for the lower limbs as a parallel distance to the WA plane (5,7 ± 4,7 mm). The worst accuracy was observed for the upper limbs as a parallel distance to the WA plane (25,6 ± 14,2 mm). This result seems reasonable as the algorithm was calculating the position of the adjacent joint, starting from the ankle joint. The accuracy of the overall COM estimate was 6,8 ± 5,3 mm for the perpendicular distance and 16,9 ± 10,2 mm for the parallel distance from the WA plane.

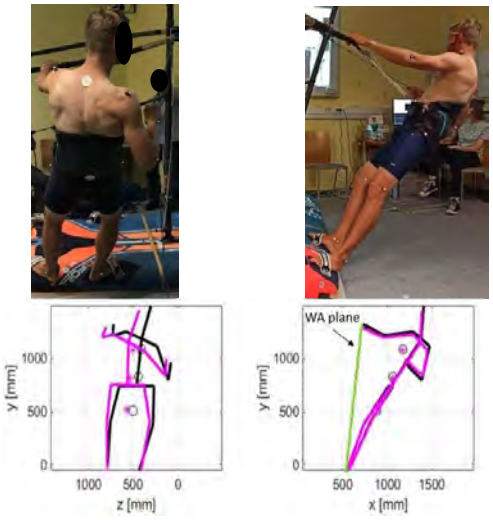

Figure 1 An example of photo input data and body position reconstruction with the *iQFOiL_photo* algorithm in the form of stick biomechanical model and determined COM.

CONCLUSIONS

The *iQFOiL_photo* successfully reconstructed body position and location of COM although addressing the question whether its accuracy is sufficient to observe the change in athlete's performance, demands further study.

INTRODUCTION

Anterior cruciate ligament (ACL) injuries are common in dynamic sports, with high loading to the knee being a risk factor [1,2]. Screening is crucial in identifying individuals with high injury risk. The gold standard laboratory-based screening is costly, so field-based screening methods have emerged, including the Landing Error Scoring System (LESS). LESS, developed in 2009, is a simple and reliable kinematic assessment tool that evaluates 17 items during a jump-landing task and is commonly used in studies [3]. Volleyball is a sport prone to ACL injuries, with players requiring jumps for attacking and defending [4,5]. This study aims to determine the LESS score of volleyball players and explore gender differences.

METHODS

22 injury-free UiTM volleyball players were tested in a laboratory. 11 male (mean ± SD: age 21.18 ± 1.54 years, height 172.68 ± 7.75 cm, mass 69.41 ± 11.58 kg) and 11 female (mean ± SD: 22.27 ± 1.10 years, height 155.55 ± 4.23 cm, mass 53.88 ± 6.80 kg) participants were tested in the UiTM lab using 2 video cameras to record 3 trials of the jump landing task. Kinematic assessments were made using the LESS and analyzed with 2D-motion analysis software (Kinovea v0.8.25).

RESULTS AND DISCUSSION

This study's findings showed no significant differences in the mean LESS scores between genders ($t(20) = -.909$, $p > 0.05$). However, individual LESS scores revealed that one male and one female player had moderate scores ($5 < \text{LESS score} \leq 6$) and two female players scored poorly (LESS score > 6) in their jump landing biomechanics. Male players tended to land with a more upright body position compared to female players, and most female players scored lower in overall impression compared to males. Both male and female players demonstrated narrow stance width (5/11 males, 7/11 females) and knee valgus displacement (5/11 males, 10/11 females). Although the overall LESS scores suggest low injury risk for both male and female volleyball players, attention should be paid to the individual items in the LESS protocol. Poor scores in specific items may increase their risk of future ACL injury.

CONCLUSIONS

The results suggest that the use of LESS scores did not reveal significant differences between genders in this study. It is possible that individual assessments may provide more valuable information for injury risk screening and classification, rather than relying solely on group data. Further research may be necessary to confirm these findings and to investigate the utility of individual assessments in injury prevention.

ACKNOWLEDGEMENTS

The authors extend their thanks to the UiTM volleyball players and Miss Farah Afiqah Mohamed Razali for their collaboration and help during the process of collecting data

INTRODUCTION

The mechanics of each sport differ, yet the same calculation is used to determine the human-ground interaction. Horizontal ground reaction force moment (*GRFM*) is commonly used to define human-ground interaction generating body rotation, in which the length of the moment arm is measured between the horizontal ground reaction force vector and either position of the combined center of pressure (COP), the position relative to the proportions of each vertical ground reaction force, or center of mass. *GRFM* is used across rotation-related sports, such as golf swing [1], baseball (pitchers) [2], and dance (turns) [3]. The measurement interprets the combined COP as the axis of rotation while one foot is applying forces to rotate the body. The mechanics of each rotation-related sport is different. For instance, the transition phase during the golf swing, both feet push the ground simultaneously [1]. In contrast, the baseball pitcher's lead foot (i.e., the left foot for right-handed player and vice versa) is up in the air when the trail foot pushes the ground toward the target [2]. The measurement of the length of the moment arm should differ in the golf swing, specifically between the ground reaction force vectors of each foot, which interprets one foot is the axis of rotation while the other foot applies forces. We proposed the suggested measurement is more associated with body rotation than the combined COP measurement. This study aimed to compare the two measurements of the length of the moment arm in calculating the horiozontal *GRFM* during the golf swing. We hypothesize that peak horizontal *GRFM* with the suggested measurement is more associated with peak pelvis angular velocities than the combined COP measurement during the golf swing.

METHODS

Professional male golfers (n = 13) participated in this study. The thirty-five reflective markers placed on the Plug-in-Gait model and ground reaction force were collected using 8-infrared cameras (Vicon, 250Hz) and force platforms (AMTI, 2000Hz). *GRFM* was defined by cross product between the horizontal ground reaction force and length of the moment arm, in which Method 1. *CC* uses the combined COP, and Method 2. *CL* and *CT* use the COP of the lead and trail foot, respectively, as the axis of rotation. We have eliminated the next step of summing the free moments of each foot as not affecting the result of comparison between measurements. The angular velocity of the pelvis in the horizontal plane ($AV_{P,Z}$) and *GRFM* were calculated at its peaks. Pearson correlation coefficients were performed between the *GRFM* and $AV_{P,Z}$. The critical significance was set at $p < 0.01$.

RESULTS AND DISCUSSION

Peak *GRFM* from Method 1 showed small but non-significant association with peak $AV_{P,Z}$ (lead foot: r = 0.67, p = 0.013, trail foot: r = 0.66, p = 0.014) (Figure 1a and 1c, respectively), whereas peak *GRFM* from Method 2 was associated with peak $AV_{P,Z}$ (lead foot: r = 0.82, p < 0.001, trail foot: r = 0.84, p < 0.001) (Figure 1b and 1d, respectively). Method 1 was not considered significant due to an extremely conservative adjustment of the Type II error rate. All peaks occurred during the early downswing. Our results demonstrate Method 2 might be more accurate way to calculate horizontal *GRFM* during the golf swing.

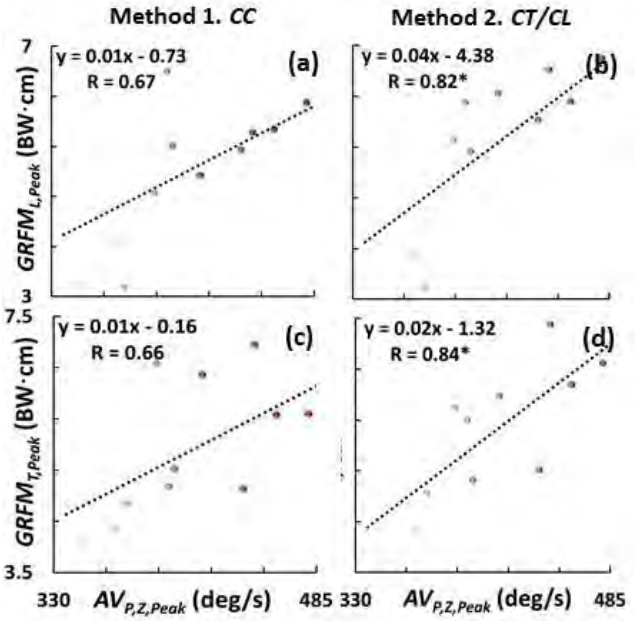

Figure 1. Pearson correlations between the peak horizontal ground reaction force moment, *GRFM*, from the combined COP (Method 1) and suggested measurements (Method 2) of the lead (a, b) and trail (c, d) foot and peak pelvis angular velocity, $AV_{P,Z}$.

CONCLUSIONS

Different methodologies should be considered in investigating human-ground interaction mechanics across a variety of rotationally based sports. Future research is needed to identify clear classification criteria for using different methodologies.

ASSOCIATIONS AMONG LAND-JUMP BIOMECHANICS AND IMAGING OF THE PATELLAR TENDON IN MALE BASKETBALL PLAYERS DURING THE PRESEASON

Erin Argentieri[2], Andrew Kraszewski[1], O. Kenechi Nwawka[1]
[1] Hospital for Special Surgery, New York, USA.

Email: KraszewskiA@hss.edu

INTRODUCTION

Patellar tendinopathy (PT) or "jumper's knee" is a common degenerative condition that affects jumping athletes. Symptoms may be subtle or non-existent at preseason, but structural abnormalities may be present. Imaging PT prevalence via conventional and quantitative MRI and ultrasound (US) may provide useful insights if combined with biomechanics. [1]

Objective: Explore how clinically pertinent PT affects biomechanical land-jump patterns and predictive classsification using biomechanical and advanced imaging measurements.

METHODS

26 NCAA Division I and II male basketball players were recruited during preseason. Player VISA-P scores were collected. We measured lower extremity sagittal joint kinematics and kinetics from dual force platforms during a land-jump test. Clinical variables were: presence of radiologic PT (rPT: no/yes) as seen on conventional US and MRI, positive symptoms (no/yes: VISA-P≤80), and presence of Doppler hyperemia (no/yes). Tendons were imaged proximally and distally with quantitative UTE-MRI acquisitions; short proton density fraction PS and T2*S and T2*L decay constants (ms) were taken from a bi-exponential fit to the time echo signal. Quantitative tendon ultrasound shear wave velocity (SWV) was measured at proximal, mid, and distal tendon regions.

Statistics: Each limb was an observation (N=52). Effect of biomechanics with rPT (no/yes), symptoms (no/yes: VISA-P≤80), and hyperemia (HYP) (no/yes) was tested with multivariate models. Logistic regression fit biomechanical and imaging variables to classify VISA-P, rPT, and HYP observations.

RESULTS AND DISCUSSION

We identified 8 limbs that were symptomatic, 13 limbs with rPT, and 11 limbs with hyperemia. MANOVA tests (Table 1) saw increased joint flexion velocity and decreased maximum vertical limb associated with rPT.

Per outcome a sample of 278,256 five-variable models were fit from a 34-variable pool. From these, the best models in terms of 95th percentile AICc and accuracy (Figure 1) had these most frequent variables: 1) Max Hip FlexVel, 2) Max VGRF, 3) Hip Flex IC, 4) Time to max VGRF, 5) Knee Flex IC, and 6) SWV Proximal. Accuracy ranged above 90%.

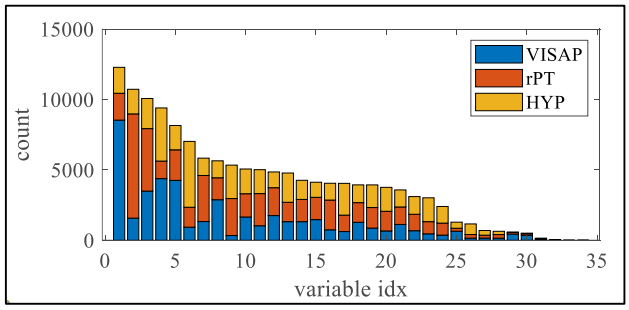

Figure 1. Stacked cumulative frequencies of best model variables.

CONCLUSIONS

This study links clinical, imaging, and functional metrics that may benefit a multi-modal screening tool for athletic populations at risk for PT.

Future work should focus on pre- to post-season changes and development of better statistical power.

BIOMECHANICAL KNOW-HOW OF LEARNING BICYCLE KICK AND JUMPING SIDE VOLLEY IN SOCCER

Gongbing Shan
Department of Kinesiology, University Lethbridge, Lethbridge, Canada.
Email: g.shan@uleth.ca

INTRODUCTION

In soccer, both bicycle kick and jumping side volley have provided viewers breathtaking moments that seem virtuosic in scope. Since the establishment of FIFA Puskás Award (the aesthetically significant goal of the year) in 2009, goals achieved by the two soccer socoring techniques (SSTs) have been nominated 31 times by FIFA nomination committee, 21.7% of all nominees [1]. Yet, the two kicks are biomechanically under-studied and, even worse, there is a dearth of biomechanical approach on their learning and training. Relying on the talent of athletes to improvise on the kicks can hardly be considered as a viable learning method [2]. The current study aims to provide biomechanical know-how of learning the two acrobatic SSTs.

METHODS

Using 3D motion capture technology and full-body biomechanical modelling, key features of the two SSTs were quantified, and hereafter, their motor sequencing were identified. The identified motor control uniqueness was applied to design a training program for learning the two SSTs at college-level players.

RESULTS AND DISCUSSION

Bicycle kick is a back-facing-goal, overhead kick performed in the sagittal plane [3]; whereas jumping side volley is a side-facing-goal, side kick performed in the transversal plane [4]. Both SSTs can be divided into three phases: jumping, airborne and landing (Figure 1).

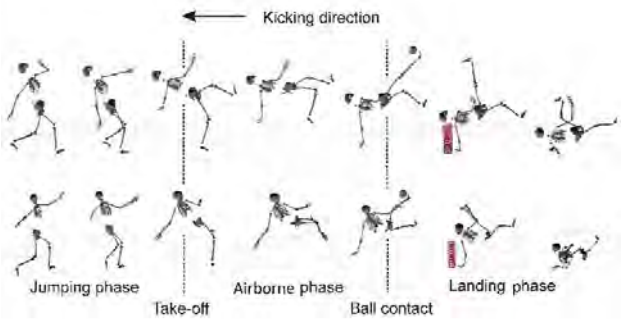

Figure 1 3D quantification of bicycle kick (top) and jumping side volley (bottom).

The 3D kinematics revealed the following features. **For bicycle kick**: 1) Just before take-off, non-kick side leg moved up toward the athlete's chest, as the trunk reached a horizontal position. 2) In airborne phase, two control characteristics – bicycle-like legs' control and whip-like kick-leg control – were identified. 3) During landing, damping the impact force during falling was achieved through an arm-hip landing, i.e. sharing the load using a sequence of partial landings (Figure 1, top). **For side volley**: 1) Before jumping, athletes' trunk and hips rotated away from the goal, and during the take-off, the non-kick leg was raised while the trunk and hip reversed rotational directions and came to twist toward the goal; at the same time, the trunk approached a more horizontal position. 2) While airborne, the kicking foot followed a smooth rainbow-like trajectory accompanied by continuous body rolling towards the goal. 3) Dispersion of landing impact is accomplished through an arm-hip landing strategy (Figure 1, bottom).

Based on the biomechanical quantification, we designed a reversed training method (i.e. landing training first) and applied successfully in college-level training. Eleven students mastered the two SSTs (Figure 2).

Figure 2 Repetitive kick training (top: bicycle kick, bottom: jumping side volley) with biomechanically proper landing technique.

CONCLUSIONS

Due to the fact that repetitive practice will not happen without a proper landing technique to prevent injuries, the learning of the two SSTs should begin with the last phase – landing. Mastering a safe landing technique is the foundation that can ensure repetitive practice to improve kick quality.

INTRODUCTION

Compared to males, females have a higher risk for suffering a non-contact anterior cruciate ligament (ACL) injury [1]. ACL injury prevention programs appear to lack game specificity, and relationships between knee loading, technique, and performance have rarely been reported. This study aimed to determine if a handball-specific ACL injury prevention program can lower knee joint loading while enhancing performance and optimizing cutting techniques in females.

METHODS

Full-body kinematics (Qualisys, 200 Hz), ground reaction forces (AMTI, 1000 Hz), and sprint performance (1080 Motion, 333 Hz) of 51 female handball players performing a 180° change of direction task (CoD) were captured at baseline (T0). Athletes approached from 5 m, performed a 180° turn, and returned with game-like intensity. Following baseline testing, 23 athletes (INT) (17 ± 1 years, 1.71 ± 0.06 m, 69.9 ± 10.6 kg) returned for post-testing (T1). INT were assigned to a nine-week intervention program, including hip and calf muscle strength and cutting technique training, focusing on forefoot landing and avoiding knee valgus. The remaining 28 athletes (CON) continued their regular training. After nine weeks, 20 INT (17 ± 1 years, 1.76 ± 0.06 m, 70.8 ± 8.3 kg) and 20 CON athletes returned. The external peak knee abduction moment (KAM) within the first 60 ms after touchdown was used as an injury risk metric. Changes in cutting technique were determined using the center of mass velocity and knee valgus angle at touchdown and ground contact time. CoD performance of the athletes was assessed using the average approach (start to 180° turn) and exit (180° turn to start) speed and the total time. Mixed-rANOVAs (group x time) were used (α = .05) to assess differences between the time points, groups, and their interaction.

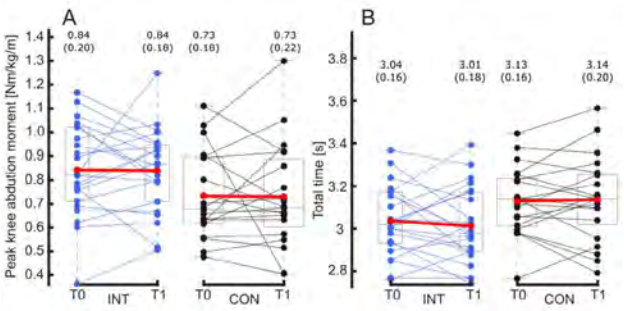

Figure 1: Peak external knee abduction moment (A) and total time (B) for the control and intervention group at T0 and T1.

RESULTS AND DISCUSSION

No KAM changes were observed in either group over time. In the INT group, half of the athletes reduced KAM while the other half increased KAM, resulting in no changes on average. INT had significantly greater KAM (T0 and T1) than CON (Fig.1A, Tab.1). Changes in cutting technique were similar in both groups. From T0 to T1, the average approach speed significantly increased in INT (2%) and decreased (-2%) in CON ($p_{interaction}$ = .03). Both groups showed lower exit speeds at T1 than at T0 (p_{time} < .001). No improvements in the total time (Fig.1B) were observed for either group (p_{time} and $p_{interaction}$ > .05) .

CONCLUSIONS

The handball-specific ACL prevention program tends to improve technique and performance without affecting KAM during CoD. A longer intervention period might be required to induce reductions in KAM and further improve technique and performance.

INTRODUCTION

Jumping is one of the most fundamental lower body movements among sports [1]. Jump tests can also be used to assess lower body performance for athletes and patients. The identification of reference values for jump tests may help clinicians to evaluate the risk of lower extremity injuries or readiness to return to sport after injury. For example, single-leg jump tests can be prognostic for future knee-related outcomes in individuals after ACL injury [2]. To date, no reference values for spatiotemporal variables in healthy people are available in the scientific literature. Our study aimed to present sex-stratified reference values for spatiotemporal variables in healthy adults via insole-embedded inertial measurement units (IMUs).

METHODS

One-hundred and eighty-seven healthy participants wore insole-embedded IMUs and performed the following jump tests: consecutive countermovement jump (CCMJ), cyclic jump (CJ), single-leg jump for distance (SLJD), and single-leg jump for height (SLJH). Outcomes included: relative strength index (RSI), average jump height (AJH), maximum jump height (MJH), and maximum jump distance (MJD). Statistical differences between sexes were tested using an independent samples t-test.

RESULTS AND DISCUSSION

Eighty-nine females (age: 42.3±11.6 y; height: 1.68±0.06 m; mass: 62.4±9.2 kg) and ninety-eight males (age: 41.4±12.5 y; height: 1.81±0.06 m; mass: 76.7±8.9 kg) completed all jump tests and were included in the analysis. The reference values for all participants are presented in Table 1, stratified by sex. There were significant differences between males and females in all jump outcomes (p<0.05). Specifically, the maximum and average jump height and distance of males were significantly greater than females. There was no statistical difference in asymmetry values of SLJD and SLJH between sexes (p>0.05).

CONCLUSIONS

Our study presents reference values for healthy males and females for the most common jump tests. These values can be used to assist clinicians to screen for lower body sports injuries and assess athletes for return to sport following injury. We found that Males demonstrated greater average and maximum jump heights and distances compared to females. Our results agree with previous studies, which found that absolute force and power measurements were higher in males compared with females [3]. Interestingly, the previous study stated that females might be more prone to producing forces asymmetrically than males in countermovement-jump and squat-jump tasks [4]. However, our outcomes show that males and females did not differ in asymmetry values of single-leg jumps for height and distance. This inconsistency might be because previous findings were based on double-legged hops, but our asymmetric conclusions were based on single-legged hops.

Table 1. Outcomes for all jump tests stratified by sex (n=187).

ASSOCIATIONS OF ROTATIONAL RANGE AND STRENGTH OF SHOULDER WITH REGARD TO ELBOW VALGUS STRESS DURING PITCHING IN YOUTH BASEBALL PLAYERS

Yu-Chun Lin[1], Yang-Hua Lin[1], Chih-Hao Chiu [2], Hsiao-Yun Chang[3], Cheng-Yu Chen[4], Po-Tsun Chen*[1,2]

INTRODUCTION

Medial elbow pain occurs frequently in youth baseball players[1]. The injured elbow demonstrates instability when bearing high stress during pitching [2], which may be related to the unbalanced strength of rotator cuff and periscapular muscles and the restriction of range of motion (ROM) in shoulder [3]. However, there was no study to show the changes of medial elbow after improving restricted ROM and imbalanced strength of the shoulder in youth baseball players. This study aimed to analyze the effects of twelve-week conditioning exercise for shoulder on the stress of medial elbow during pitching in youth baseball players.

METHODS

Sixteen male youth baseball players (mean age 10.4±0.7 years) were recruited. All the participants received the evaluations before and after the conditioning exercise, including ROM and strength of shoulder external and internal rotation (ER and IR), the strength of periscapular muscles, ball speed, and elbow valgus torque (Nm), arm speed (rpm), and arm slot (°) during pitching. The twelve-week conditioning exercise included scapular stabilization training, rotator cuff resistance training, and stretching exercises for shoulder. Pair-t test was used to compare the outcomes before and after twelve-exercise. The level of statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

After exercise, both ROM and strength of ER and IR were increased significantly. The increases in strength of middle deltoid and lower trapezius were noticed. The ball speed after exercise was faster significantly than before exercise. A significant increase in arm speed and a decrease in arm slot were also found during pitching, while elbow valgus torque was not altered after exercise. Although the less am slot may lead to the risk of an elbow injury, the normal arm slot was reported between 43-49°[4]. The increases in shoulder strength and ROM after twelve-week exercise may allow players to pitch with bearing higher stress.

CONCLUSIONS

Conditioning exercise for shoulder can improve the imbalance in ROM and strength of shoulder in youth baseball players. The elbow valgus stress is not only affected by shoulder movement, but the correctness of movement chain during pitching also plays a critical role. For reducing valgus, the components of pitching technique may also be integrated into training exercise to correct the pitching mechanics.

INTRODUCTION

In cold environments, heat dissipation from the body surface decreases the muscle temperature (Tm), which inhibits muscle contraction and reduces jump performance [1]. Warm-up (WUP) is important to avoid Tm reduction and improve performance. However, there have been no reports on the effects of cold exposure and subsequent WUP on jump performance using ground reaction force (GRF). Therefore, this study aimed to examine the effects of cold exposure and subsequent WUP on Tm and jump performance.

METHODS

Thirteen healthy male college students (age: 21.4 ± 1.2 years) participated in this randomised crossover design study. This experiment was conducted in a laboratory and the temperature was set at 10°C or 24°C. The participants sat and rested for 30 min. The Tm of the vastus lateralis and CMJ were measured on a portable force plate (Ex-jumper, DKH Inc., Tokyo, Japan) before and after the WUP. The WUP intensity was set at 60% of maximum oxygen uptake. The GRF data before and after the WUP with the maximum jump height were used for further analysis. CMJ phases were attributed to the following three phases: unloading, eccentric, and concentric phases using GRF data and centre of mass (COM) velocity obtained by the time integral of acceleration [2]. Jump height was calculated using the following formula:

$$(\text{Jump height}) = (\text{Takeoff velocity})^2 / (2 \times 9.81)$$

The peak, braking, and unloading GRF were defined as follows: maximum GRF during CMJ, GRF at the end of the eccentric phase, and minimum GRF during CMJ, respectively. Peak power was defined as the maximum power during CMJ (GRF×COM velocity). The net eccentric and concentric impulses were calculated using the time integral of the GRF above the system weight during the eccentric and concentric phases. The duration of each jump phase was calculated as the time spent in the jump phase. A two-way repeated ANOVA or Friedman test with Bonferroni correction as a post hoc test was conducted. A p-value < 0.05 was considered statistically significant.

RESULTS AND DISCUSSION

Muscle temperature significantly increased after the WUP in both conditions ($p < 0.05$), although there was no significant difference between the conditions. Jump height, peak GRF, peak power, and net concentric impulse increased after WUP in 24°C conditions, and jump height, net eccentric, and concentric impulse increased after WUP in 10°C condition ($p < 0.05$). Peak GRF after WUP in 24°C was significantly higher than that after WUP in 10°C ($p < 0.05$). The unloading and braking GRF did not change after WUP or between conditions. However, the phase times did not change significantly. Cold exposure and WUP may affect Tm, jump height, and GRF-related variables in the concentric phase (i.e. concentric muscle contraction). Hence, cold exposure and WUP may not affect certain GRF-related metrics during the unloading and eccentric phases of eccentric muscle contraction or the jump phase time.

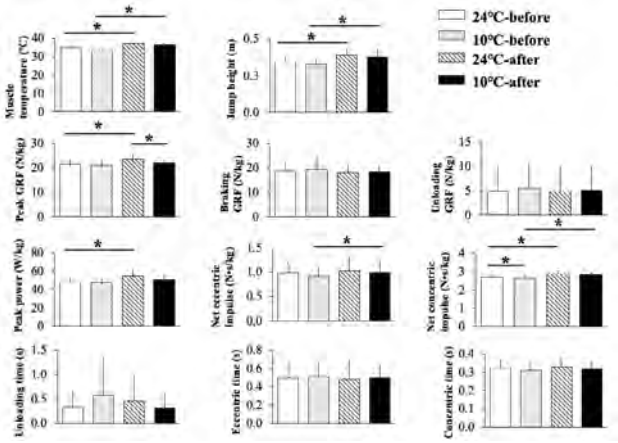

Figure 1. Comparisons between ambient temperature conditions and before and after WUP; * significance less than 0.05

CONCLUSIONS

Cold exposure and WUP may affect force output during jumps but not kinematics. Cold exposure may decrease the effects of WUP on jump performance. Further research is necessary to clarify the relationship between ambient temperature and athletic performance enhancement after the WUP.

INTRODUCTION

The scrum is a rugby union set piece used to restart play after a rule infringement or stoppage. Whilst scrum injury incidence appears to be less than that of other rugby activities, the mean severity of injury appears to be relatively high [1], with the front-row players being most susceptible [2]. Experimental investigation with risk of injury to participants is unethical but insilico methods allow for simulation of injurious scenarios without fear of harm. Investigation of the forces acting on players within the scrum may allow researchers to better understand the mechanisms of injury. However, directly measuring forces in-field is currently impossible. Thus, the aim of this study was to create a scrum-based contact model of the shoulder to investigate forces experienced by the front-row.

METHODS

Coordinate data [3] of live scrums was used to inform the kinematics of an OpenSim 5-sphere contact model (Figure 1) representing the shoulders of front-row players. Contact forces were described via Hunt-Crossley formulations. Data from five different shoulder-to-shoulder impacts were used to optimise for stiffness, dissipation, and 3D sphere positions, minimising the error in simulated peak forces. Forces were compared to live force data [3] from Tekscan pressure sensors (model 3005) placed on the front row players' shoulders. Median parameter values across trials became the final model. For preliminary evaluation of the model, forward dynamic simulations were constructed with only the pelvis x-translation. Initial states (positions and velocities) and controls (accelerations) were derived from the 5 original trials (training set), and 3 new trials (test set). The mean absolute peak error between the live and simulated force across trials was calculated.

RESULTS AND DISCUSSION

All data sets produced mean absolute peak force errors comparable to those of Tekscan pressure sensors during impact events [4] (Table 1). However, an error of 254N is considerable and the data exhibited a large mean time to peak error (12% of simulation duration). Although the sensors' sampling frequency (500Hz) may be limiting, a major limitation of this study is potential errors in transcribing kinematics to the model. Exact points of reference for the coordinates were unknown so these were approximated to anatomical landmarks, potentially affecting penetrations of the contact spheres, and generating aberrant forces.

Table 1. Comparison of mean Absolute Peak Error and Absolute Time to Peak Error between Data Sets and TekScan Sensors [4]

	Peak Error (N)	Time to Peak Error (s)
Training Data (n = 5)	207 ± 90.8	0.170 ± 0.307
Test Data (n = 3)	331 ± 285	0.0991 ± 0.0384
All Data (n = 8)	254 ± 179	0.143 ± 0.236
Tekscan Sensor	320 ± 228	N/A

Moreover, pressure data provides the sum of absolute forces applied to the sensor in the normal direction (direction of travel). Thus, only simulated forces acting along this axis can be used. Furthermore, forces applied to the sensor are assumed to be evenly distributed in each direction of application, so the current model can only be used when acceleration is zero (initial impact). The model also lacks ground reaction forces, limiting predictions of the scrum's 'sustained push' phase. Next, more data and relatable kinematics with net forces may improve the model.

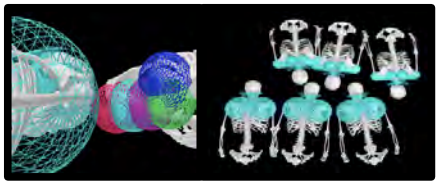

Figure 1: The Contact Model and Full Model

CONCLUSIONS

This study is a first step, supporting the possibility of replicating peak force to the standard of wearable technology. However, it is the hope of the authors to strive for a model encapsulating all force characteristics of the scrum with implications for acute and chronic injuries.

EFFECT OF DIFFERENT SPEED IN ECCENTRIC PHASE IN SQUAT PROTOCOLS ON HIP FLEXORS AND EXTENSORS ACTIVATION

Anna Pisz[1], Dominik Kolinger[1], Michal Wilk[1,2], Michal Krzysztofik[1,2] and Petr Stastny[1]

INTRODUCTION

Many studies have used the squat as a trigger to induce post activation potentiation and evaluated its effect on strength and power performance due to its wide application by practitioners and researches [1]. However, different movement speed during squat might affect the results [4]. Although there are studies supporting the use of eccentric loading as a conditioning activity [2], there is still missing evidence supporting its effect on the hip flexors/extensors with manipulation of time under tension.

METHODS

16 professional male handball players (age 16.5 ± 1.2 years; body mass 79.8 ± 9.9 kg; height 184 ± 6.5 cm; personal body fat 10.3 ± 5.2 %; 3RM 74.1 ± 19.1 kg) participated in the study. During familiarization session, each subject underwent a 3RM front squat assessment and was introduced to the experimental protocols. After the first visit, subjects returned to the laboratory on 2 occasions separated from each other by 2 to 5 days. In one session, 90% 1RM front squats at a maximum speed with plyometric effect were used as a conditioning activity, where subjects performed the exercise individually. In the other session, an eccentric load of 120% 1RM in the front squat was used as conditioning activity, where the downward movement lasted 2 seconds, and assistants helped lift the weight to the starting position. In both protocols, the total number of repetitions of the conditioning activity was 3. The order of the protocols was randomly selected. Each session began with a standardized warm up protocol, after which subjects performed 3 repetitions of hip flexion/extension with 180°/s speed on Biodex Isokinetic Dynamometer laying in supine position, that served as baseline (Pre). Two minutes after the baseline measurement, the subjects started conditioning exercise according to the chosen protocol. Post measurements, the same as Pre, were recorded respectively at 5th, 7th and 9th minute after the end of the conditioning activity.

RESULTS AND DISCUSSION

Significant improvement in peak torque for concentric hip flexion (Flex_Con) ($p = 0.02$), eccentric hip extension (Ext_Ecc) ($p = 0.04$) and for concentric hip extension (Ext_Con) ($p < 0.01$) were detected compared to baseline in both groups, only in eccentric hip flexion (Flex_Con) there was not significant improvement observed after conditioning activity in both protocols ($p = 0.43$) (Table 1). No significant differences were detected between the protocols.

CONCLUSIONS

Based on the results it can be concluded that both eccentric loading front squat and front squat perfomed at a maximum pace shows similar improvements in concentric hip flexion/ extension and eccentric hip extension. Therefore, practitioners can use both protocols interchangeably as a tool to induce post activation potentiation with the purpose to enhance hip strength.

SAGITTAL PLANE LOWER EXTREMITY BIOMECHANICAL RESPONSE TO SOCCER CLEAT STUD LENGTH DURING A CUTTING TASK

Emily Karolidis[1], Michael E. Hahn[1]
[1] Department of Human Physiology, University of Oregon, Eugene, USA.
Email: ekarolid@uoregon.edu

INTRODUCTION

In the sport of soccer, anterior cruciate ligament (ACL) injury incidence is 3x higher in female athletes than male [1]. Unique to females, dynamic control patterns of the knee joint demonstrate quadriceps dominance, where developmental imbalances tend towards greater knee extensor strength, recruitment, and coordination [2]. This unmatched strength ratio in the knee joint stabilizers tends towards altered sagittal plane mechanics, subjecting the female knee to greater ACL loading and overall injury susceptibility. Despite mechanical differences between sex, soccer footwear is designed for males. High traction footwear may exceed ligament loading capacity, exacerbating female risk of ACL injury [3]. Due to body mass differences between sex, traction may be unsuitably high due to excess stud length. The purpose of this study is to determine the effect of soccer cleat stud length on female athlete knee mechanics and muscle activity. It is hypothesized that there is an ideal zone of stud length (50-75% original length) that produces more favourable knee mechanics.

METHODS

Four pairs of Nike Mercurial soccer cleats (women's 7.5) were tested, three pairs of which were abraded to a stud length of 25%, 50% and 75% of the original (control). Contact surface area matched the control condition. Seven competitive female soccer athletes, age 21 ± 1.3, weight: 58.4 ± 4.3 kg, height 166.8 ± 3.2 cm performed cutting tasks in an indoor turfed facility in accordance with IRB approval. Consenting athletes performed 6 cuts (80% maximum speed to 120° cut, 3 trials each direction) in each condition. Cut direction and footwear condition order were randomized.

Trajectories of 18 retroreflective markers were collected with an 18-camera system (Vicon, 100 Hz), and ground reaction force data were collected using 4 force platforms (AMTI, 1500 Hz). Surface electromyography (sEMG) (Noraxon DTS, 1500 Hz) recorded biceps femoris (BF) and vastus lateralis (VL) activity on the right limb. The sEMG signals were bandpass filtered (3-500 Hz, 4th order Butterworth), full-wave rectified, linear enveloped (6 Hz) and normalized to maximum dynamic contraction magnitude (control shoe). Integrated EMG (iEMG) analysis was performed from initial foot contact until peak flexion, standardized to 0.5 s. The ratio between VL and BF iEMG was compared, representing knee stabilizing muscle involvement. Peak knee flexion and internal knee extensor moment at peak flexion were calculated using the Plug-in-Gait model. Repeated measure ANOVAs were used to detect differences in knee flexion, extensor moment, individual iEMGs and ratios across conditions (α=0.05).

RESULTS AND DISCUSSION

Table 1 presents descriptive statistics of knee mechanics and muscle activity, with green colour fill denoting preferred mechanical landing strategy [3]. No statistically significant differences in knee flexion, extensor moment, iEMG muscle summation of VL or BF nor iEMG ratio were found across conditions. However, preferred mechanics were most often found in the 50 and 75% stud length conditions, encouraging greater knee flexion, reduced extensor moment, reduced quadriceps and increased hamstring contributions, and a preferential ratio of knee stabilizer muscle activity in favour of the hamstring muscle.

CONCLUSIONS

While this research does not provide definitive conclusions on the relationship between stud length and female knee mechanics, it does offer suggestive evidence that a reduction of stud length holds potential in reducing knee loading during cutting tasks.

INTRODUCTION

The take-off phases of the pole vault are final touchdown (TD), pole plant (PP), and final take-off (TO) [1,2]. The purpose of the take-off phase of the pole vault is to reduce the decrease in horizontal velocity; the impact that occurs during PP has been found to decrease horizontal velocity. In addition, a study of elite athletes reported that they exhibited PP in the late ground phase [1].In the take off posture, it has been reported that the upper grip, during PP, can be raised higher overhead to increase the bend of the pole [3].From these results, PP appears in the late ground contact phase in pole vault take off, and it is important to reduce the deceleration of horizontal velocity and increase pole bending by increasing the grip height during PP.
However, there are no studies on the timing of PP and take-off posture in Japanese pole vaulters, nor are they explicitly stated in the guidelines[4]. This study aims to clarify kinematic and kinetic characteristics during the Take-off Phase, for Japanese pole vaulters including top-class Japanese athletes.

METHODS

This study was conducted with seven male pole vaulters (PB: 5.46 ± 0.23 m, height: 178 ± 4.7 cm, weight: 70 ± 5.2 kg). Athletes ranged from those who had competed in World Championships to those who had competed in regional competitions. Participants performed five trial runs, each with the same number of preparatory strides as in an actual competition. The trials were captured using a three-dimensional motion analysis system (VICON) to acquire three-dimensional kinematic data. Ground reaction forces (GRF) during the Take-off Phase were recorded using a force plate (KISTLER) situated underneath the runway and box. The three-dimensional kinematic data were filtered at 10-12 Hz using a fourth-order Butterworth low-pass filter after determining the optimal cut-off frequency. The analysis was performed from the crossing (TD) to the height of peak gravity (HP), as determined from the best trial run in the subjective evaluation. The GRFs were defined as anterior/posterior (Fy), mediolateral (Fx), and vertical (Fz).

RESULTS AND DISCUSSION

Ground contact time showed a similar trend among subjects.Vertical GRF at TO was high (13.2 N/BW) at the beginning of contact and then decreased toward TO. Athlete A considered the top performer, exhibited the greatest propulsive GRF (0.5 N/BW) compared to other athletes. The time of TD to PP varied among subjects, but athlete A arrived at PP when the peak propulsion GRF of the stance leg was achieved (as indicated in Table 1). Athlete A had a higher grip height and center of mass height at PP compared to other athletes and was nearly at the same height as at TO, but the horizontal distance between their toes and the upper grip at PP tended to be shorter than that of other athletes (Table 1). Athlete A demonstrated a propensity to have a higher horizontal velocity of the center of mass at TO, with PP appearing later in the contact phase, consistent with previous research. Nonetheless, some athletes, such as Athlete E, exhibited a high horizontal velocity of the center of gravity at the time of release from the ground even though their PP appeared in the first half of the ground contact, suggesting an exceptional ability to bring the PP forward in the initial half of contact phase to enhance the horizontal velocity of the center of mass at TO.

Table 1: Comparison of variables for each subject (n=7)

Variables	Unit	A	B	C	D	E	F	G
HP	(m)	5.38	5.26	5.19	5.11	4.99	4.94	4.78
Contact	(s)	0.11	0.12	0.11	0.13	0.12	0.11	0.12
TD-PP	(s)	0.088	0.088	0.036	0.076	0.12	0.084	0.068
Fy@PP	(N/BW)	0.5	-1.3	-1.3	0.2	0.0	0.1	-0.7
Fy@Propulsive peak	(N/BW)	0.5	0.2	0.3	0.4	0.3	0.3	0.3
Grip height@PP	(m)	2.20	2.11	2.02	2.09	2.16	2.08	2.17
COM height@PP	(m)	1.18	1.12	1.07	1.16	1.23	1.14	1.17
Grip height@TO	(m)	2.22	2.16	2.11	2.15	2.17	2.13	2.24
COM height@TO	(m)	1.22	1.29	1.21	1.24	1.24	1.21	1.30
Grip height(TO-PP)	(m)	0.02	0.05	0.09	0.07	0.01	0.05	0.08
COM height(TO-PP)	(m)	0.04	0.17	0.14	0.08	0.01	0.07	0.13
Horizontal velocity@TO	(m/s)	8.02	6.86	7.19	6.88	7.49	6.85	6.64

CONCLUSIONS

Most of the Japanese pole vaulters' times at PP appeared in the braking phase. Top athlete A's time at PP was near the maximum value of propulsive ground reaction force at take off. It was also considered that a shorter horizontal distance between the upper grip and toe during PP would result in a higher grip height.
From these results, it was considered that reaching the time of PP at the point of maximum propulsive ground reaction force would reduce the deceleration of the horizontal velocity of the center of gravity, and that the higher the grip height at PP, the greater the pole bend

A new approach to evaluate the ACL risk of re-injury after reconstruction

Sahar Ostadrahimi[1], Siavash Kazemirad[1, *]
[1] School of Mechanical Engineering, Iran University of Science and Technology / Tehran, 16846-13114, Iran.
[*]Email: skazemirad@iust.ac.ir

INTRODUCTION

The second anterior cruciate ligament (ACL) injury is very propable in professional football players in both the ipsilateral and contralateral legs [1]. In order to enhance the injury prevention and rehabilitation programs, different test procedures have been proposed to determine whether or not an athlete is ready to return to sport after the ACLR. These test procedures, however, typically lack validation [2]. Therefore, there remains a need to develop effective screening test procedures to identify athletes at the risk of a secondary ACL injury. The aim of this study was to propose a return-to-sport procedure to prevent the athletes from a second ACL injury.

METHODS

Six professional football players which three of them experienced the ACL reconstruction (ACLR) performed the gait test. It is worth mentioning that all three ACLR subjects experienced the ACL injury in their dominant leg. All subjects performed the gait test in the Gait Analysis Laboratory. The muscle activation force, knee joint kinetic and kinematic parameters, and ACL loading were obtained by the Opensim musculoskeletal analysis. Then we present an index for assessing the risk of the second ACL injury in professional football players after the reconstruction by comparing the maximum ACL graft force during the gait cycle and the intact ACL ultimate tensile load were used. The suggested criterion for the classification of the ACL health status for the injured and non-injured leg was called the ACL injury risk index (IRI).

RESULTS AND DISCUSSION

The possibility of the ACL re-injury of the subjects tested was obtained through the proposed IRI. Figure1 illustrates the mean value and standard division of the IRI for both aACL and pACL bundles for the dominant and non-dominant legs in the ACLR and control groups. According to Figure 1, it was observed that the IRI value was significantly higher in the ACLR group compared to the control group for both aACL (p=0.015, 99%) and pACL (p=0.006, 99.8%) bundles. The increase in the ACL force of the ACLR group may be explained by the changes in the muscle activation force and the knee contact force after the ACLR. It was also noted that the mean IRI was higher for the non-dominant (contralateral) leg in both the control and ACLR groups, which may be due to higher knee contact forces that caused higher ACL loading. Using the proposed IRI and observations made on the ACLR and control football players, the observations of other researches that indicated an increase in the ACL injury risk for both the dominant and non-dominant legs after the ACLR was confirmed [3].

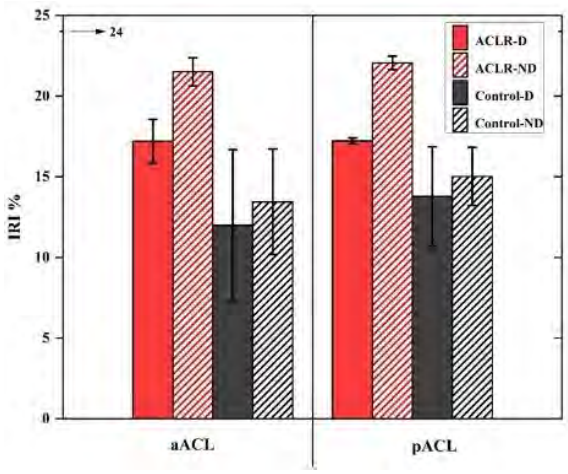

Figure 1 The mean value of IRI for the ACLR and control groups.

CONCLUSIONS

An injury risk index which was proposed in this study based on the maximum ACL force during the walking gait cycle to identify the football players under the re-injury risk. The results of this study in the comparison of the ACL bundles loading during the gait tests in football players control and ACLR groups indicated the lack of proper rehabilitation of the lower limbs rehabilitation in the recovery programs after the reconstruction. The new approach can be used in a new return-to-sport procedure which takes into account the ACL loading for both the injured and contralateral legs. It may help physicians to prescribe specific recovery programs for both legs of football players and reduce the risk of re-injury. The obtained results also suggested that the proper rehabilitation of quadriceps and gastrocnemius muscles is required in the recovery programs after the ACLR for reducing limb asymmetries.

Effect of resin on ball velocity of the step-shooting in female handball players

Aoi Fujimoto[1] , Tsuyoshi Iitake[1], and Hiroyuki Nunome[2]
Graduate School of Sports and Health Science, Fukuoka University, Fukuoka, Japan[1],
Faculty of Sports and Health Science, Fukuoka University, Fukuoka, Japan[2]

INTRODUCTION

In handball, the use of resin as an non-slip material has been permitted by the rules and has become the standard in national and international games (International Handball Federation [IHF], 2022; rule3:2). To date, only a few studies have focused on the effect of resin on handball shooting. Sasakura et al (1982) reported that the use of resin had an apparent effect to increase initial ball velocity in handball jump shooting of male players. However, it is still unknow whether the use of resin enhances the resultant shooting velocity in female players. Although female players allowed using a smaller size of the ball by the rules, their relatively weaker grip strength might disturb a firm gripping of the ball (Japan Sports Agency, Physical Fitness and Athletic Performance Survey, 2021). We hypothesed that the use of resin would provide famele players a better grip of the ball, thereby inducing a faster resultant shooting velocity. The purpose of the presenty study was, therefore, to assess the effectiveness of resin on the resultant shooting velocity of female handball players.

METHODS

Nine university-level female handball players (age:20 ± 1.3 years, height: 160.6 ± 3.6 cm, weight: 58.0 ± 4.8 kg) participated in the present study. The participants were asked to perform five step-shootings with and without resin, respectively.

The three-dimensional coordinates of the shooting arm (prefered side) were captured by a 12 camera optoelectronic motion capture system (Vicon, VANTAGE) at 500 Hz. Geometric center of the ball was estimated from five markers attached on ball surface using the least square technique. The ball velocity was obtained from the first derivative of the raw trajectory of the ball center in the anterior-posterior direction.

Statististical comparison was conducted for the initial ball velocity between the two conditions using a paired t-test ($p < 0.05$) and Cohen's d was used to calculate the effect size and evaluated as trivial (0–0.19), small (0.20–0.49), medium (0.50–0.79) and large (0.80 and greater) .

RESULTS AND DISCUSSION

The initial ball velocity of with resin (19.4 ± 1.0 m/s) was significantly higher than that of the condition without resin (18.5 ± 0.9 m/s) with a larger effect size ($p = 0.001$, $d = 0.84$). Figure 1 shows the average (± SD) changes in the ball velocities with and without resin. The difference in the ball velocities between the two conditions was not appreciable until 80% of the normalized time, and then, the difference became apparent in the latter half of the shooting motion (80–100% of the normalized time). It can be seen that the use of resin may increase resultant shooting velocity of female handball players. In addition, the relative linear velocity between ball and third metacarpal head at ball release with resin (4.4 ± 0.5 m/s vs. 4.8 ± 0.6 m/s) was significantly larger than that of without resin with a large effect size ($p = 0.02$, $d = 0.9$). This finding suggested that the use of resin made some differences regarding the contribution of wrist and/or finger movements to increase ball velocity.

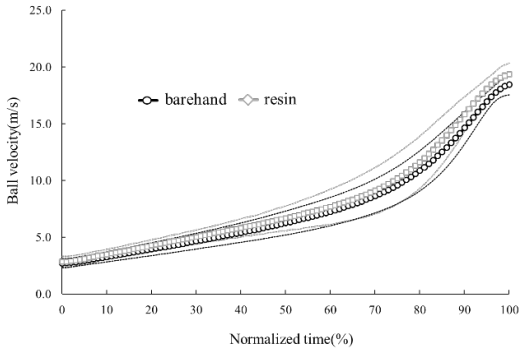

Figure 1: Average ball velocity changes with and without resin.

CONCLUSIONS

In handball, the use of resin as an non-slip material demonstrated a significant effect to increase resultant shooting velocity of female players. The use of resin most likely enchances the contribution of hand motion to ball velocity during the final phase of shooting.

Email: wttang@gmail.com

INTRODUCTION

Japanese Shinai kendo evolved into an athletic-centered sport in the 1950s from its mid 16th century origin. Unlike traditional kendo, which focuses on defeating enemies, athletic kendo focuses on acquiring valid strikes. This difference in purpose may lead to the development of differentiated striking movements in athletic kendo and also, the formation of "atekko kendo" [1]. This study aim to investigate the difference between the kendo movements of elite Kendokas (who practices traditional kendo), and elite tournament players (who practices athletic kendo). Focusing on the trajectory of the Shinai(bamboo sword), Shinai tip, and hilt, and the speed of the Shinai tip during the “men” strike (head strike), as it is the major wining area in athletic kendo.

METHODS

Four elite Kendo participants were recruited and grouped: two traditional Kendokas (learned kendo in Japan, 6th and 8th Dan, aged 60 and 70) as the “KR” group, and two tournament players (learned kendo in Taiwan, 3rd and 6th Dan, aged 24 and 34, one a 6th year national player, the other an national champion) as the “TR” group. This study was approved by the Ethics Committee, and all participants signed the consent form. Eight trials are collected after warm up and practice. The KR group performed Head Strike using traditional movements, and the TR group used athletic movements in tournaments. The striking movement is divided into 4 phases: preparation (Ph1), backswing (Ph2), acceleration I (Ph3), and acceleration II (Ph4) by 5 events: initiation with ground reaction force (T1), initiate of the shinai tip’s backswing (T2), end of the backswing (T3), the top of tip (T4), first contact on target (T5). Rear foot force was measured using AMTI triaxial force plate. Motion data are collected through the Motion Analysis System with 11 high-speed cameras (200Hz) and data processed through Cortex7.1. Forty nine reflective markers on the participant and 5 markers on the Shinai are attached according to manual. Motion trajectory were drew using Excel. Independent t tests was used and equality of variance was verified using the *Levene* test in SPSS 20.0 to compare shinai tip speed of the two groups.

RESULTS AND DISCUSSION

Regarding the movements of the Shinai tip, the results showed that in Ph1 (Figure1), only TR had a downward movement. Furthermore, in Ph2, the tip’s backswing distance of TR is smaller than KR. Then, in ph3 and ph4, the tip moved forward for both groups but only KR integrated an upward movement in ph3. For the Shinai hilt, the hilt moved forward for both group similarly in ph2~4. However, only TR have a similar downward movement in ph1 as the tip. These results illustrated TR tendency to initiate the striking movement by lowering the whole shinai, and with a smaller backswing in the ph1. KR however, did not initiate with the shinai, but with ground propulsion while holding the shinai still. Inferring that KR initiate the attack in a less prominent way, while TR initiate the attack with a forestall movement, conforming to the hypothesis. Table 1 showed the difference in the tip velocity of the two groups. KR has higher tip velocity at T1(V) and T4 (Vx, V), and TR had higher tip velocity at T2(Vz,V) and T3 (Vx, V). Yet, both groups have a similar tip velocity at T5. Table 1 also showed that tip velocity at T1 and T2 share a similar value for KR, while TR showed a increase in tip velocity from T1 to T2. Both groups showed the rise in tip velocity mainly from T3 to T4, demonstrating two different speed patterns contributing to the tip’s striking speed.

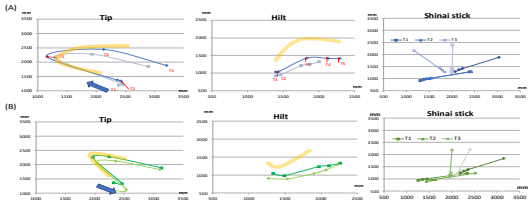

Figure 1. Tip, hilt trajectory and Shinai at 5 events (a) KR and (b) TR group.

CONCLUSIONS

Elite tournament players tend to lower the hilt first then up during preparation, followed by a small backswing of the tip, while traditional Kendokas tend to initiate with only foot propulsion and without moving the shinai to be less prominent. And despite the slower initiation and backswing speed, traditional Kendokas are capable of, through greater acceleration, reach striking speeds similar to that of elite tournament players on impact. Results testifies that traditional kendokas (averagely aged 65) are capable of reaching same striking speed as elite tournament players (averagely aged 30) using traditional kendo skill. Therefore, despite harder to master, more emphasis should be focused on traditional kendo skills in teaching.

Effect of different knee angles on hamstring muscle activity during Nordic hamstring exercise with a sloped platform

INTRODUCTION

Nordic hamstring exercise (NHE) is commonly prescribed for preventing hamstring injury [1]. Performing NHE on the incline slope of the lower leg support at 20° and 40° allows the participants to perform the movement through an entire knee angle [2,3]. Alteration of the knee and hip angle affects hamstring activity during hamstring exercise [2,3,4]. However, the magnitude of hamstring activity with changing knee and hip angle during NHE on incline slope planform is still unknown. Therefore, this study aimed to investigate an electromyographic (EMG) activity in the hamstring during NHE on incline slope planform with a variation of the knee and hip angle at isometric contraction to identify a preferable exercise for recruiting hamstring activity.

METHODS

Thirteen male volunteers performed NHE with three different knee extension (120°, 130°, and 150°) and three different hip flexion angles (0°, 30°, and 45°) goniometer was used to monitor the knee and hip joint angle for maintaining NHE at isometric contraction for 5 seconds. The electromyographic data obtained during each condition was normalized with the values collected during maximal voluntary isometric contraction of each muscle (nEMG). A multivariate analysis of variance with repeated measures using syntax was used to compare the normalized electromyography of each muscle across the different knee and hip angles. Significant main effects were followed up by Turkey post-hoc procedures. Significance was set at $P<0.05$.

RESULTS AND DISCUSSION

There was a significant main effect among the knee and hip angles for the BFl and ST ($p < 0.05$). There was an interaction between knee and hip angle for the BFl and ST ($p < 0.05$). The nEMG activity values during hip 0° for the BFl and ST at knee extension at 150° and hip 0° were significantly higher compared to the knee extension at 120°and hip 0° and knee extension at 130°and hip 0°($p < 0.05$). This might be explained by the fact that when the knee is extended to a greater extent with spine angle relative to the horizontal is increased and, hence, the force gravity moves away from the center of rotation of the trunk leading to an increase in gravity force.

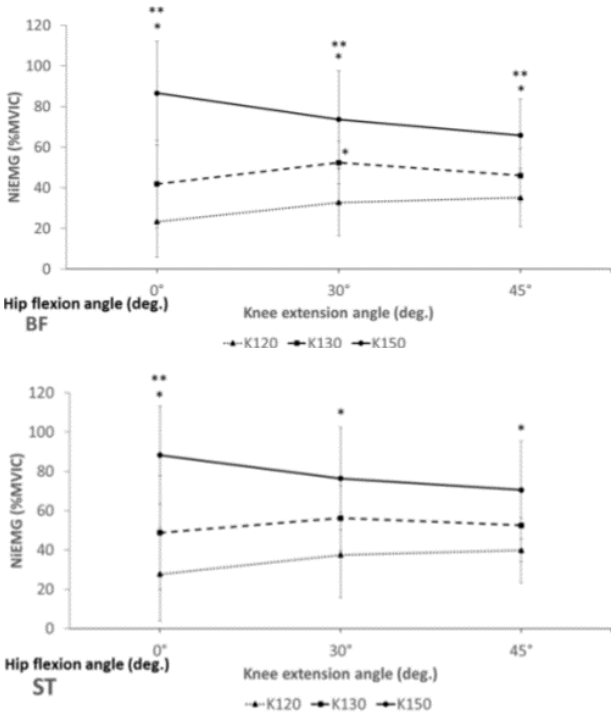

Figure 1 Differences in nEMG (%MVIC) activity during knee extension (120°, 130°, 150°) and hip flexion angles (0°, 30°, 45°) in the BF and ST muscles during isometric NHE on a sloped platform inclined at 30° The symbol * indicates a statistically significant difference between 120°and other angles. The symbol ** indicates a statistically significant difference between 130°and other angles.

CONCLUSIONS

The finding of this study showed that BFl and ST EMG activities during isometric NHE on the incline slop planform at 30° at knee 150° and hip 0° might be better for recruiting hamstring activity. However, it is still unclear in other degrees of incline slope planform.

ANGULATION OF HANDLE FORCE APPLICATION FROM THE CABLE DIRECTION IN ACHIEVING A TURN IN THE HAMMER THROW.

INTRODUCTION

Hammer throw is a continuous high-speed rotational motion that requires a large handle force application to accelerate the hammer head. The hammer acceleration is largely determined by the cable force [1], even with its small directional component to the hammer velocity [2] (Figure 1A). A hammer consists of a series of three segments: a handle, a cable (about 0.95 m long), and a hammer head (4.00 kg for females and 7.26 kg for males), with two torque-free ball joints. Under these structural constraints, the hammer head is driven only by the cable force in the cable direction, while throwers can control its magnitude and direction by exerting the handle force angled from the cable direction with couple of forces applied by their hands. Previous studies [1-5] have provided valuable insights into the cable force to accelerate the hammer head, while none of the insight into the handle force with angulation. Thus, we examined the angulation of the handle force and investigated its effect on the hammer movement during a turn that alternates hammer deceleration and acceleration. We hypothesized that hammer throwers exert the handle force with angulation to control the hammer movement.

METHODS

We analysed motion data of indoor hammer throwing from four male and four female throwers collected by a motion capture system (VICON-MX, 29 cameras, 250 Hz). The handle force–cable angle ($\theta_{H\text{-}C}$) was calculated from the motion data during the third turn and its significant difference from zero was assessed by a one-dimensional statistical parametric mapping (SPM1D) two-tailed one-sample *t*-test ($\alpha = 0.05$).

We simulated the hammer movement with and without $\theta_{H\text{-}C}$ to investigate its effect using a three-segment force-driven computer simulation, with its initial conditions matched with the experimental data.

RESULTS AND DISCUSSION

Hammer throwers exerted the handle force significantly angled opposite to the hammer velocity during the 59–68% time-segment of the turn, when the hammer was accelerated, with peak and mean $\theta_{H\text{-}C}$ of -0.83±0.33 and -0.12±0.073 deg (Figure 1B). This result supported our hypothesis. Brice et al. [2] showed that the cable direction relative to the hammer velocity determines whether the hammer accelerates or decelerates. We further added that the cable direction is controlled by the handle force with angulation. This finding expanded our understanding of possible options for hammer throwers to accelerate the hammer head with the cable force.

Despite the small $\theta_{H\text{-}C}$ (about 1 deg, Figure 1B), our simulation revealed that the handle force without angulation led to the hammer head moving out of the throwing circle (Figure 1C). This indicated that observed $\theta_{H\text{-}C}$ was small, and in the negative direction for the hammer acceleration, but essential to achieve the turn in the hammer throw inside a throwing circle with 2.13 m diameter. Theoretically, a small mass of the cable and handle means a small inertial resistance when controlling them toward the direction perpendicular to the cable. We suggest that hammer throwers achieve a continuous high-speed rotational motion under the highly directional sensitivity of a large handle force.

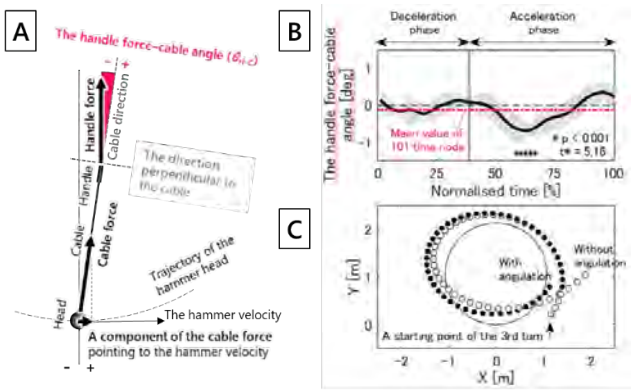

Figure 1 (A) Factors involved in hammer acceleration. (B) The handle force–cable angle $\theta_{H\text{-}C}$. The vertical line is a starting point of the hammer acceleration. (C) The hammer movements with and without angulation of the handle force (Blacked and whited circles, respectively).

CONCLUSIONS

Hammer throwers exerted the handle force with angulation, especially when the hammer accelerated. Despite its small value of around 1 deg, the simulated removal of the angulation moved the hammer head significantly outside the throwing circle. Hammer throwers may achieve a high-speed rotational motion under the highly directional sensitivity of handle force.

INTRODUCTION

Trampoline gymnastics requires athltes to performa 10 different acrobatic rouines in their flight phase. While difficulty and execution scores are resulted in their performance, flight height is prerequite of the higher scored somersaults. Therefore, the straight jump is the basic skill of trampoline gymnastics. From the view point of the conservation of energy, since their jumps are sometimes over 8m, it is easily assumed that large amount of reaction force acts to the athlete during his landing and pushing phases on the trampolin bed. This heavy reaction force might cause the great physical load to the athlete's lower extremities and their spine. The purpose of this study was to investigate and the quantify the kinematics and kinetics of the trampoline straight jump motion during the landing phase.

METHODS

The subjects were four top-level athletes who had been certified as S-rank designated athletes in trampoline competitions set by the Japan Gymnastics Association. The experiment was conducted in the Trampoline facility in Japan Institute of Sports Science. Twenty optical motion capture cameras (Vicon MX-T20 , 200Hz) were settle up around the trampoline target areas viewed from ground to 2nd/3rd floored catwalks. Fifty reflective markers were attached onto the subject's whole body. The inertial parameters of the subject were calculated using Ae's estimation equations [1].

RESULTS AND DISCUSSION

The authors hypothesized that trampoline jump is 2-dimensional motion on the sagittal plane, the whole-body joint forces and torques were solved by the inverse dynamics method using Newton-Euler equations from the distal end of the upper extremity and head during the landing phase. The bed reaction force (BRF) acting at the COP was estimated. For this calculation, the authors hypothesized COP location was at the middle of ankle and MP3 joint. BRF was also validated by using conservation of energy of subject's kinetic and potential energy on the trampoline bed. As the results, the stiffness of the trampoline bed might have a non-linear characteristic. The estimation of the reaction force at the ground contact point was tested using inverse dynamics and the conservation of energy law, but the results showed good agreement at low jumping heights, but not at high jumping heights and large reaction forces, suggesting a nonlinear spring. During leg extension on the bed, the body's center of gravity was always located in front of the ground point, and during the latter half of the jump, the body tilted backward due to the increased hip torque exerted, which was predicted to place a large burden on the lumbar spine.

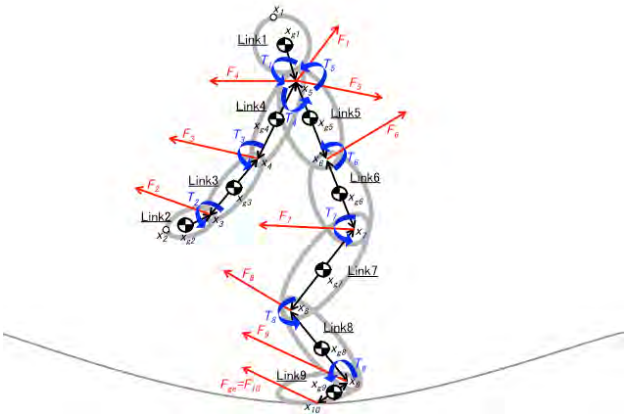

Figure 1 Two dimensional linked segment model of the trampoline athlete.

CONCLUSIONS

This study clarified the kinematics and kinetics acting on the lower limbs during straight jumps on the trampoline bed. It was suggested that the very large force acting on the lumbar spine during hip torque exertion in the latter half of the jumping motion may contribute to the low back pain observed in trampolinists.

THE EFFECTS OF FOOTWEAR ON THE PLANTAR PRESSURE UNDER THE METATARSAL HEADS DURING ROPE SKIPPING

Kaicheng Wu[1], Jun Li[1], Dongqiang Ye[2], Baoren Cao[2], Liqin Deng[1], Songlin Xiao[1], Weijie Fu[1,*]

Email: fuweijie@sus.edu.cn

INTRODUCTION

Rope skipping has grown in popularity recently as a simple and practical at-home exercise due to the gradual rise of the "home exercise" concept. Previous research has indicated that the peak pressure mainly occurred in the metatarsal heads during jump rope exercises [1]. Prolonged high plantar pressure during rope skipping may increase the risk of metatarsalgia and metatarsal stress fractures and lead to soft tissue degeneration [2]. Footwear serves as an interface between the foot and the ground to protect the plantar surface and modify the plantar pressure distribution. A shoe with thicker midsoles would reduce ground reaction forces during drop landing, as would a specially designed shoe. Therefore, the purpose of this study was to investigate the effects of footwear on the plantar pressure under the metatarsal heads during rope skipping.

METHODS

Sixteen healthy male college students with more than six years of physical activity (age: 25 ± 2.7 years, height: 175.77 ± 3.7 cm, body mass: 72.3 ± 6.49 kg) were recruited. The Novel Pedar-X (50 Hz) was used to collect plantar pressure of the dominant leg. Three regions (medial forefoot, MedFF; middle forefoot, MidFF; and lateral forefoot, LatFF) of the collected data were evaluated, crossing from the first to fifth metatarsals. During the test, the participants were randomly assigned to perform a two-legged jump rope trail at a fixed frequency (2.2 Hz) in two footwear conditions: Asics GT-2000-10 running shoes (24mm forefoot, 32mm rearfoot) with an upturned forefoot design and a gel insert under the first metatarsal area; Health 2255 rope skipping shoes (9mm forefoot, 15mm rearfoot) with a flat forefoot design and no inserts in the midsole. Paired *t*-tests were used to determine the differences in all variables. The 95% confidence intervals and effect size (Cohen's d) of each parameter was calculated. The significance level α was set at 0.05.

RESULTS AND DISCUSSION

The plantar pressure results show that the peak fore of MedFF area and MidFF area; peak pressure of MedFF area and MidFF area; pressure–time integral of MedFF area and MidFF area were significantly lower in Asics brand shoes ($p < 0.05$, Table 1). This may have been affected by the cushioning materials (gel) and midsole thickness in the forefoot of the footwear. There was no statistically significant difference found in the LatFF area for peak force, peak pressure, and pressure–time integral between the two footwear conditions (Table 1). The above suggests that choosing the Asics running shoe may prevent plantar injuries by lessening the force and pressure on the 1st to 4th metatarsal heads during rope skipping.

CONCLUSIONS

The thicker midsole with a particularly cushioned forefoot design helped to reduce plantar pressure in the metatarsophalangeal joint, which may have beneficial effects on the plantar injury during jump rope exercise. Thus, the Asics shoe may be more suitable for long-term jumping exercise.

INTRODUCTION

The ability to maintain balance is critical to a soccer player's performance. Good balance gives stability during diverse motions such as dribbling, shooting, and defending, allowing players to control the ball more efficiently and with more accuracy. These specific adaptations or techniques are believed to result from soccer players' experience in a competitive environment. The current study aims to investigate the differences of dynamic balance in terms of medial-lateral (M/L) and vertical displacements of the body's center of mass (COM) during level walking between the starting and non-starting lineup of a high school soccer team which is in the High School Football League of Taiwan.

METHODS

Eight starting and eight non-starting soccer players from National Hualien Senior High School participated in the current study with informed written consent, as approved by the Institutional Research Board. Each subject walked at a self-selected pace on an 8-meter walkway. Thirty-nine infrared retro-reflected markers were placed on specific landmarks of the body to track the motion of the segments. The kinematic and kinetic data were measured with a 7-camera motion analysis system (Vicon, Oxford Metrics, U.K.) and two force plates (AMTI, U.S.A.). A 13-body-segment model of the whole body was used to calculate the position of the body's COM as the weighted sum of the segmental COMs of all body segments. Body segmental inertial properties were obtained using the Dempster's coefficient. The M/L and vertical displacements of the COM are described as the differences of the maximum and minimum values in the medial-lateral and superior-inferior axis of a gait cycle respectively. All the calculated COM displacements were normalized to leg length. An independent t-test was applied to compare the variables (M/L and vertical COM displacements) between the starting and non-starting groups. All significance levels were set at α=0.05.

RESULTS AND DISCUSSION

The starting soccer players showed significantly decreased M/L COM displacement during walking compared with the non-starting ones (p=0.01, Table 1). On the other hand, no significant differences of the vertical displacement of the COM were found between groups (p=0.49, Table 1). The results of the study found that the starting soccer player have better balance performance in M/L direction in terms of decreased COM displacement. The level of competition for soccer players was positively linked to their postural stability. Studies have shown that there is a positive correlation between M/L displacement and energy expenditure, suggesting that the starting group may have a lower rate of fatigue, leading to better performance on the field. The advantage of balance ability in the starting players may be caused by different training program or innate superior characteristics of their body. On the other hand, previous studies have shown a lack of correlation between vertical COM displacement and metabolic cost, suggesting that minimizing displacement doesn't necessarily minimize metabolic cost. This is likely why no significant differences of vertical COM displacement between groups were observed in the current study. It is suggested that the training regimen for the control of COM in the M/L direction may be necessary for the soccer players.

CONCLUSIONS

Overall, the study's findings indicated that the starting soccer players demonstrated better postural performance in the M/L direction, as seen by a reduced rate of COM displacement, when compared to the non-starting players.

THROWING PERFORMANCE AND KINEMATIC ANALYSIS OF OVERHEAD THROWING IN MALE ELITE AND VARSITY CUP CRICKETERS

INTRODUCTION

Throwing is one of the most dynamic movements performed, requiring significant segmental co-ordination and rhythmical muscle activation to execute. Most available research of the overhead throw pertains to baseball, with distinctly less in cricket. Throwing performance represents the combination of throwing speed (TS) and throwing accuracy (TA). These are both critical to performance but cannot be optimized simultaneously [1]. This phenomenon is referred to as the speed-accuracy trade-off. It describes that any increases in velocity results in improved accuracy until a threshold is reached. Any further increases above this threshold velocity produces decrements in throwing accuracy. From the distinction of the phases of throwing, three critical points can be identified. These are considered crucial for injury prevention and include the following: Maximal External Rotation (MER), Ball Release (BR), Maximal Internal Rotation (MIR).

METHODS

The three-dimensional (3D) kinematic metrics were analysed using a six camera Vicon Vantage motion analysis system capturing at 240 Hz. A custom 78-piece marker set was applied to participants (N=12). Each participant threw 26 throwing trials, 13 static and 13 dynamic with the following objective breakdown: three maximal efforts to establish maximal throwing speed (MTS), five >75% MTS, five Self-Paced (SP) per throwing approach. Throwing velocity was measured using a radar gun. Participants threw towards an accuracy target, which was placed 20 meters away. The target illustrated ICC regulation stumps that had colour coded surrounding areas that denoted the point system. Three points for stump contact, two points for the white area, one point for the green area and zero for missing the target completely.

RESULTS AND DISCUSSION

Originally, the speed-accuracy trade-off began as a hypothesis that was accepted after being supported with ample evidence. The highest throwing speeds were achieved during the dynamic approach. Accuracy scores were highest (50% greater than during Max) during the static approach and when participants selected their pace (SP). Along with an almost 15% drop off in throwing velocity when throwing SP compared to Maximal. The highest throwing arm shoulder rotational velocity at BR in deg/s was achieved during the maximal throws of each respective approach, as expected. However, the static approach exhibited a higher velocity, which makes us consider the effect of the run-up on the throw. The players potentially recorded faster throwing speeds without the expected increases in shoulder rotational velocities due to the force being generated during the forward motion of the run up and not entirely by the upper limb, like during static throwing. Specifically, up to 55% of the energy required to pitch can be attributed to lower body force contributions [2].

CONCLUSIONS

The speed-accuracy trade off tends to persist in elite male cricketers. Throwing kinematics illustrate that this cohort shows higher shoulder rotational velocities at BR during static throwing versus dynamic throwing (Max & >75% MTS), alluding to the lower body force contribution during a run-up for force generation at the shoulder. Throwing from a dynamic position could provide a protective role on the shoulder in the long run.

INTRODUCTION

Tensiomyography (TMG) is one of the mechanomyographic evaluation methods and is a device that evaluates the static contractile properties of skeletal muscle in response to a single electrical stimulus of 0 to 100 mA for 1 ms [1-3]. Because it does not involve motivation or volitional effort, it is possible to objectively evaluate the muscle contractile properties, and it has been used to characterize the muscle contractile properties of specific sports athletes and to establish the relationship between sports performance abilities [4,5]. As such, it is necessary to obtain functional information that can predict the athletic performance of athletes with measurement variables derived from TMG. Therefore, the purpose of this study is to compare the static contractile properties of skeletal muscle in major leaguers, second-team players, and ordinary person.

METHODS

This study was conducted with 1 major leaguer, 1 2nd team player, and 1 normal person each from the general public. TMG (TMG-100 System electrostimulator, Slovenia) was used to compare and analyze the static contractile properties of erector spinae muscles. To compare and analyze the contractile properties of the measured muscle, measure-remeasurement and intra-rater reliability index (ICC) were the highest variable, maximum radial displacement (Dm, 0.91-0.99), a variable that records the maximum contractile displacement of the muscle, and 10 to 10 of the maximum contractile displacement. A contraction time (Tc, 0.70-0.98), a time variable required to contract to 90%, was used [3].

RESULTS AND DISCUSSION

As a result of comparing the contractile properties of the erector spinae muscle, the major leaguers had the lowest results in all variables <Table 1>.

A previous study comparing power and endurance athletes showed lower Tc and Dm in power athletes. In addition, since the major leaguers had the lowest results in Tc, which has a significant positive correlation with Type I, it is judged that the ratio of Type II is higher in the erector spinae muscles of major leaguers than other groups [6]. In addition, reduced Dm would have been shown due to improvement in passive stiffness, such as increased muscle tone and stiffness due to muscle hypertrophy, which can be suggested to contribute to improved muscle performance [7].

CONCLUSIONS

As a result of analyzing the static contractile properties of the erector spinae muscle, the Tc and Dm of the major leaguers were lower than the other groups due to the type of muscle fiber and the characteristics of muscle hypertrophy, and it was judged that the muscle performance was the best.

INTRODUCTION

Deadlift is one of the basic resistance exercises performed to improve and evaluate muscle strength, and it is used in exercise programs by effectively inducing muscle strength and neuromuscular development using the muscles of the whole body [1-3]. Deadlift performed by move the hip joint, knee and ankle joints with maintaining a neutral spine during the movement, and conventional deadlift is one of the most widely performed [4,5]. Among the conventional deadlift movements, the powerlifting deadlift (PD) exhibits a high hip position and horizontal trunk angle to the ground, in contrast, the weightlifting deadlift (WD) exhibits a lower hip position and vertical trunk angle [6]. Previous studies have reported that muscle activation patterns in the lumbar spine and lower extremities may vary between PD and WD, but analysis of muscle overuse or risk of sprains was not performed because muscle activity was not measured during motion [7]. Therefore, the purpose of this study is to analyze muscle activity by comparing EMG between PD and WD.

METHODS

For this study, 9 adult males under the age of 30 with more of weight training experience were recruited (age; 20.78±1.09 years, height; 176.11±4.22 cm, weight; 71.58±4.01kg). The subjects repeated both PD and WD 5 times each with 70% of 1 repetition maximum for this experiment. PD placed the barbell on a straight line from the inferior angle of the scapular to the ground and performed the motion in a high hip and horizontal body position. WD placed the barbell on a straight line from the collarbone to the ground, allowing the movement to be performed at a lower hip and a near-vertical trunk position. For muscle activity analysis, 8-channel wireless EMG equipment (Ultium^{TM}, Noraxon, USA) was used, and EMG sensors were attached to the erector spinae (ES), gluteus maximus (GM), biceps femoris (BF), and vastus lateral muscle (VL) based on previous studies. For statistical analysis, a paired *t*-test was used for the SPSS 26.0 (IBM, USA), and all variables were calculated as mean and standard deviation. The statistical significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

A result of this study, the EMG values of ES, GM, and VL were significantly high than during WD operation than PD (p=0.000). According to previous studies, since WD increases horizontal distance between the center of gravity and the barbell compared to PD, it can exhibit higher ES activity by increasing torque and external shear force of the lumbar spine, and it can also exhibit higher VL activity by increasing knee extension moment [6]. The difference between the results of previous studies and this study is that the activity of GM was significantly higher in WD than in PD. Based on previous studies showing that the activity of GM increases as lower pelvis position is shown during squats, it is thought that lower pelvis position, greater extension moment of the hip joint [8].

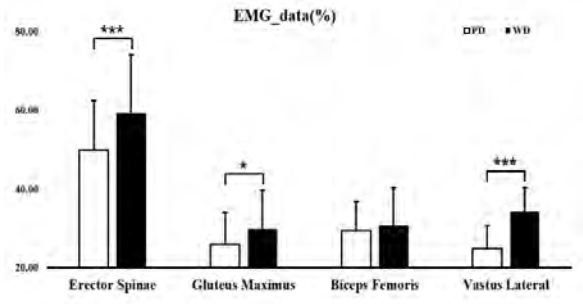

Figure 1. EMG comparison between PD and WD

CONCLUSIONS

As a result of this study, greater muscle activity was shown in the ES, GM, and VL muscles during the WD compared to the PD, and there was no significant difference in the BF.

INTRODUCTION

In many ball games, an ability to travel a given distance in a shorter time is advantageous for getting a loose ball or evading opponents. Hence, superiority of starting techniques and an effectiveness of training methods have widely been discussed [1-2]. Although the sprinting direction depends on the game situation, most previous studies focused on the forward sprint start and the following sprint. Our previous study demonstrated that soccer players use the forward step and false step techniques with similar frequency when they start sprinting in a sideward direction from a standing position [3]. However, effective training methods for improving the acceleration performance in the sideward sprint starts are still unclear. Therefore, to obtain an insight on improvement of the sprint performance, this study aimed to identify key variables influencing the acceleration performance in a sideward sprint starts by using the forward step and false step techniques.

METHODS

Ten male soccer players and ten male lacrosse players participated to this study. They started 5-m sprints in the right direction from a stationary standing position with a parallel stance. After a ready signal, each participant self-initiated sprinting by using either the forward step or false step technique according to the instruction. Reflective markers were attached on their anatomical landmarks, and the three-dimensional coordinates data were recorded by a motion capture system sampling at 200 Hz. Fifteen force plates sampling at 1000 Hz were used to measure the ground reaction force (GRF) from the ready signal to the second step in the springing direction. Frame at the movement initiation was detected based on the change in the vertical components of the GRFs. Velocity of the participant's center of mass was calculated at the movement initiation and the flight phase after the second step in the sprinting direction (v_i and v_f). Body mass data of each participant was adjusted based on the impulse-momentum relationship between v_i, v_f, and GRF impulse. Correlation analyses on the deterministic models were utilized to identify the key variables influencing the performance outcome in each sprint start technique [4]. v_f was set as the outcome measure, and factors producing that were v_i and the change of the velocity (Δv) generated by each of the following step events: initial push-off by the right and left foot, false step (only in the false step technique), and the first and second step in the sprinting direction (1st and 2nd step).

RESULTS AND DISCUSSION

In the deterministic model of the forward step technique, v_f correlated to Δv of the initial push-off of the left foot and the 1st step significantly (Figure1). Since a significant correlation between v_f and Δv of the 2nd step was not found, it is suggested that enhancements of accelerating before the 2nd step can improve the acceleration performance.

In the deterministic model of the false step technique, v_f correlated to Δv of the initial push-off of the right foot, the false step, and the 2nd step significantly. Although the false step and the 2nd step accelerate the COM, the initial push-off of the right foot generated deceleration (Figure1). These results suggest that the acceleration performance can be improved by not only enhancements of accelerating but minimization of decelerating.

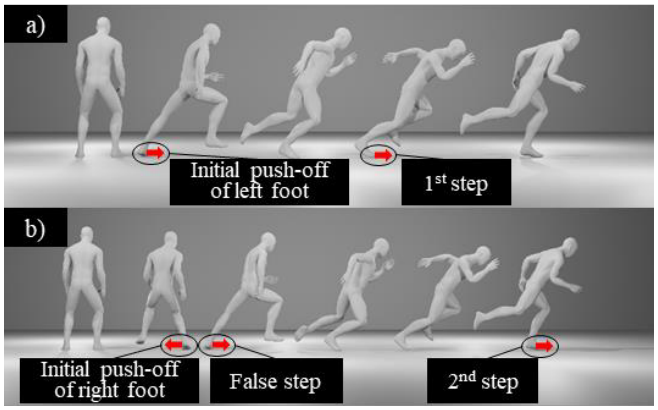

Figure 1 Step sequences and directions of Δv significantly correlated to v_f in a) forward step and b) false step techniques.

CONCLUSIONS

This study demonstrated the key variables influencing the acceleration performance in sideward sprint start by using the forward step and false step techniques. These findings can be useful knowledge for establishing the training methods to improve the performance of acceleration in a sideward sprint start and the following sprint.

INTRODUCTION

The aim of this study was to compare the angular momentum (H) values of five groups of body segments during an entire throwing cycle in the overhand (OS), three-quarter (TS), sidearm (SS), and underhand (US) styles of the baseball pitching motion.

METHODS

Ninety-one male amateur pitchers (25 high school, 62 collegiate, 4 post-collegiate) participated in this study. Ninety-five maximum-effort fastball pitches from the pitcher's mound to the catcher were videotaped with two cameras at 240 Hz at a baseball stadium. The 3D coordinates of body landmarks and ball were calculated using the DLT method. After discarding seven pitches that fell within the buffer zones that overlap between TS and SS, the remaining 88 pitches by 84 participants were classified into the four delivery styles (30 OS, 26 TS, 20 SS and 12 US) using the arm slot angle criteria reported in a previous study [1]. Landmark coordinates were expressed in a right-handed reference frame in which the X axis pointed toward the right, the Y axis pointed forward in the direction of the pitch, and the Z axis pointed upward. The landmark coordinates of the left-handed participants in the sample (eight) were subjected to a symmetrical transformation to make them appear right-handed. The 16 body segments and the ball were combined into five segment groups: trunk-head, left leg, right leg, left arm, and right arm and ball. Their angular momentum components (HX, HY and HZ) were calculated during the wind-up (P1), stride (P2), right arm-cocking (P3) and right arm-acceleration (P4) phases using the methods of a previous study [2], and were standardized for the standing height and body mass of each participant. All times were expressed as percentages of the total duration of the throw. ANOVA was performed to assess the differences in the physical characteristics of the participants (age, standing height, body mass and throwing experience) and in the ball velocity between the styles with a multiple comparison using Bonferroni corrections. Statistical parametric mapping (SPM) analysis was performed to detect differences among the styles in the time-dependent curves of the H components [3]. Significance level was set at 5% (p<0.05) in all statistical analyses.

RESULTS AND DISCUSSION

No significant differences between the styles were found in the physical characteristics of the participants. Significant differences in ball velocity (34.9±1.9 m/s for OS; 35.3±1.9 m/s for TS; 33.8±1.9 m/s for SS; 32.0±1.9 m/s for US) were found between the OS and US styles and between the TS and US styles (both p<0.001).

In the latter half of P3 and in P4, the HY of trunk-head, right leg, and left arm had counterclockwise angular momentum in the view from the back, while those of the right arm and ball and of the left leg had clockwise angular momentum. Overall, these segment groups cancelled the angular momentum values of each other and kept the body in balance.

Significant differences between the styles were found in all three H components of the five segment groups. The differences were concentrated in the late P2 phase and in the P3 and P4 phases for HX and HZ, and in the middle of the P2 phase and in the P3 and P4 phases for HY. The exception was the right leg HX, which showed almost no differences between the styles. In the P3 and P4 phases, the increase in the HX of the right arm and ball, which contributes to increase the ball velocity, was progressively smaller for OS, TS, SS and US. Conversely, the increase in the HZ of the right arm and ball was progressively larger for OS, TS, and SS and US, although there was no difference between the last two. It was suggested that the HX of the five segment groups (especially the right arm and ball and the trunk-head) in the OS, TS and SS from the late part of the P2 phase to the end of the P4 phase contributed to increase ball velocity, but it was not enough to cause significant differences in ball velocity between these three styles.

CONCLUSIONS

This study revealed the time-dependent patterns of angular momentum of the five body segment groups, as well as differences in the angular momentum values of those body segment groups, during an entire throwing cycle in the four styles of baseball pitching motion.

AN INTERACTION BETWEEN LANDING HEIGHT AND GROUND CONDITION IN GROUND REACTION FORCE DURING TWO-LEG LANDING

Jeongeun Moon[1], Geon-Tak Kim[2], Jae-Kyun Ryu[2], and Jihong Park[1]
[1]Athletic Training Laboratory, Kyung Hee University, Yongin, Korea.
[2] Biomechanics Laboratory, Kyung Hee University, Yongin, Korea.
Email: jihong.park@khu.ac.kr

INTRODUCTION

Athletes who frequently perform high jumps and acrobatic movements such as Taekwondo (TKD) Shibum are susceptible to injuries [1]. Vertical ground reaction force (vGRF) is one of the primary contributing factors known to increase the risk of injury, which is associated with landing height [2] and ground conditions [3]. For example, the magnitude of vGRF is attenuated when landing on a cushioned ground (e.g., sponge mats). However, the relationship between the landing height and ground condition remains unknown. Hence, this study examined the interaction between landing heights and ground conditions in peak vGRF (PvGRF) and time to PvGRF (TTPvGRF).

METHODS

Nineteen healthy, collegiate male Taekwondo Shibum athletes (20.7 years, 172.6 cm, 65.5 kg) volunteered. Participants visited the laboratory once and performed two-leg landings from three different heights (0.45 m, 0.90 m, and 1.35 m) on three different ground conditions (ground—force plate, TKD mat—2 cm thick, and sponge mat—14 cm thick) in a counterbalanced order. Five successful trials for each height and ground condition were recorded. A successful trial was defined when each foot completely landed on each force plate (960 Hz). The PvGRF (body weight: BW) and TTPvGRF (ms) during the stance phase (initial contact >25 N to peak knee flexion—not reported in this abstract) of each side (dominant vs. nondominant) were separately compared using a two-way mixed model analysis of variances and Tukey tests (p<0.05). Cohen's d effect size (ES) was calculated for the statistical significances.

RESULTS AND DISCUSSION

The PvGRF on the dominant side was different (height × condition: $F_{4,144}$=11.71, p<0.0001, Table 1). Specifically, on the ground (force plate), as the landing height increased, vGRF also increased (0.45 m: ×2.4 BW, 0.90 m: ×3.7 BW, 1.35 m: ×6.3 BW, p<0.0001, ES>3.66). When landing on the TKD and sponge mat from a height of 1.35 m, vGRF was attenuated to ×5.2 BW (p=0.0002, ES=0.76) and ×3.3 BW (p<0.0001, ES=3.11), respectively. The vGRF on the nondominant side (height × condition: $F_{4,144}$=8.91, p<0.0001) showed a similar pattern to the dominant side. TTPvGRF on the dominant side was different (height × condition: $F_{4,144}$=7.62, p<0.0001). Specifically, on the ground, (force plate) TTPvGRF was decreased from a landing height of 0.45 m (44.4 ms) to 0.90 m (36.9 ms, p<0.05, ES=0.85). When landing from a height of 1.35 m, using the sponge mat can increase the time to reach PvGRF by 19.1 ms, compared with landing on the ground (p<0.0001, ES=3.91). The non-dominant side (height × condition: $F_{4,144}$=4.78, p=0.001) also showed similar patterns to the dominant side.

CONCLUSIONS

The vGRF increases as the landing height increases. Using the TKD mat does not seem to be beneficial for a height <0.90 m. While the landing impact goes up to ×6 BW when landing from 1.35 m, the sponge mat should be used in order to reduce vGRF by 52 %.

Email: jihong.park@khu.ac.kr

INTRODUCTION

A single-leg landing from a jump or a single-leg landing followed by immediate jumping is frequent athletic movements that have the potential to cause injuries. If the movement task is performed under an unanticipated situation (e.g., the task after landing is not preplanned), the injury risk could be greater [1]. Appropriate muscle activation (e.g., timing and magnitude) is essential for dynamic stabilisation of the lower extremity joints. Therefore, the purpose of our study was to examine the lower extremity muscle activation patterns during the anticipated and unanticipated single-leg drop jump tasks. Subjects under the unanticipated condition would have less activation before and after initial contact when compared with those under the anticipated condition.

METHODS

Surface electromyography (EMG, 1,500 Hz) was collected from 17 healthy young male subjects (24 years; 173 cm; 72 kg) and included measurements from the gluteus medius (GM), rectus femoris (RF), vastus medialis (VM), semitendinosus (ST), biceps femoris (BF), tibialis anterior (TA), and medial gastrocnemius (MG) on the dominant leg. Subjects were asked to drop down from a wooden box 40 cm high with their dominant leg (landing), then immediately jump with their dominant leg as high as possible (jumping). For the anticipated condition, subjects were informed of the drop jump task prior to the initial drop. For the unanticipated condition, the specific task was visually shown on a light-emitting diode screen with an upward or downward arrow for jumping or landing, respectively, which was triggered by the infrared sensor when a subject's foot was sensed prior to initial contact. Three successful trials on each condition were averaged for analysis. Muscle activation patterns were identified during the drop phase (200-ms prior to initial contact to initial contact) and the weight acceptance phase (initial contact to peak knee flexion); normalised by the peak amplitude recorded on each trial; smoothed (a 4th order zero-phase-shift Butterworth high- and low-pass with a cutoff freqency of 15 and 20 Hz, respectively); then compared using functional linear models [2] to detect differences between conditions (p<0.05) and Cohens' d effect sizes (d).

RESULTS AND DISCUSSION

During the drop phase (0% being 200 ms prior to initial contact, and 100% being initial contact), activation of the VM (75%) and ST (73 to 82%) were less (VM: < 32%, d=0.48; ST: < 34.2%, d=0.52), but activation of the TA (1 to 6%) was greater (< 43%, d=0.60) for the unanticipated condition relative to the anticipated condition. During the weight acceptance phase (0% being initial contact, and 100% being peak knee flexion), activation of the GM (66 to 77%, and 85 to 98%), RF (55 to 97%; Figure 1), VM (71 to 97%), ST (44 to 53% and 72 to 73%), BF (92 to 100%), and TA (63 to 94%) were less (GM: < 34%, d=0.60; RF: < 45%, d=0.85; VM: < 38%, d=0.71; ST: < 36%, d=0.69; BF: < 44%, d=0.70; TA: < 34%, d=0.64) for the unanticipated condition relative to the anticipated condition.

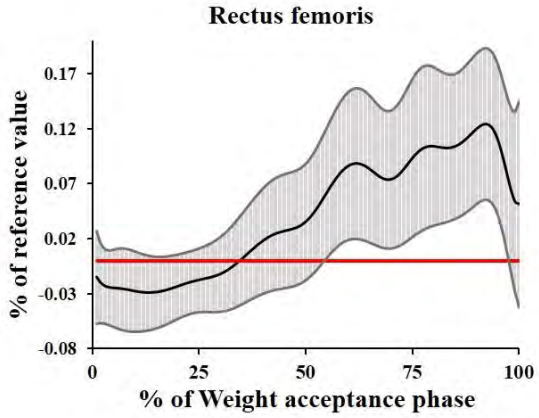

Figure 1. Result for the rectus femoris during the weight acceptance phase. The black line represents the mean difference between conditions (anticipated – unanticipated), and the grey band represents the 95% confidence intervals. When the grey band does not pass the red zero line, a statistical difference between the conditions exists.

CONCLUSIONS

Overall, less muscle activation in the lower extremity was observed when the movement task (e.g., landing or jumping) was not preplanned. These neuromuscular changes could alter joint kinematics and stability in the lower extremity, which may increase the injury risk [3]. Therefore, practitioners or coaches in open-skill sports should be aware of these aspects and establish the appropriate injury prevention strategies.

NEUROMUSCULAR FATIGUE OF VASTUS LATERALIS DURING FATIGUING SQUAT EXERCISES IN TRAINED AND UNTRAINED PEOPLE: TIME-FREQUENCY ANALYSIS

Jihong Park[1], Hoon Kim[2], Dongkyun Seo[1], Sungkyu Jeon[1], Seunghun Lee[1]

INTRODUCTION

Exercise-induced fatigue affects neuromuscular functions such as muscle force and muscle activation. Because these neuromuscular fucntions affect movement alterations such as joint kinematics and kinetics, which may increase injury risks, it is important to understand neuromuscular patterns during fatiguing exercises. Many previous studies have reported neuromuscular fatigue during exercises, but single-joint exercises such as ankle dorsiflexion, thumb adduction, knee extension, and elbow flexion were traditionally investigated using electromyography (EMG) amplitude analysis [1]. Although the existing data are valuable, further investigation is needed because single-joint movements do not occur in daily activities and because frequency contents are also affected by fatigue, not only EMG amplitude. Additionally, experiences of specific exercises may affect neuromuscular responses under fatiguing status. Therefore, the purpose of the current study was to examine the effects of the set and repetition on muscle activation of the vastus lateralis during fatiguing squat exercises in trained and untrained people.

METHODS

Eighteen trained and 16 untrained people participated in this study. Participants performed five sets of multiple repetitions of squats with a fatiguing protocol. One video camera and an EMG electrode on the vastus lateralis of the dominant leg were used to collect motion and muscle activation data, respetively. Concentric and eccentric phases were identified using bar trajectories in video data with Kinovea software. Muscle activation data were analysed with wavelet transformation with 30 non-linearly scaled wavelets, then we summed the intensities across all time points for each wavelet [2]. We extracted Principal Components (PCs) and PC scores using Principal Component Analysis (PCA). Then, we performed three-way analysis of variances ($p<0.05$). Independent variables were set (1–5 sets), and repetition (initial vs. end), group (trained vs. untrained). Dependent variables were their PC scores. In the current abstract, we report differences in PC2 scores, which captured frequency contents because our main interest was EMG frequency response in muscle activation.

RESULTS AND DISCUSSION

There are significant main effects for the repetition (Figure 1B, $p=0.001$) and set (Figure 1C, $p=0.03$) in the PC2 score measured during the concentric phase of the squat. There was a significant main effect for repetition (Figure 1E, $p=0.003$) in the PC2 score measured during the eccentric phase of the squat.

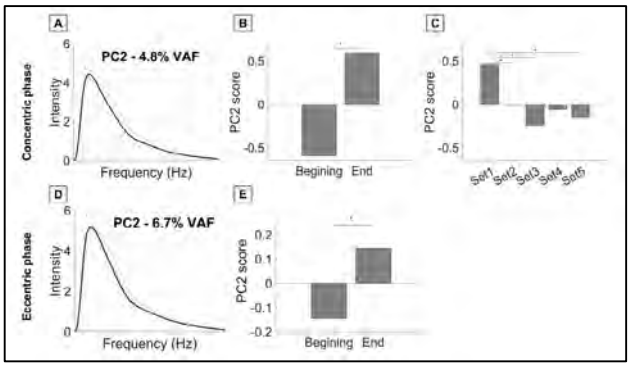

Figure 1. Effects of ±1SD of PC scores in PC2 of vastus lateralis EMG data during concentric (A) and eccentric (B) phases of squats. PC2 scores patterns depending on repetition (B and E) and set (C). VAF: variance accounted for.

Our results showed that the accumulated repetitions shifted EMG frequency toward the low frequency ranges during the concentric phase. Conversely, EMG intensity was shifted more toward the high frequency ranges as sets were accumulated, compared to the first set during the concentric phase. In the eccentric phase, the EMG intensity was shifted toward the low frequency ranges as repetitions were accumulated.

CONCLUSIONS

The training status did not affect the fatiguing responses of the vastus lateralis. However, the accumulated repetitions and sets were factors that influenced the frequency contents of activation of the vastus lateralis. Importantly, the direction of frequency shift was the opposite between accumulated repetition and sets. Our results suggest that trainers should consider repetitions and sets as different factors on neuromuscular fatiguie during squats. For example, the fatiguing squat exercises should increase repetitions and sets depending on frequency ranges that are targeted for training.

ACKNOWLEDGEMENTS

The results were parts of data collected as a class project (SM32602) in the Department of Sports Medicine at Kyung Hee University.

INTRODUCTION

Knowledge of ground reaction forces (GRF) between the foot and the ground is essential for Paralympic athletes with lower limb amputees who practice running and jumping in order to analyse and optimize the biomechanics of the sporting gesture, to improve safety and reduce the likelihood of injury. Different approaches can be found in literature for the measurement of GRF; a large number of force platforms embedded in the track [1] involve dedicated expensive installations, running on instrumented treadmills [2] or treadmills placed on 4 force platforms [3] requires specific training and limits high acceleration sprinting, direct sensing from instrumented and calibrated RPF using strain gauges [4] limits the study to pre-instrumented RPF. Aim of the present work was the design, installation and track testing of a wearable load acquisition system capable of acquiring six load components at the RPF enabling the quick evaluation of different RPF or different alignments.

METHODS

The wearable load acquisition system consists of a commercial thin six-axis load cell (diameter 65mm, thickness 9mm, mass 0.19kg) equipped with two custom made titanium plates designed and built to connect mechanically with the pyramid adapters present in the RPS for athletes with TF amputation. The load cell calibration was bench validated applying known masses and torques. The device was installed between the Ottobock 1E91 Runner Std. Cat. 3.5 C-shaped foot clamp and the Ottobock 3S80 SPORT sports knee of the prosthesis of an elite female athlete of the Italian Paralympic national team (55 Kg, 1.60 m). The system was connected to a wearable data logger (DTS SLICE NANO, DTS, USA) placed in the backpack worn by the athlete during test sessions, together with its Lithium-Polymer battery, while a six degree of freedom inertial sensor (6DX PRO-A, DTS, USA) was placed under the clamp on the RPF (Figure 1a). The Palaindoor athletics track located in Padova was covered with a total of 28 motion capture cameras (Vicon Motion System, Oxford, UK), 22 mounted on tripods placed all along the runway, covering approximately 20-metres-long acquisition volume, and 6 cameras installed on a double portal structure, placed in the centre of the runway. Indoor test sessions consisted in six sprint trials: in the first three the start occurred in the calibrated volume, in other three the athlete reached the calibrated volume at constant speed around 6.5 m/s (approximately 60% of personal maximal speed). Clamp Reaction Forces acquired in the load cell reference system (X_{LC}, Y_{LC}) were filtered using a 4th order, low pass Butterworth filter (cut-off 52 Hz) while GRFs in the Ground reference frame (X_{GR}, Y_{GR}) were computed using the clamp orientation matrix (sagittal angle θ_{LC}), obtained from Motion Capture data.

RESULTS AND DISCUSSION

GRFs from steady state running are in agreement with literature findings [2], GRFs during start show clear differences with steady running and represent an original result for transfemoral paralympic elite athletes. The delayed vertical peak and the positive horizontal component confirm the need of track testing for the appropriate evaluation of running biomechanics.

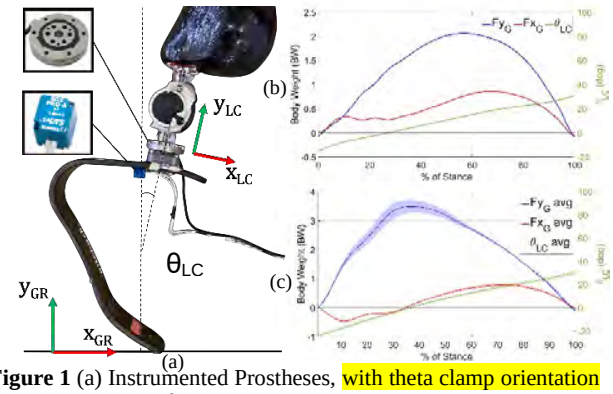

Figure 1 (a) Instrumented Prostheses, with theta clamp orientation (b) GRF from the 4th step in a START event. (c) GRF mean curves

CONCLUSIONS

A wearable system for RPF clamp load collection was developed and applied to a transfemoral elite paralympic sprinters to measure GRFs. The system will give insight into sprinting biomechanics and allow investigating the effect of RPF stiffness and alignment.

INTRODUCTION

The rotational technique is becoming the mainstream technique in recent shot put competitions (Dinsdale et al., 2017). This technique involves rotating the body in a similar way to the discus throw, which is also a throwing event in athletics, during the preparatory phase before delivering the throwing material. There are many similarities between the rotational shot put technique and the discus throw, with several athletes having competed in both events at the international level. However, threr is limited knowledge available on biomechanical comparisons between the shot put and discus throw.

Therefore, the aim of this study was to clarify the biomechanical similarities and differences between the rotational shot put technique and the disucs throw.

METHODS

Sixteen male shot putters (stature: 1.77 ± 0.06 m, body mass: 111.38 ± 9.78 kg, shot put record: 15.31 ± 1.38 m) and 16 male discus throwers (stature: 1.79 ± 0.05 m, body mass: 92.63 ± 9.92 kg, discus throw record: 48.29 ± 4.07 m) participated this study. Both groups were comparable in WA scoring tables of Athletics 2022 (shot put: 841.81 ± 81.74, discus throw: 845.88 ± 74.35). Their throwing motions during athletic competitions were recorded using two or three DV cameras at 60 fps with a shutter speed of 1/1500 s for the shot put (HDR-CX675, Sony, Tokyo, Japan) and at 300 fps with a shutter speed of 1/3000 s for the discus throw (EX-F1, Casio, Tokyo, Japan). The throwing material and 25 end points of each body segment were manually digitized at 60 Hz for the shot put and at 100 Hz for the discus throw, and three-dimensional DLT method was applied to collect coordinate data. A Butter worth digital filter with the cut-off frequencies ranging from 3 to 9 Hz was used to smooth the coordinate data. Smoothed coordinate of the shot put motion was converted to a 100 Hz equivalent time axis using a spline function.

The initial velocity of the throwing material at the moment of release (RV) was obtained. The throwing material and the athletes's body were assumed to be a system. The velocity of centre of gravity of the system (CGV), the linear momentum of the system (LM), the angular momentum of the system (AM) and the impulse of the throwing material were calculated.

The Pearson product-moment correlation coefficient was used to understand the relationship between the RV and other variables. The Welch t-test was used to compare the variables between shot put and discus throw. All significant level was set at 0.05.

RESULTS AND DISCUSSION

A significant positive correlation was found between the RV and total CGV at release in the discus throw (r = .634). However, only the shot put showed a significant positive correlation between RV and LM just before the release (r = .583).

Figure 1 illustrates the total CGV and toral LM throughout the throwing motion (initiation-release of the throwing material) with the normalized time as 100% of whole motion. The discus throw had significantly higher CGV than shot put in almost all phases of the throwing motion (25-97% time, $p < 0.05$). In contrast, shot put and discus throw generally showed comparable values of LM during the entire throwing motion, although there were significant differences in some phases (36-48, 71-76, 82-89 and 95-100 % time, $p < 0.05$). One of the critical differences between the shot put and discus throw is the size of the space available for the throwing motion. These differences between the shot put and discus throw represent the characteristics of each event.

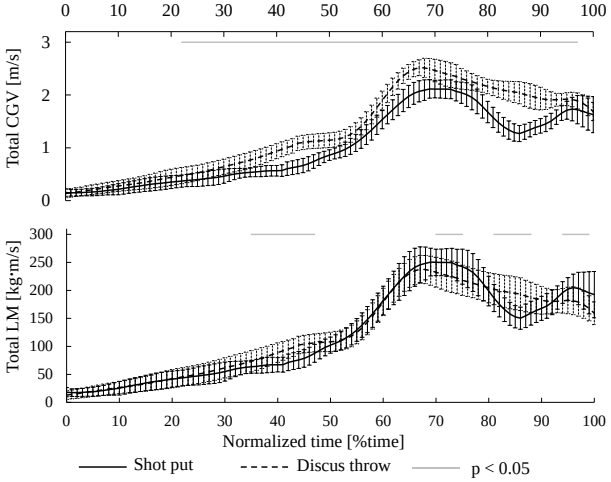

Figure 1: Comparison the Total CGV and total LM between the shot put and the discus throw during the whole throwing motion.

CONCLUSIONS

Based on these findings, discus throwers utilize the available space to accelerate the system, whereas shot putters control the system within a restricted space and increase the linear momentum of the system, resulting in higher throwing records.

THE EFFECT OF SINGLE-LEG ROTATIONAL LANDING ON KNEE KINEMATICS

Weerawat Limroongreungrat[1], Nuttaput Phuvachaivivate[1], Jim Richards[2], Parunchaya Jamkrajang[1]
[1]College of Sports Science and Technology, Mahidol University, Nakorn Pathom, Thailand.

INTRODUCTION

High or repeated single-leg landing, particularly unpredictable landings, can lead to a high load to the lower extremities. A previous study showed that the risk of lower limb injury increases when the direction of the landing task changes from forward to lateral due to a stiff landing strategy [1]. However, while most research has focused on knee biomechanics with forward-directed landing tasks, the impact of landing orientations on knee kinematics in other planes still needs to be determined. Moreover, little research has been conducted investigating rotational landings in different directions. Therefore, this study aimed to investigate the effect of single-leg rotational landing on knee kinematics between altered landing locations. We hypothesized that the knee kinematics of the dominant leg would significantly differ between the rotational landing directions.

METHODS

Fifteen healthy male basketball players volunteered for this study. Single-leg landing tasks were recorded using 44 reflective markers attached to the participant's trunk and lower limbs following a previously published model [2] using a 3D motion analysis system and a force platform. Prior to data collection, participants warmed-up for 10 minutes. For the landing tasks, participants were asked to stand on their dominant leg with the knee extended and hands on the side of the body, then jump from a 30-cm high box and then land on the dominant leg in three directions; forward landing (FL), right rotational landing (RRL) and left rotational landing (LRL), using their dominant leg (DL. Participants were instructed to look forward and balance as quickly as possible and hold the single limb stance for 5 seconds on landing. The order of landing directions was randomized using a ballot method. A 30-second rest was provided between each trial. Three successful landing trials in each direction were analyzed. Knee joint kinematics at the initial contact (IC) and maximum knee flexion (MKF) were calculated using Visual 3D. All data were normally distributed and differences between the directions were explored using Repeated Measure ANOVA tests ($p<0.05$) and significant main effects were explored using post-hoc Tukey tests.

RESULTS AND DISCUSSION

There was a significant difference in knee joint internal rotation among the three conditions at MKF (Table 1). The post-hoc test further revealed significantly greater internal rotation in RRL compared with FL. Landing with the knee internally rotated may have increased the load on the ACL [3], which may be considered risky and could lead to ACL injury.

CONCLUSIONS

When performing different single-leg rotational landing directions, there are differences in knee joint angles, particularly knee internal rotation at the MKF. Changes in this angle may lead to an increase in the risk of ACL injury. Using such tasks needs to be carefully considered when being used in individuals who may be at a higher risk of such injuries and during the rehabilitation of ACL injuries.

INTRODUCTION

Inspired by Wolff's law, many bone remodelling algorithms have been developed and evaluated, but their application has not been explored in the foot. This study aims to extend the application further, evaluating numerically predicted osteogenic responses at the foot against experimental hopping data collected during the COVID-19 lockdown in New Zealand. Two different subject-specific finite element (FE) models were developed to investigate the spectral (Model A) and temporal (Model B) modelling behaviour.

METHODS

Following ethical approval participants attended scanning sessions on a SIEMENS scanner (Model A) and a 1.5T Avanto Fit scanner (Model B). Their feet were segmented in Mimics and meshed in HyperMesh to provide a finite element geometry that was solved in Abaqus. A linear elastic lumped soft tissue model was used with Young's modulus of 1.15 MPa, and Poisson's ratio of 0.49. Plantar fascia was represented by linearly elastic connectors whose stiffness was 200N/mm. Plantar pressure measured during gait, and Achilles tendon force were applied to load the foot. Model A considered walking to reproduce morphogenesis induced by the most dominant daily activity, where the subject's bone mineral density (BMD) distribution was measured by computed tomography (CT). Model B replicated an experimental study where a subject performed a hopping exercise on the allocated exercise leg while the other leg served as a control. The exercise lasted one year, with the COVID-19 pandemic lockdown happening during the first eight months. BMD changes at the foot were measured by dual X-ray absorptiometry (DEXA). A continuum damage mechanics based anisotropic bone remodelling model [1] with an ability to evolve the setpoint value following the cellular accommodation theory [2] was employed to predict the osteogenic responses.

RESULTS AND DISCUSSION

A cortical bone layer of similar thickness as the measurement was predicted in Model A by the bone remodelling algorithm around the outer edges of the calcaneus (Figure 1A), denoted by the representative density value of cortices. Density changes predicted in Model B also shared a similar trend with the measured data (Figure 1B); both legs showed subtle density changes during the lockdown interval, but they gained densities after the lockdown, with more increase happening at the exercise leg. Both models showed good agreement between the numerical prediction and the measured data, demonstrating a reliable performance of the bone remodelling algorithm in temporal and spectral aspects.

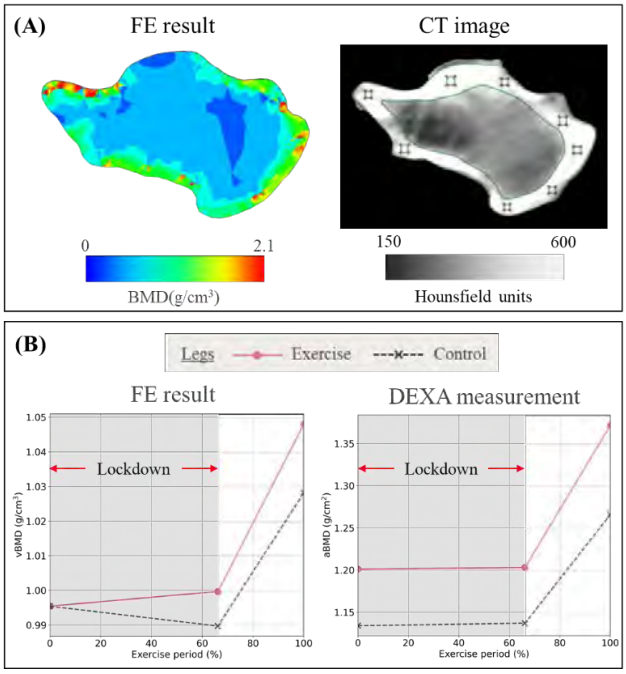

Figure 1 (A) Density distribution predicted by the bone remodelling algorithm in Model A, and CT showing relative Hounsfield units at the calcaneus. (B) Predicted and measured density changes during the hopping exercise.

CONCLUSIONS

This study showed that a widely used bone remodelling algorithm can be successfully extended to the foot and reproduce morphological features of a relatively thick cortical bone layer, and how the frequency and the intensity of daily loading influence density changes.

INTRODUCTION

As a mission's success relies on its troop's ease and speed of travel, it is crucial to objectively evaluate a soldier's movement pattern and joint stress under different equipment configurations [1]. Traditional optical motion capture involves the time-consuming process of placing reflective markers directly on the skin, which is challenging when wearing clothing and bulky body-borne loads. An emerging option is markerless motion capture (e.g. Theia3D, Theia Markerless Inc., Canada) which uses deep neural networks to track the position of anatomical landmarks from an array of synchronized RGB video cameras. The aim of this study is to determine whether a markerless motion capture system can accurately capture the joint loading of heavily equipped participants, compared to an optical motion capture system.

METHODS

Data were collected simultaneously from 7 video cameras recording at 60 Hz (Vue, Vicon, UK) and 11 infrared optical motion capture cameras recording at 120 Hz (Vantage V5, Vicon, UK). 16 participants (8 females; 8 males; height = 1.7 ± 0.1 m; weight = 72.8 ± 10.0 kg) performed a series of three walking and running trials over a 6-metre distance and under four different equipment configurations: C1 = 5 kg, C2 = 21 kg, C3 = 35 kg (C2 + 14 kg small pack), and C4 = 41 kg (C2 + 20 kg rucksack) [2]. Data from the video cameras were processed using the Theia3D software. Resultant joint angles and joint centres were used to perform subject-specific scaling and inverse kinematics (IK) in OpenSim v4.3 (SimTK, USA) using the Rajagopal full-body musculoskeletal model [3]. Residual reduction analyses (RRA) and static optimization (SO) were also conducted to estimate muscle forces and subsequently compute lower limb joint loading. For the optical data, marker coordinates were used to perform these same steps in OpenSim v4.3, again with the Rajagopal model. Both joint angles and contact forces were compared between the systems via root mean square error (RMSE) and Pearson's correlation coefficients.

RESULTS AND DISCUSSION

Overall, kinematic results show good agreement between the optical and markerless motion capture systems for the lower body joint angles. Results of joint loading RMSEs for the heaviest configuration (C4) at the ankle, knee, and hip joints were found to be 0.53 ± 0.14 xBW, 0.44 ± 0.13 xBW, and 0.49 ± 0.19 xBW, respectively. These results are presented in (Figure 1) for walking trials only. The results from both systems were very highly correlated during both walking and running at all joints (r > 0.90). RMSE between systems systematically increased as body-borne load increased, which may have been caused by optical data quality during trials with bulkier equipment.

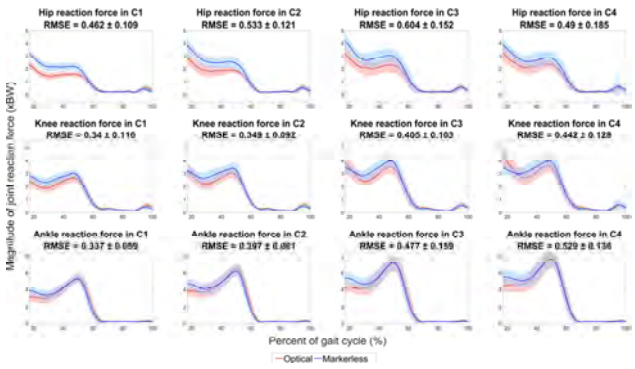

Figure 1. Plots of lower limb joint reaction forces through gait under all loading conditions for walking trials.

Although there is an offset between the joint loading estimated from both motion capture systems, they both predict similar changes in peak joint loading through the equipment configurations. Future work will aim at evaluating the cause of this joint loading offset, probably related to coordinate system alignment issues.

CONCLUSIONS

Markerless motion capture appears to be a feasible alternative to measure soldier joint loading of the lower limbs, even when carrying bulky equipment. In a military context, it could potentially facilitate in-field assessment of soldiers' biomechanics in different equipment configurations to contribute to their safety.

The effect of subscapularis repair following posterosuperior rotator cuff tear severities on superior joint shear force during abduction in reverse shoulder arthroplasty

Donghwan Lee [1] and Choongsoo S. Shin [1]
[1] Department of Mechanical Engineering, Sogang University / Seoul, Republic of Korea.
Email: cshin@sogang.ac.kr

INTRODUCTION

Reverse shoulder arthroplasty (RSA) is a surgical procedure to treat pain and provide functional improvement in patients with severe rotator cuff tear arthropathy [1]. Previous clinical studies reported that severe rotator cuff tears in RSA may increase the risk of postoperative dislocation [1,2]. For this reason, subscapularis repair in RSA has been considered to improve glenohumeral joint stability [2].
Increased superior joint shear force in RSA may contribute to joint instability in the superior-inferior (SI) direction during abduction [3]. However, the effect of subscapularis repair in RSA following posterosuperior rotator cuff (supraspinatus and infraspinatus) tear severities on the superior joint shear force is unclear. Therefore, the purpose of this study was to examine the effect of subscapularis repair following posterosuperior rotator cuff tear severities on the superior joint shear force during abduction in RSA.

METHODS

7 male subjects (age: 24.7±2.4 years, mass: 74.2±6.2 kg, height: 176±5.7 cm) participated in experiments. The subjects were instructed to take 3-seconds to perform 120° abduction in the coronal plane. Motion capture data were recorded for each subject using a motion capture system with 10 infrared cameras (9 Eagle, 1 Raptor; Motion Analysis Corp., Santa Rosa, CA, USA). A 3-dimensional musculoskeletal shoulder model was implemented using the AnyBody Modeling System (V7.3.4., AnyBody Tech., Aalborg, Denmark). The musculoskeletal model of RSA was then developed using the Equinoxe Reverse Shoulder System (Exactech, Gainesville, FL, USA). Posterosuperior rotator cuff tear severities were modelled into 4 types (Figure 1).
The superior joint shear force of both subscapularis torn and repaired RSA models was compared with that of the intact rotator cuff RSA model, respectively. The effective rate of subscapularis repair in the superior joint shear force was calculated as the number of effective cases divided by the number of all cases (8 cases).

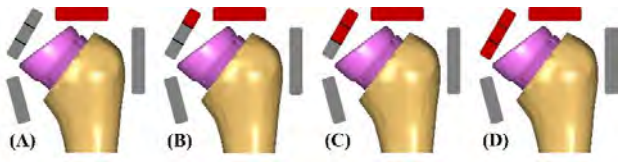

Figure 1 Rotator cuff configuration in the RSA model: (A) type A, isolated bundle tear of the supraspinatus; (B) type B, superior bundle tear of the infraspinatus; (C) type C, middle bundle tear of the infraspinatus; (D) type D, entire bundle tear of the infraspinatus.

RESULTS AND DISCUSSION

Table 1 The effect of subscapularis repair on the superior joint shear force in comparison with 3 models.

			(n = 7)
Type A	E[a]	4 (75°/90°/105°/120°)	Effective rate
	IE[a,b]	4 (15°/30°/45°/60°)	50%
Type B	E[a]	5 (60°/75°/90°/105°/120°)	Effective rate
	IE[a,b]	3 (15°/30°/45°)	62.5%
Type C	E[a]	4 (75°/90°/105°/120°)	Effective rate
	IE[a,b]	4 (15°/30°/45°/60°)	50%
Type D	E[a]	3 (90°/105°/120°)	Effective rate
	IE[a,b]	5 (15°/30°/45°/60°/75°)	37.5%

E, effective; IE, ineffective.
[a]Significant differences between the intact rotator cuff RSA model and subscapularis torn RSA model ($P < .05$).
[b]Significant differences between the intact rotator cuff RSA model and subscapularis repaired RSA model ($P < .05$).

In the type A, B, and C conditions (isolated bundle tear of the supraspinatus to the middle bundle tear of the infraspinatus), the effective rate of subscapularis repair in the superior joint shear force was greater than or equal to 50% (Table 1). In the type D condition (entire bundle tear of the infraspinatus), the effective rate was 37.5% (Table 1). A previous simulation study reported that posterosuperior rotator cuff tears in RSA increased the superior joint shear force and may reduce joint stability in the SI direction during abduction [4]. Our results suggest that the subscapularis repair in RSA could improve joint stability in the SI direction by sufficiently decreasing the superior joint shear force during abduction.

CONCLUSIONS

Patients who underwent RSA may require subscapularis repairing to sufficiently decrease the superior joint shear force during abduction.

INTRODUCTION

Musculoskeletal simulation models have been widely used in field of biomechanics. In this model, muscles have been generally simplified as wires, but volumetric muscle models have been developed in recent years [1,2]. The volumetric data of the bone and muscle were created from cadaver [1] or medical imaging data [2]. There is a database that publishes three-dimensional shape models of organs of the whole body, but the shape is limited to certain standard shape [3]. There is no database which has an average shape and its variation of the bones and muscles. For the use of muscle skeletal simulation, the bone and muscles should be represented by homologous models. The homologous model is a model in which the data of any subject is reconstructed to consist of the same number of grids of the same topology, and each grid is defined to have the same anatomical meaning. Thus, we aimed to develop a morphological musculoskeletal database using homologous modeling.

METHODS

Eighty-nine male young adults were asked to participate in this study. This study was approved by the institutional review board, and the participants provided written informed consent. Magnetic resonance (MR) images of left upper extremity from shoulder joint to wrist joint were acquired by a 3-Tesra MR system (MAGNETOM Vida, Siemens, Erlangen, Germany). The participants were asked to lie on the spine position so that the left upper extremity was positioned in the center of bed. The left upper extremity was covered by three coils (two Body-coils and a flexible-coil). We acquired three images for covering the entire left upper extremity on the coronal plane by 3D image acquisition sequence (T1-wighted VIVE Dixon sequence, FOV: 480 mm × 480 mm, resolution: 1.0 mm × 1.0 mm × 1.5 mm, scan time: 6 minutes). Three images were composed to acquire image of the entire upper extremity. For an automatic extraction of bone and muscle region of the left upper arm, a learning dataset was constructed by manual segmentation for a part of subject. Then, the bone and muscle regions were automatically extracted from the MR image of all subjects by the trained deep neural network (U-Net).

A template model which has a regularly arranged grids was created from bone and muscle regions extracted from one subject (Figure 1-a and -b). The origin and insertion of the muscle cannot be identified on the MR image, and these points were determined on the bone based on the anatomical knowledge. Thus, the template model has entire path of the muscle from origin to insertion. To create homologous models for eighty-eight subjects, the template model was fitted to the bone and muscle regions extracted from each subject's MR image by the initial pose alignment and following free-form deformation technique.

RESULTS AND DISCUSSION

Figure 1-c shows the fitted homologous models of two subject with different physiques and postures. The subject on the left had the well-developed muscles and the scanned posture was in abduction. In contrast, the subject on the right had slim muscles and the scanned posture was in neutral compared with subject on the left. The homologous modeling enabled to represent the bone and muscles in different physiques and postures between subjects.

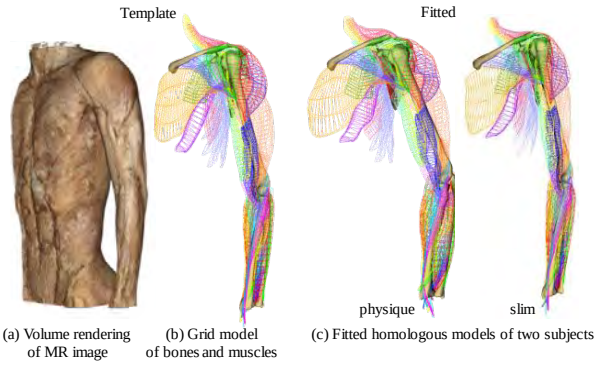

Figure 1 Homologous modeling of upper extremity.

CONCLUSIONS

We developed the morphological musculoskeletal database of left upper extremity using the automatic extraction from MR image and the homologous modeling. The homologous modeling enables the statistical shape analysis. In future study, musculoskeletal database of whole body may be created, and it is expected to be used in the simulation studies.

EFFECTS OF CHRONIC ANKLE INSTABILITY ON ANKLE JOINT ANGLES AND LIGAMENT STRAINS DURING UNANTICIPATED CUTTING TASKS

Hoon Kim[1], Kristof Kipp[2]

INTRODUCTION

Chronic ankle instability (CAI) is one of the most common injuries for active people [1]. Previous studies reported that people with CAI have greater risks of recurrent ankle sprains by reporting differences in talocrural and subtalar joint angles separately between people with and without CAI. However, risks of the sprain in anterior talofibular (ATFL), posterior talofibular (PTFL), and calcaneofibular (CFL) ligament may not be simply estimated with a joint angle because the ligament length is not only affected by joint angles but also other factors (geometry). Hence, it is important to study ligament strain as well as joint angles to better understand risks of ankle sprain. Therefore, the purpose of this study was to compare ankle joint angles and ligament strains between people with and without CAI.

METHODS

Eleven healthy people and 11 people with CAI participated in this study. Participants performed unanticipated cutting tasks while motion data were collected with motion capture cameras. We scaled a generic OpenSim [2] model to create a subject-specific model which includes ATFL, PTFL, and CFL (Fig. 1F). We used Inverse Kinematics to calculate ankle joint angles and Point Kinematics to calculate ligament lengths (L) during the task and a neutral position (L_o). Ligament strain was then calculated as $(L - L_o)/ L_o$. The talocrural and subtalar joint angles and ligament strains were trimmed to the ground contact phase. Statistical Parametric Mapping was used to compare joint angles and ligament strains. The alpha value was set to 0.05. In addition, we used Curve Fitting to show how CFL strain varies with ankle joint angles (Fig. 1E).

RESULTS AND DISCUSSION

There was a significant difference in subtalar joint angle between people with and without CAI during 14-15% of the ground contact period of an unanticipated cutting (Fig. 1A) ($p = 0.049$). However, there were no significant differences in ankle ligament strains (Fig. 1BCD) between people with and without CAI during an unanticipated cutting ($p > 0.05$). These results suggest that studying mechanics related to injury risk of lateral ankle sprain should include analysis of ligament strains in addition to ankle joint angles.

CONCLUSIONS

Although people with CAI exhibited different subtalar joint angle compared to healthy controls, the estimated ankle ligament strains were not different. Therefore, the current study suggests that biomechanical studies should include not only ankle kinematics but also ligament strains as dependent variables when investigating risks of ankle sprains in people with CAI.

Comparison of Synergy Extrapolation and Static Optimization for Estimating Multiple Unmeasured Muscle Activations during Walking

Di Ao[1,2], Benjamin J. Fregly[1]

INTRODUCTION

Electromyography (EMG)-driven musculoskeletal modeling and static optimization (SO) are two primary computational approaches used for estimating muscle forces. EMG-driven modeling method depends on reliable EMG signals to bypass the muscle redundancy problem while simultaneously allowing for calibration of musculotendon properties, while SO is typically used when EMG data are missing from important muscles. Synergy extrapolation (SynX) has been developed recently for estimating unmeasured muscle excitations within EMG-driven modeling [1][2], which can resolve the difficulties caused by technical gaps in experimental EMG measurement, such as inaccessibility of deep muscles using surface electrodes or an insufficient number of EMG channels. However, SynX was validated in cases where EMG data from only one important hip muscle group (iliopsoas) was assumed to be missing at a time [1], and how well multiple missing muscle excitations can be predicted concurrenly using SynX ramains unkonwn. Furthermore, it would also be worthwhile to compare SynX and SO for estimating muscle activations when only eight channels of EMG signals (typically provided by a EMG-recording device) are experimentally available.

METHODS

A generic full-body OpenSim musculoskeletal model [3] was scaled to match each subject's anthropometry using OpenSim 4.0 [4]. Each leg of the model possessed six degrees of freedom (DOFs). SynX and SO were evaluated using gait datasets collected from two subjects post-stroke performing treadmill walking at self-selected and fastest-comfortable speeds, which include sixteen channels of measured EMG (collected using surface and fine wire electrodes) per leg. Eight EMG signals measured either using fine-wire electrodes or associated with muscles making small contributions to joint moments were treated as "unmeasured" and used to evaluate the reliability of SynX and SO quantitatively. SynX used nonlinear optimization to calibrate model parameters, synergy vector weights and average values for constructing unmeasured excitations and for constructing residual excitations simultaneously [1], while SO solved a time frame of muscle activation at a time while incorporating generic model parameter values. To evaluate the performance of both approaches, we also performed EMG-driven calibration using the full set of EMG signals, where no EMG signals were treated as "unmeasured" ((henceforth referred to as "experimental"). Root mean square error (RMSE) and Pearson correlation coefficient r between experimental and estimated muscle activations for unmeasured muscles were computed to quantify matching of magnitude and shape, respectively.

RESULTS AND DISCUSSION

Overall, SynX estimated unmeasured muscle activations with reasonable accuracy (r=0.55±0.13 and RMSE=0.08±0.06) (figure 1). Comparing to standard SO (r=0.11 ±0.30and RMSE=0.15±0.15), SynX made significantly more accurate predictions of unmeasured muscle activations in terms of similarity of both magnitude (p for RMSE=0.021) and shape (p for r<0.01).

CONCLUSIONS

SynX outperformed SO for a large number of estimating muscle activations, which broadens the possibilities for EMG-driven calibration of muscle-tendon properties and may eventually contribute to the design of personalized treatments for mobility impairments, when difficulties exist with collecting EMG signals from important muscles.

INTRODUCTION

One of the most important aspects of physiotherapy is the problem of muscle balance in the pelvis girdle region. The typical observed scheme include hip flexors shortening and hypertension and hip extensors weakening and elongation. The scheme is present both in typical posture defects [2] and low back pain [1]. The idea of the hip flexion resistance training arised basing on muscle resistance training morpho-physiological adaptation mechanisms [3,4]. Since typical daily activities include a variety of hip extension resistance and endurance training, the oposite exercise was selected as a potential sollution to the pelvis stabilizing muscles inbalance.

METHODS

The movement of the resistance hip flexion was recorded with the BTS Smart system for one healthy individual (woman, age 29, weight 49 kg, height 168 cm). There were 28 movement cycles recorded. Each trial contains the exercise performed with both legs in the order: 1) right leg, 2) left leg. Equipment used in the exercise was a free weight machine constructed according to the patent P.435615 (Figure 1B). The exercise was performed with the use of the device weight only. Strain gauges were placed under the feet platforms (separately for the front foot and the back foot) and in the bindings (placed on the back of the feet). A motion capture-driven Musculoskeletal Model (MS) (Figure 1A) was created in the AnyBody Modeling System (AnyBody Technology A/S, Denmark) with the measured forces applied as boundary conditions.

RESULTS AND DISCUSSION

The MS model inverse dynamics study showed that all crucial hip flexors and abductors were highly activated in the exercise. The force generated by each muscle (Figure 1C) was determined by its size and function and did not reflect the muscle activity level. The exercise was designed as a multijoint opposite equivalent of the squat exercise. The resistance application in the movement was therefore untypical for human motor system anatomy. The obtained training conditions showed that the most active muscles generate unproportionally low forces. The disproportion suggests a potential for hypertrophy in long term training [5].

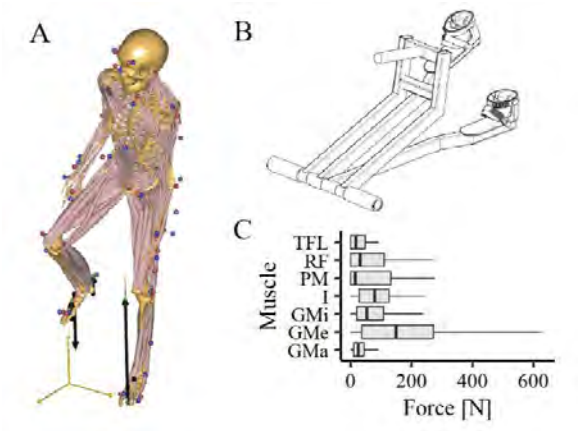

Figure 1A MS model of the exercise, **1B** training equipment construction scheme, **1C** Selected muscles forces in hip flexion resistance training, GMa – Gluteus maximus, GMe – Gluteus medius, GMi – Gluteus minimus, I – Iliacus, PM – Psoas major, RF – Rectus femoris, TFL – Tensor fasciae latae.

CONCLUSIONS

The results show that the proposed exercise activates targeted muscles (hip flexors and abductors) and has a potential to build hypertrophy in muscle groups that present the scheme of shortening in individuals diagnosed with posture defects or chronic low back pain. The exercise requires further validation as a candidate for posture and pain kinesitherapy.

THE EFFECT OF MULTIPLE MEASUREMENT ANGLES ON THE PREDICTION OF JOINT TORQUE-ANGLE PARAMETERS

Amy O. Parkinson[1], Paul J Felton[1], Martin G.C. Lewis [2] and Charlotte Apps[1]
[1] School of Science and Technology, Nottingham Trent University, Nottingham, UK.
[2] Qualisys AB, Gothenburg, Sweden.
Email: amy.parkinson@ntu.ac.uk

INTRODUCTION

The joint torque-angle relationship exhibits a bell-shaped curve, where peak isometric torque occurs in the mid-range. This relationship has previously been modelled using a quadratic function where parameters are optimised to best fit experimental data [1]. Experimental joint torque is typically measured at multiple joint angles throughout the joint range of motion using an isokinetic dynamometer [1,2]. Despite this, it is currently unknown how the number and location of these measurement angles affects prediction of the torque-angle relationship. The purpose of this study was, therefore, to investigate the effect of multiple measurement angles on the prediction of the torque-angle relationship for knee flexors and knee extensors.

METHODS

A two-parameter quadratic was used to model torque production as a function of joint angle for the knee flexors and knee extensors (Equation 1):

$$T_\theta = \left(1 - k_2\left(\theta - \theta_{opt}\right)^2\right).T_0 \qquad \text{Eq1.}$$

where optimal angle (θ_{opt}), width (k_2) and peak isometric torque (T_0) were extracted from literature and used to calculate isometric torque production (T_θ) at 10° intervals throughout the joint range of motion (flexion: 90°; extension: 85°). To simulate submaximal torque production, random noise (0-10Nm) was subtracted from the torque data at each measurement site to create 100 torque-angle curves for each joint action. The effect of the number and location of multiple measurement angles was determined for all possible measurement combinations for a minimum of three joint angles up to the maximum available in the joint range (flexion: 10, extension: 9). Simulated annealing was used to optimise parameters θ_{opt}, k_2 and T_0 and minimise the unweighted unbiased RMS difference [1] between the simulated torque data and the joint torques calculated by the quadratic function. The percentage error between the original parameters derived from the literature and optimised parameter values was calculated for all joint torque-angle curves.

RESULTS AND DISCUSSION

The percentage error between optimised and original parameter values for θ_{opt}, k_2 and T_0 decreased as the number of measurement sites increased for both the knee flexors and knee extensors (Table 1). Larger percentage errors for knee flexion may be explained by the nature of the torque-angle profile, which is predominately ascending and flat, compared to that of the knee extensors which demonstrates a more acute ascending-descending curve. The shape of the torque-angle curve may also explain observably larger percentage errors in k_2, particularly for the knee flexors. Generally, smaller percentage errors were observed for combinations that included a measurement site nearest to the optimal angle, which was close to full extension for the knee flexors (0°) and near the mid-range for the knee extensors (60°). For the knee flexors, combinations consisting of measurement sites closest to the optimal angle (e.g., [0°, 10°, 20°]) resulted in small errors in T_0 and θ_{opt}. Such combinations, however, resulted in larger errors in k_2 compared to combinations which spanned more of the joint range (e.g., [0°, 50°, 80°]). For the knee extensors, combinations consisting of measurement sites closest to the optimal angle (e.g., [60°, 70°, 80°]), or of purely ascending (e.g., [20°, 30°, 40°]) or descending (e.g., [80°, 90° ,100°]) sites exhibited larger errors across all parameters.

Table 1. Mean (±SD) percentage error between optimised and original parameter values across measurement combinations

	Number of measurement sites			
	3	**5**	**7**	**Max**
Knee Flexion				
T_0	6.1 ± 3	4.5 ± 1.1	3.9 ± 0.7	3.9
θ_{opt}	7.9 ± 2	4.9 ± 1.4	3.7 ± 0.7	3.4
k_2	57 ± 31	23 ± 7.7	16 ± 3.5	14
Knee Extension				
T_0	3.0 ± 1.3	2.1 ± 0.4	2.1 ± 0.2	1.9
θ_{opt}	0.7 ± 0.9	0.1 ± 0.1	0.1 ± 0.0	0.1
k_2	8.7 ± 7.9	2.6 ± 1.2	2.0 ± 0.4	2.4

T_0 = peak isometric torque (Nm), θ_{opt} = optimal angle (°) and k_2 = width

CONCLUSIONS

More accurate predictions of the torque-angle relationship should be expected for protocols with more measurement sites. The magnitude of this effect, however, decreases exponentially such that measuring all available sites may not be necessary. Furthermore, the strategy of measurement site selection can increase measurement accuracy. Practitioners should, therefore, consider the research question, muscle group under investigation and practical constraints when formulating an experimental protocol.

3D MODELING OF LEVER ARM AND MOMENT-GENERATING CAPACITY OF STERNOCLEIDOMASTOID AND SCALENUS MUSCLES IN RESPIRATORY MOVEMENT

David Biteau [1], Véronique Feipel [1,2], Serge Van Sint Jan [1], Benoit Beyer [2]

[1] Laboratoire d'Anatomie, Biomécanique et Organogénèse, Université Libre de Bruxelles, Brussels, Belgium

[2] Laboratoire d'Anatomie Fonctionnelle, Université Libre de Bruxelles, Brussels, Belgium

Email: david.biteau@ulb.be

INTRODUCTION

Sternocleidomastoid and scalenus muscles may be involved in musculoskeletal and/or respiratory disorders. Moment generating capacity of these muscles were previously explored during cervical movements [1] but their respiratory motion lever arm and moment generating capacity are still to be determined. Therefore, the aim of the present study was to determine lever arm and moment generating capacity of the muscles of interest using 3D modelling approach.

METHODS

Previously published kinematic data [2] computed from CTscan performed at three lung volumes (TLC: total lung capacity, MIC: middle of inspiratory capacity and FRC: functional residual capacity) were used in the present study.

3D thorax bone models and breathing kinematic data (ranges of motion, mean helical axis (HA) location and orientation) were combined to a generic cervical spine model (GCSM). With LHPFusionBox software (http://lhpfusionbox.org), anatomical landmarks (AL) were positioned on each model for further registration and at the insertion sites of scalenus anterior (Sant), medius (SMed) and sternocleidomastoid (SM). The GCMS was then registered on the first thoracic vertebra of each subject using similarity transformation. (Figure 1A). Length and LA were computed according to the HA of the first costovertebral joint (Figure 1B) using the direct method (shortest distance between muscle line of action and HA). Force and isometric moment generating capacity (MGC) at different lung volumes was computed using data from [1]. The relative variations were calculated as a percentage of the FRC reference position.

RESULTS AND DISCUSSION

Globally, all muscles displayed an increase of LA and MGC from FRC to TLC.

The relative LA variations ranged between 22 ± 18.3% and 35 ± 38.7% for SAnt and SMed respectively.

Relative MGC variations at TLC compared to FRC ranged from 17 to 33 % for SMed and SM, respectively. (table 1). Note that the greatest variations of both LA and MGC occurred between FRC and MIC (i.e. under 50% of the inspiratory capacity) and can be explained by the greater range of rib motion during this phase [2]. Prior work [1] reported scalene muscles maximal LA close to 20 mm for cervical spine lateral bending while the present study showed a minimum LA of 25.1 mm for respiratory contribution. The present minimal LA of SM (32.5 mm) represents approximately 50% of the value obtained for cervical spine lateral bending (55 mm) and 200 % of the value reported for axial rotation (15 mm).

Considering the MGC, for SC, minimal respiratory contribution represents around twice the value reported to generate the flexion and almost the same as for axial rotation.

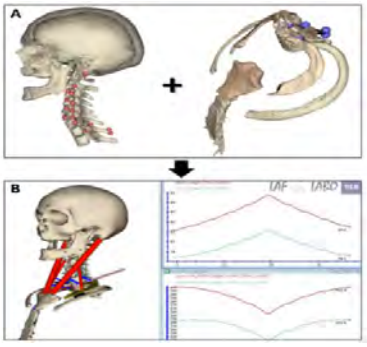

Figure 1: A: Left: GCSM with AL on insertion sites and Th1; Right: Upper thorax model with AL on Th1. B: 3D visualization of SAnt and SM with results of length and LA over

Table 1: Lever arm (mm) force capacity (N) and Moment generating capacity (N.m) for each muscle at different lung volume.

Muscle	Respiratory Position	Lever arm (mm)	Force capacity (N)	MGC (N.m)
SAnt	FRC	29,5	45,4	1,3
	MIC	33,9	49,4	1,7
	TLC	35,0	50,4	1,8
SMed	FRC	25,1	72,0	1,8
	MIC	29,2	70,9	2,1
	TLC	30,2	69,9	2,1
SM	FRC	32,5	65,6	2,1
	MIC	39,3	68,2	2,7
	TLC	41,3	68,4	2,8

CONCLUSIONS

Absolute and relative SAnt, SMed, and SM muscle LA and MGC during respiratory movement were quantified using a modelling approach. For all muscles, LA and MGC increased during inspiration. Respiratory contribution could be compared to cervical movement capacity. Further research will explore interaction of respiratory mechanics in clinical conditions.

INTRODUCTION

Femoroacetabular impingement (FAI) syndrome is an increasingly recognized impairment in high-impact sports athletes. Mostly, an abnormal morphology of the femoral neck (CAM) is present. Coupled with high-impact movements and a high range of motion it can lead to degeneration of the labrum and ultimately to osteoarthritis [1]. In badminton, movements such as the lunge, which involve extreme hip flexion, internal rotation, and partly adduction, are likely to cause FAI. The purpose of this study was to use a subject-specific modeling approach to define the femoroacetabular clearance (FAC) and the pathomechanics of a badminton player with FAI syndrom.

METHODS

One subject (age: 27, height: 1.94 m, weight: 94 kg, CAM-deformity: left) was positioned in supine recumbency in a 3 T Tesla MRI. Sequences were taken in sagittal, transverse and dorsal plane with isotropic voxels (1x1x1 mm^3). The subject then moved through six steps to the maximum flexion, adduction & internal rotation (FADIR) position, with quasi-static pauses between each step for further MRI captures. Afterwards, motion capture data was recorded with 12 cameras (250 Hz). The subject performed three badminton movements (chasse step, back lunge and ready position) and a supposed FAI inducing (FADIR) movement. To create the subject-specific hip model, the neutral position of the subject in the MRI was segmented using 3D Slicer. Due to incomplete capture of the distal femur on the MRI, a statistical shape model (MapClient) was fitted to the subject's anatomical landmarks and merged with the segmentation using the host mesh fitting Plugin in MapClient [2]. Hip Joint Centre (HJC) was calculated using the best spherical fit method. OpenSimCreator was utilized to embed the segmentations with the Gait2392 Model settings, resulting in a subject-specific hip model for calculating minimal FAC. The MRI of the maximum FADIR position visualized the impingement and served to validate the OpenSim model. FAC was defined as the minimal Euclidean distance between the CAM-deformity and superior edge of the acetabulum.

RESULTS AND DISCUSSION

The FAI inducing motion result showed a FAC of 2.14 mm (Tab. 1). The subject reported a stabbing pain during the final position, indicating that an impingement may have occurred. Further analysis of badminton-specific motions revealed similar FAC levels, providing further indication of an impingement. Despite the limitations in determining the exact location of the HJC during high-impact movements due to soft tissue compression, the labrum was likely impinged upon, given its average height of 6 to 7 mm [3] and the small FAC observed. Also, the model allows the analysis of the biomechanics, enabling the identification of potential compensatory movements, such as pelvic list, which may assist to an increased FAC (Fig. 1).

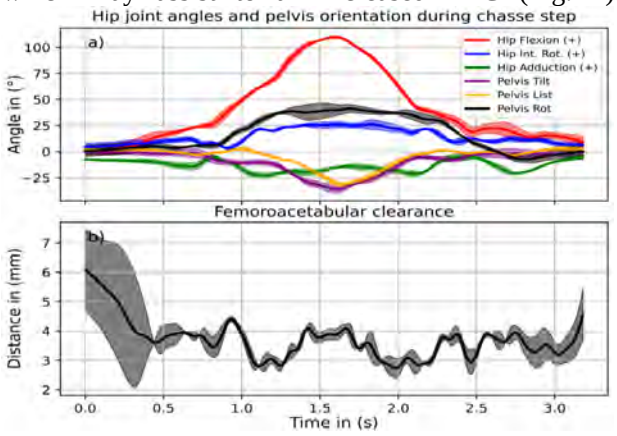

Figure 1 a) Hip joint angles and pelvic orientation according to ISB coordinate system b) FAC between Cam-def. and acetabulum.

CONCLUSIONS

The hip model enables the analysis of FAC of the athlete coupled with its biomechanics. Badminton specific movements demonstrated a potential FAI risk throughout several intervals of the motion but more subjects are needed to define patterns.

INTRODUCTION

Temporomandibular joint disorder(TMD) is a complex disease caused by various factors such as trauma, malocclusion, and many studies on treatment methods were conducted. The TMD was an area that can be recovered through proper diagnosis at an early stage, but in vivo analysis of the temporomandibular joint(TMJ) is difficult to perform in a clinical situation. In order to overcome this problems, biomechanical characteristics were analyzed through electromyography and mandibular movement trajectory[1-3]. however, it is only applied as an supported methods because it is difficult to analysis the muscles of the TMJ in vivo. Therefore, to improve the diagnosis and treatment of the TMD, this study analyzed the muscle characteristics of the TMJ according to the movement of the TMJ using motion capture analysis techniques and a inverse dynamics-based musculoskeletal model.

METHODS

In order to conduct this study, 4 healthy adult women who did not have the TMD or missing teeth and were able to perform normal masticatory movements was selected. The maxillary and mandibular tooth shapes for each subject were extracted through an oral scanner, and a customized mouthpiece was designed through a CAD program and outputted through a 3D printer. The TMJ movements was defined as three main movements such as open-close, side-to-side, protrusion-retraction. The open-close was subdivided into two operations, the max and half open-close. Using a three-dimensional motion capture system based on 8 infrared cameras, motion analysis was performed by repeating movements 3 times for 3 movements, and changes in chewing characteristics were measured. At this time, EMG sensors were attached to both cheeks to verify the inverse dynamics model. Through motion analysis, subjects with representative masticatory characteristics were selected among 4 subjects, and analysis of the inverse dynamics-based musculoskeletal TMJ model was performed by applying representative motion data. In the inverse dynamics model, three movements (half open-close, side-to-side, protrusion-retraction) were considered. The reaction force of the TMJ and the muscle characteristics of the joint periphery were measured according to each movement.

RESULTS AND DISCUSSION

The reaction force of the TMJ for the three movements tended to be highest in the upward and medial directions (Fig 1). In the lateral movement, it was confirmed that the reaction force was high in the anterior direction only (Fig 1). Regarding the muscle characteristics around the TMJ, it was confirmed that the superior lateral pterygoid had the highest contractile force in common in the three movements (Fig 1). This muscle was involved in the forward movement, anterior-inferior rotation, lateral rotation and movement of the mandible. In addition, it was confirmed that the temporal muscle was activated to stabilize the joint during the three movements of the TMJ. It was confirmed that the activated muscles appeared differently as the occlusal and non-occlusal states occurred during one mastication cycle for three movements (Fig 1).

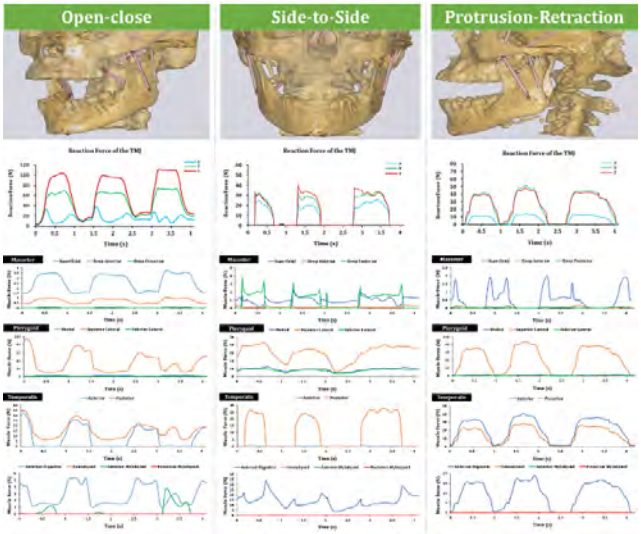

Figure 1 Results of temporomandibular joint reaction force and four major muscle activity for three masticatory movements.

CONCLUSIONS

Based on our results, the correlation between movements and muscles of the TMJ can be analyzed, and it is thought that a more appropriate diagnosis can be made by analyzing the in vivo muscle characteristics of the TMD.

IMPACT OF ACROMIOCLAVICULAR AND CORACOCLAVICULAR LIGAMENT IMPLEMENTATION ON THE SHOULDER MUSCULOSKELETAL SIMULATION

INTRODUCTION

In shoulder musculoskeletal (MSK) simulations, the acromioclavicular (AC) and coracoclavicular (CC) ligaments have not been considered in numerous studies. Additionally, posterior rotation of the sternoclavicular (SC) joint has often been estimated through the motion of the scapula and clavicle [1] or constrained. Therefore, the availability of ligaments, which are significant force generators, and the extent of the SC posterior rotation can affect the validity of simulation outcomes. The purpose of this study is to determine the effects of ligament and degree of freedom (DoF) for SC posterior rotation on the accuracy of muscle activity estimation.

METHODS

We conducted synchronous motion capture (Motion Analysis, USA) and surface electromyography (EMG; Delsys, USA) measurements on two male participants (A:24 years, 165 cm, 60 kg; B:23 years, 169 cm, 57 kg) during arm elevation in the coronal, scapular, and sagittal planes. Joint angles were calculated using inverse kinematics from marker trajectories. EMG was recorded for the 12 muscles of the shoulder and arm. Using OpenSim 4.4 [2], based on an existing shoulder model [3], the ligaments were incorporated as nonlinear springs. In addition, the SC posterior rotation DoF was added and the rotation was estimated [1]. Muscle activation was estimated using a computed muscle control algorithm under four conditions: combinations of SC posterior rotation input (NR: no rotation; ER: estimated rotation) and absence (NoLig) or presence (Lig) of ligaments. To evaluate the validity of simulation, the time-normalized (201 points) EMG and estimated muscle activation under each condition were compared using Spearman's correlation coefficient (r); waveforms deemed similar if $r \geq 0.5$.

RESULTS AND DISCUSSION

In both participants and for all tasks, the validity was higher for Lig than for NoLig. This can be attributed to the disregard of the role of ligaments and the reliance on muscle activity alone to elevate the arm. Furthermore, for Lig across most tasks, the validity was higher for the upper trapezius, serratus anterior, and latissimus dorsi for NR and for the middle trapezius and anterior deltoid for ER (Table 1). Since neither SC posterior rotation inputs showed high validity for all muscles, the treatment of SC posterior rotation should be carefully considered by the muscle of interest. Furthermore, there may be other SC posterior rotation input besides NR and ER that yield more valid simulation results.

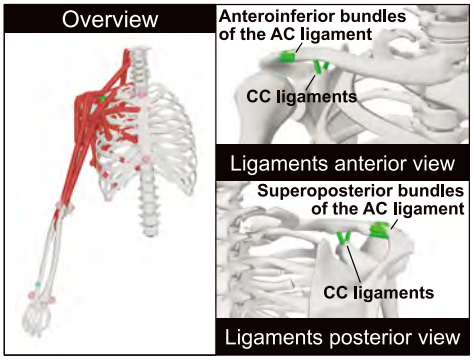

Figure 1 MSK model developed by OpenSim 4.4.

Table 1 Correlation coefficient between measured EMG and estimated muscle activities during scapular plane elevation in participant A ($r \geq 0.7$ for red and $r \geq 0.5$ for pink).

Muscle		NoLig		Lig	
		NR	ER	NR	ER
Trapezius	Upper	0.46	**0.58**	**0.82**	**0.59**
	Middle	**0.69**	**0.70**	0.40	**0.71**
	Lower	**0.68**	**0.71**	**0.81**	**0.71**
Deltoid	Anterior	0.28	**0.82**	0.44	**0.87**
	Middle	**0.66**	**0.64**	**0.69**	**0.63**
	Posterior	0.50	0.45	**0.56**	**0.61**
Pectoralis Major	Clavicle	-0.17	0.25	-0.24	**0.54**
	Sternum	-0.04	-0.72	-0.31	-0.70
Infraspinatus		**0.54**	**0.53**	**0.58**	**0.56**
Serratus Anterior		0.28	0.26	**0.88**	0.28
Teres Minor		0.45	0.46	0.49	**0.51**
Latissimus Dorsi		**0.61**	0.43	**0.90**	**0.62**

CONCLUSIONS

In shoulder MSK simulation, incorporating the AC and CC ligaments leads to more accurate muscle activity estimations. Further refinement of SC posterior rotation input may allow for more valid simulations.

INTRODUCTION

Energy-optimal human movement theories are widely accepted to understand human behaviors [1]. Minimizing the sum of squared muscle activations has been frequently used to determine muscle recruitment during musculoskeletal simulation due to the benefit of computational cost [1, 2]. A previous study reported that minimizing squared activations and metabolic energy consumption had practically similar results in muscle forces [2]. However, minimization of energy consumption affected muscle kinematics, which is important to pathologic gaits of cerebral palsy [3]. The objective of this study was to quantify the effect of optimization criteria that minimized squared activations or energy consumption on muscle length and velocity.

METHODS

The study was approved by the IRB of KAIST. Full-body motion capture data of a healthy subject (23 years, 65.4 kg, 171.2 cm) was obtained during normal walking. A reference gait kinematics was prepared using the motion data.

A full-body musculoskeletal model with 150 muscles was constructed (Figure 1A). The metabolic energy consumption was estimated based on maintenance heat rates, shortening heat rates, and mechanical works of muscles along with a basal metabolic energy rate [4].

Two neural-network-based gait controllers were trained using a deep reinforcement learning method [5]. One gait controller pursued minimization of the sum of squared muscle activations along with motion tracking to the measured gait kinematics. The other pursued minimization of metabolic energy consumption.

Forward dynamics gait simulations were performed for 20 gait cycles. For statistical analysis, gait kinematics, ranges of normalized muscle length (RNML), and peak normalized muscle velocity (PNMV) of rectus femoris, soleus, and tibialis anterior were calculated. The differences in RNML and PNMV between the two controllers were statistically tested via student t-test.

Table 1: RNML, eccentric PNMV, and concentric PNMV for rectus femoris, soleus, and tibialis anterior of the activation and energy minimization controllers (*significant difference with $p<0.05$)

	Rectus femoris		Soleus		Tibialis anterior	
	activation	energy	activation	energy	activation	energy
RNML	0.30 (0.00)	0.30 (0.01)	0.50* (0.01)	0.45* (0.02)	0.16* (0.00)	0.15* (0.01)
PNMV (eccentric)	0.95* (0.07)	0.51* (0.04)	0.86* (0.04)	0.11* (0.07)	0.42* (0.06)	0.28* (0.03)
PNMV (concentric)	0.45 (0.06)	0.47 (0.04)	0.55* (0.06)	0.13* (0.01)	0.46* (0.04)	0.34* (0.02)

RESULTS AND DISCUSSION

Full-body kinematics generated by the activation controller and energy controller were similar (Figure 1B). Root-mean-squared (RMS) differences of lower limb kinematics were less than 2.0°.

RNMLs of the soleus and tibialis anterior were significantly smaller in the energy controller than in the activation controller. Eccentric PNMV and concentric PNMV were also significantly smaller in the energy controller than in the activation controller. The RNML and PNMV results are summarized in Table 1.

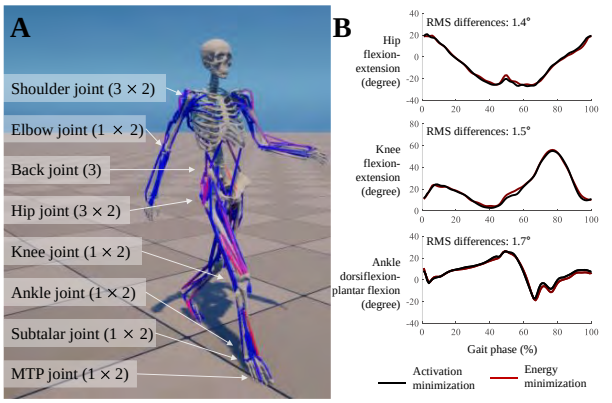

Figure 1 (A) a full-body musculoskeletal model with 150 muscles and (B) lower limb kinematics during gait simulation

CONCLUSIONS

The results of the study showed that muscle kinematics such as RNML and PNMV generated by the energy controller were significantly smaller than those of the activation controller. The differences in muscle kinematics might be caused by shortening heat rates and mechanical works of muscles [4]. The implementation of energy minimization would represent muscle kinematics behavioral characteristics to optimize muscle metabolic energy.

INTRODUCTION

Inertial measurement units (IMUs) are an increasingly popular modality for biomechanical data collection outside the constraints of the laboratory environment. IMU-based joint kinematics are subject to errors from signal noise and drift, soft tissue artefacts, device calibration, and model scaling [1]. Hence, data collection has been predominately limited to controlled laboratory environments or involved few isolated outcome measures. Optimal control simulations can combine a predictive and tracking approach to modelling gait - including physiologically based objectives of locomotion, and having less reliance on experimental data [2]. The aim of this study was to pilot a more holistic and dynamically consistent approach to biomechanical modelling with wearables, using optimal control simulations to track IMU signals with subject-specific musculoskeletal models.

METHODS

Gait data were collected on a subject running on a treadmill at 12, 14 and 16 km/h. Eight Blue Trident IMUs were attached to the torso and lower limbs. Optimal marker-based motion capture was collected simultaneously in Vicon as a data reference standard. Accelerometer, gyroscope and magnetometer signals were fused offline to obtain sensor quaternions [3]. Sensor orientations on the subject were calculated from two static poses [4]. The 3D torque-driven OpenSim model was scaled using statistical shape modelling (MAP Client), via anatomical landmarks on a skeletal mesh fitted to the LiDAR point cloud of the subject [5]. Ground contact was modelled using eleven Hill-Crossly contact spheres attached to the model's feet. Optimal control simulations were performed in OpenSim Moco (V4.4, SimTK, USA). System dynamical equations governing the model states and controls were solved for implictly on a discretized mesh of 100 nodes. As the primary objective, IMU accelerations, angular velocities and orientations were tracked with virtual IMUs at analogous positions on the OpenSim model. Lowly weighted objectives to minimize effort, maintain symmetry and track generic running kinematics and ground contact forces were included. An initial guess was generated from a tracking simulation of generic running kinematics.

RESULTS

The LiDAR scan and marker-based model scaling factors were congruent. In comparison with optical motion capture, mean RMSE errors of 8°, 16°and 14°were seen at the hip, knee and ankle respectively (Figure 1).

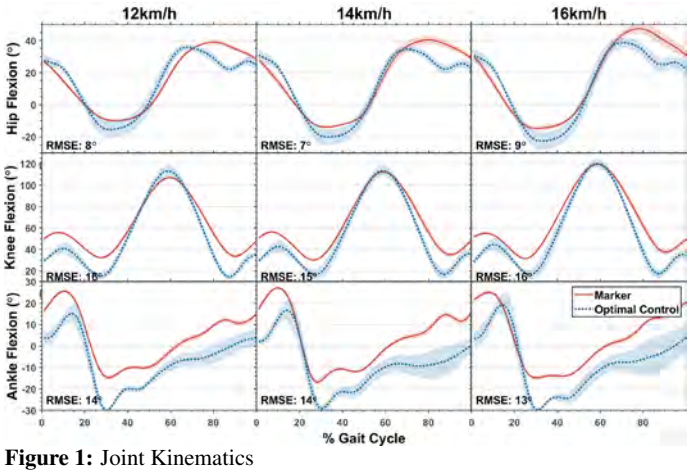

Figure 1: Joint Kinematics

CONCLUSIONS

This work employs IMU sensors within an optimal control framework to model running gait. An appropriately scaled musculoskeletal model with a hybrid objective function combining IMU tracking and effort terms, produced dynamically consistent, kinetic and kinematic measures. Further tuning of the simulation can improve agreement with optical motion capture data. Future work will involve a larger cohort and use muscle-driven models to estimate internal forces and the cost of locomotion. Applications range from modelling experimental data captured outside the laboratory setting, to predicting intervention outcomes in areas such as rehabilitation and sports performance.

INTRODUCTION

Due to the high velocity nature of horse racing, when jockeys fall it can result in career-ending and life-altering injuries [1]. Musculoskeletal simulations provide a controlled, non-invaisive method for studying injury mechanisms of falling jockeys. Estimating forces experienced by the jockey when impacting the ground is necessary to correctly identify injury mechanisms and design preventative interventions. The aim of this study was to estimate paramaters of an equestrian helmet-head-ground contact model, which is a key element to perform realsitic predictive simulations in horse racing.

METHODS

Forward dynamic simulations were performed to replicate a monorail drop rig test [2]. The resultant acclerations were digigisted for 6 conditions: 3 head orientations (front, front boss, and rear boss) and 2 anvil orientations (flat and 45°). An OpenSim model of the skull, using masses of a Hybrid III head form (4.54kg) and a commercial helmet (0.65kg). A single-sphere contact model was used with a Hunt-Crossley force. The initial model positions and velocities were set to match the drop test immediately before impact, and the accelerations were set to zero. The simulation time was 0.03s, to match the digitised data (Figure 1). A bounded optimisation was performed using the SciPy library (v1.9.0) in Python (v3.8.10) to find the best sphere radius, and Hunt-Crossley stiffness, dissipation, transition velocity and friction (static, dynamic and viscous) parameters. The goal was to minimise the sum of squared error between the digitised and simulated data. The optimised kinematics from each trial was used as reference data. An additional forward dynamic simulation was performed per trial with the median optimised parameter values. The RMSE was calculated between the new simulated and reference coordinates.

RESULTS AND DISCUSSION

Digitised accelerations were tracked to within an RMSE of 40 $m \cdot s^{-2}$ (4.01 BW expressed as a force). The error eminates from the inability to accurately replicate the monrail test rig. The rig constrained the dummy head after impact which cannot be simulated without external force information. When using the median values (Table 1), rotational and translational coordinates were within 4° and 1.4cm, repectively, of the optimised reference data. The stiffness value exceeded that reported for racing turfs ($5e^4$-$1.5e^5$ [3]) but was less than that of common helmet materials (e.g. ~$8e^9$ [4]), which reflected the interaction between the softer turf and stiffer helmet-head. Therefore, dissipation coefficient and sphere radius were sufficient to provide appropriate damping and depth and rate of deformation. Given the model aimed to estimate forces and not to describe the nature of the colliding bodies, these values were deemed appropriate. Similarly, the remaining friction coefficients dictate the shape of the friction model, and could be viewed as adequate within this model. Future work will aim to further scrutinise the model paramaters under different racing turf (going rating) conditions.

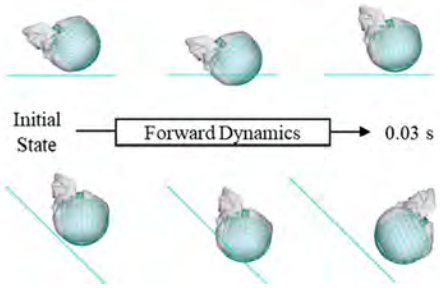

Figure 1 Visual progression of the model state during forward dynamic simulations.

CONCLUSIONS

The contact parameters derived in this study are in-line with realistic values. This allows the contact model to be integrated with predictive simulations of jockey falls, enabling the identification of injury mechanisms and the development of safe fall techniques and protective garments to mitigate against injury risk.

THE PROSTHETIC METATARSOPHALANGEAL JOINT STIFFNESS DURING WALKING ON VARIOUS ENVIRONMENTS: A SIMULATION STUDY

Pankwon Kim[1] and Choongsoo S. Shin[1]
[1] Department of Mechanical Engineering, Sogang University, Seoul, Korea.
Email: cshin@sogang.ac.kr

INTRODUCTION

The metatarsophalangeal (MTP) joint is one of the important factors in lower limb prosthetic design. The MTP joint supports over 30% of the body mass during the push-off phase [1]. MTP joint stiffness affects the ankle moment and power consumption [2]. Several studies attempted to mimic human motion by implementing the MTP joint in the prosthesis design [2,3]. However, these studies focused on the MTP joint mechanics during flat-ground walking. Therefore, the purpose of this study is to propose the stiffness of the prosthetic MTP joint during walking on flat ground, upstairs, downstairs, uphill, and downhill.

METHODS

One male participated in this pilot study. The experimental tasks were walking on flat ground, uphill, downhill, upstairs, and downstairs. The participant was instructed to walk at a self-selected speed during the experiments. A 3-dimensional motion capture system equipped with 10 infrared cameras was used to record the motion of the knee, ankle, and MTP joint at a sampling rate of 400 Hz. The ground reaction force (GRF) data were recorded using a force plate at a sampling rate of 1200 Hz.

A prosthetic model with an MTP joint was developed using OpenSim. The foot was divided into two objects: a prosthetic keel and a prosthetic forefoot section [4]. Then the MTP joint between the prosthetic keel and forefoot section was modeled as a hinge joint. A path actuator composed of a single spring was added 0.05 m below the center of rotation of the MTP joint. A cylindrical wrapping object was inserted into the MTP joint (Figure 1).

To determine the stiffness, simulations were performed in three steps. The first step was to compute the MTP flexion moment through inverse dynamics (ID) with the gait2392 model in OpenSim. The second step was to compute the MTP flexion moment through Computed Muscle Control (CMC) with the prosthetic model in OpenSim. The third step was to match the peak MTP flexion moment calculated in the second step with that calculated in the first step by changing the actuator stiffness repeatedly.

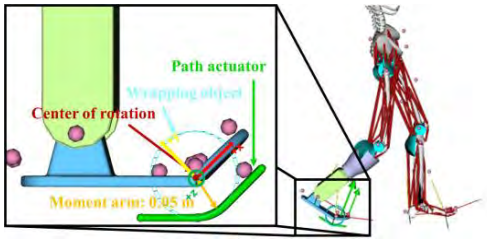

Figure 1 An actuator modelling of metatarsophalangeal joint

RESULTS AND DISCUSSION

Compared with the peak MTP flexion moments calculated through inverse dynamics, the moments calculated using CMC were matched within the error rate of 0.5%. (Table 1). The path actuator stiffness was the highest at 5.00 N/mm during stair ascent (Table 1). Since there is a difference in the MTP joint stiffness according to each walking environment, further study is needed to develop a prosthetic control algorithm to implement variable stiffness based on our results.

CONCLUSIONS

In conclusion, the MTP joint's stiffness could be determined through the developed prosthesis model using OpenSim during walking on flat ground, upstairs, downstairs, uphill, and downhill.

INTRODUCTION

The musculoskeletal simulation can calculate the muscle activity and can reproduce muscle damage that cannot be reproduced by measurement experiments [1]. It is possible to investigate how changes in muscle force, which are difficult to measure directly, affect movements such as jumping.So far, the evaluation of muscle activity is mainly electromyography (EMG). In another study, we performed a jump experiment with 4EMGs attached on lower limbs . 3D ground reaction force (3DGRF) and coordinate data measured by MotionCapture system were used as input data for Opensim's Gait2392 simulation model, and EMG was calculated. The calculated EMG was compared with the EMG measured in the experiment to evaluate the validity of the simulation model. The EMG and muscle force calculated using the Gait2392 simulation model can be taken as a standard reference. Jeffrey reported that sagittal plane jump landing can screening high-risk motion patterns [2]. It is necessary to verify the validity of EMG and muscle force estimated using a simple two-dimensional vertical GRF (vGRF) in order to apply it to motion analysis using two-dimensional image while actual sports and daily living scenes. Therefore, in this study, we analyzed the four muscles of the lower limbs during the countermovement jump (CMJ), and compared the EMG and muscle force estimated using the vGRF and the 3DGRF. Then, the validity of the muscle force and muscle EMG estimated using only the vGRF is verified.

METHODS

The experimental subject of this study is a single healthy male (age:31, height:178cm, weight:85kg). Before conducting this experiment, the content of the trial was explained to the subject in advance, and consent was obtained from the subject. In this experiment, CMJ from a standing posture were performed three times, and the attempt that reached the highest jump height was adopted for analysis. Subject was instructed to take off as quickly as possible and jump as high as possible with maximum effort, with hands on hips. Markers were affixed to 32 locations on the whole body, and images were taken using eight MotionCapture cameras (manufactured by Motion Analysis), and the sampling frequency was set to 200Hz. Using a force plate (Kistler, 600mm x 900mm) to measure the GRF of the right foot during jumping at a sampling frequency of 1000Hz. Analysis was performed using the Opensim Gita2392 model. Simulation 1 used 3DGRF data and Simulation 2 used only vGRF data. Static optimization was performed to improve the long head of the biceps femoris (BF), rectus femoris (RF), lateral gastrocnemius (LG) and tibialis anterior (TA) EMG and muscle force were compared, and validity was evaluated by Root mean square (RMS).

RESULTS AND DISCUSSION

Table 1 shows the estimated maximum EMG, muscle force, and RMS (Table 1). It was observed that EMG and muscle force estimated using vGRF only were smaller than those estimated using 3DGRF. There was a tendency to underestimate the EMG and muscle force of all the lower limbs estimated using only the vGRF, but the time to reach the maximum muscle force and the maximum EMG coincided, and the change curve are almost the same. In addition, the EMG of BF, RF, LG, and TA during the CMJ by simulation model showed similar results to the muscle force exertion patterns of previous studies [3].Since the simulation model was calculated based on the Hill model, when only the vGRF is used, muscle length and muscle contraction speed are not affected, and only the force is considered to be affected. Since the simulation model agrees qualitatively and quantitatively, it is considered to be valid, and we believe that EMG and muscle force during jumping can be predicted using only the vGRF. However, it is thought that it is necessary to clarify how large the estimated value is evaluated in future research.

CONCLUSIONS

The purpose of this study is to verify the validity of estimation of lower limbs EMG and muscle force during CMJ by a musculoskeletal simulation model using only vGRF. The results underestimated the EMG and muscle force estimated using vGRF only, but showed similar change curves. It is considered to have sufficient validity.

INTRODUCTION

Increased joint contact stresses, can lead to cartilage degeneration and thus the development of osteoarthritis. Analysis of cartilage contact mechanics using musculoskeletal model-based simulations provides insights into subject-specific articular joint loading and can provide an estimation of disease risk. While articular joint loading has been well studied in the knee, less is known about loading of the ankle and subtalar joints. Therefore, the aim of this study was to combine state of the art *in vivo* kinematics with novel *in silico* musculoskeletal simulations to estimate ankle and subtalar articular joint mechanics in healthy subjects.

METHODS

12 healthy subjects (29 ± 10 years) with no history of foot-ankle injuries provided written informed consent to participate in this study. Foot-ankle kinematics during a simulated stance phase were acquired using 4D CT imaging [1]. Individual ankle and subtalar 3D kinematics were calculated based on bone specific anatomical coordinate systems [2]. For *in silico* assessment of the hindfoot articular joint mechanics, cartilage contact for the ankle (tibia/talus) and subtalar (talus/calcaneus) joints were added to a foot-ankle model [3]. Contact components were modelled using an elastic foundation formulation based on cartilage stiffness and mesh penetration [4]. Models were then used in a forward simulation whereby ankle and subtalar rotations were prescribed based on the 4D CT measurement. Articular joint mechanics were then estimated using the OpenSim joint and articular mechanics (JAM) tool [4]. To investigate articular joint loading, the contact area as well as mean and peak pressure of the ankle and subtalar joint were analysed.

RESULTS AND DISCUSSION

The ankle joint showed a larger contact area compared to the subtalar joint while mean and peak pressure were higher for the subtalar joint (Table 1). Throughout the stance phase, tibio-talar contact occurred predominantly lateral whereas talo-calcaneal contact occurred at the medio-anterior part of the subtalar joint (Figure 1). For both joints, peak pressure and maximum contact area were found during mid stance.

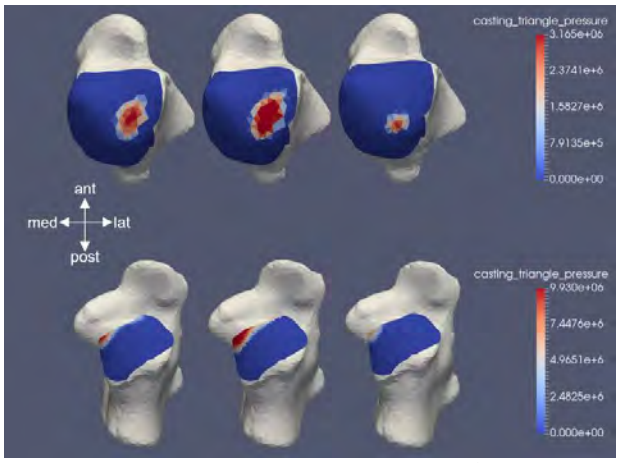

Figure 1: Cartilage contact pressure distribution of the ankle joint projected on the talus (top row), and subtalar joint projected on the calcaneus (bottom row) at initial loading, mid stance, and push off for one subject.

CONCLUSIONS

This study showed a first analysis of articular joint mechanics of the ankle and subtalar joint during simulated gait. Using a musculoskeletal foot-ankle model combined with recently developed methods to estimate cartilage contact mechanics, this study allowed novel insights on the location and magnitude of articular joint loading. While this study provided important findings in a controlled loading situation, further developments are needed to enable the use for functional analysis during other dynamic *in vivo* activities. Furthermore, analysis of pathological cohorts such as subjects with chronic ankle instability can help to understand changes in articular joint mechanics and how they are related to joint degeneration.

INTRODUCTION

Adolescent idiopathic scoliosis (AIS) is the most common type of three-dimensional spinal deformity. Patients with AIS have been found to adopt a bilateral asymmetric joint-to-end-point kinematic strategies with an increased risk of falls during obstacle-crossing [1]. However, it remains unclear of the overall control strategies of the locomotor system for obstacle negotiation in patients with AIS based on the currently known individual kinematic variables. Therefore, the purpose of the current study was to use multi-objective optimal control (MOOC) techniques [2] to identify the overall control strategy in adolescents with AIS when crossing obstacles of three different heights.

METHODS

Twelve adolescents with Lenke 1 thoracic AIS and twelve healthy controls participated in this study. Each subject walked and crossed an obstacle of three heights (i.e., 10%, 20%, and 30% of the subject's leg length) with either the concave- (AIS-A) or convex-side (AIS-V) limb leading while the kinematics and kinetics were measured. A MOOC technique was used to evaluate the control strategies during leading crossing [2], formulated as the best-compromise weighting sets for the conflicting objectives of minimizing mechanical energy expenditure and maximizing the toe-obstacle and heel-obstacle clearances. Mechanical energy expenditure, toe-obstacle and heel-obstacle clearances of the swing-limb were also calculated. Two-way ANOVA were used to study between-subject (group) and within-subject (AIS-V vs. AIS-A or obstacle height) effects on all calculated variables.

RESULTS AND DISCUSSION

Compared to the healthy controls, patients with AIS increased energy expenditure weighting for both AIS-A and AIS-V conditions (Figure 1A). Nevertheless, the mechanical energy expenditure increased under the AIS-A condition but decreased in AIS-V (Figure 1B). Patients with AIS only showed decreased toe-obstacle clearance for AIS-A but there were no any other significant differences in end-point variables in tested conditions (Figures 1C and D). With increasing obstacle height, both AIS and Control groups showed significantly increased mechanical energy expenditure (Figure 1B). These results suggested that patients with AIS were inclined to reduce energy costs compared to the healthy controls. Lower-limb joint work under AIS-A was emphasized to reduce mechanical energy expenditure at the expense of decreased toe-obstacle clearance with an increased risk of falls. The normal toe-obstacle clearance during AIS-V appeared to be a compensation for increased mechanical energy expenditure requirements, which may be affected by the geometric asymmetry of the spine in lateral deformation.

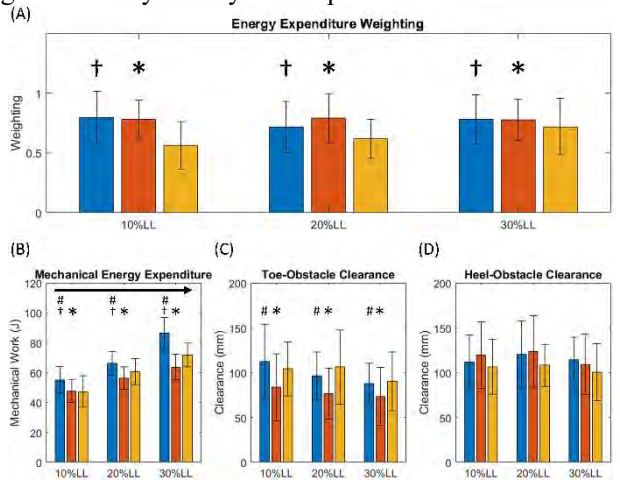

Figure 1 Comparisons of the mean (A) energy expenditure weighting, (B) mechanical energy expenditure and (C) toe-obstacle clearance and (D) heel-obstacle clearance above the obstacle during leading crossing with the corresponding standard deviations shown as error bars. *: AIS-A significantly different from Control. †: AIS-V significantly different from Control. #: AIS-V significantly different from AIS-A. With increasing obstacle height, a right arrow indicates a linearly increasing trend (blue bar: AIS-V; red bar: AIS-A; yellow bar: Control).

CONCLUSIONS

This study identified the overall control strategy in patients with AIS during obstacles crossing. Based on the current results, it is speculated that patients with AIS adopted an altered energy-efficient strategy with bilateral symmetry but showed asymmetric changes in mechanical energy expenditure and end-point control.

INTRODUCTION

Fatigue is one of the major causes of muscle and ligament injuries during many tasks and exercises. One of the most common definitions of fatigue is “failure to maintain the required force to continue performing a task” [1]. This process is described by the decline of muscle Maximal Voluntary Contraction (MVC) force [2]. Previous studies on over-training in athletes show that fatigue often occurs before muscle injuries, where muscles are very vulnerable. These injuries can lead to loss of muscle strength [1]. The role of muscle fatigue in sports performance and rehabilitation makes it necessary to investigate its influence [3]**.** The purpose of this reserch is to detect fatigue level during a physical activity in synergic muscles. The activity history of the selected muscles is obtained via simulation in OpenSim.

METHOD

A healthy 23 years old man (mass:64 kg, height:189 cm) participated in this study. A set of reflective markers were positioned on anatomical landmarks and motion capture system was used to measure the 3D markers displacement. Ground reaction forces were recorded by force plates. The subject was asked to walk continuously for 2 minutes at a constant speed 1 m/s. Therefore, each gait cycle takes about one second. Before starting the exercise, the Maximal Voluntary Contraction (MVC) of each selected muscle was recorded. Using marker trajectories muscle forces were calculated. After importing markers data in OpenSim, using inverse dynamics, muscles’ control data were obtained. In the following the computed muscle controls are used to find muscle activations.

RESULTS AND DISCUSSION

To analyse the results of two gait cycles, one at second 2 and the other at second 120, are used as starting position and terminal positions respectively. As shown in figure 1, the force produced, for example, in soleus muscle in seconds 2 and 120 is compared with each other in the corresponding gait cycle. The active forces are calculated for the other muscles in these two gait cycles. The initial and final maximum force produced in the selected muscles are shown in table 1. As it is given in table 1, the most reduction is happened in the vastus lateralis muscle.

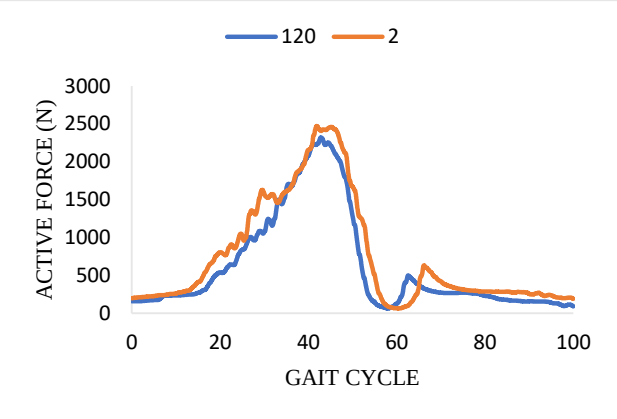

Figure 1 Force produced in soleus during gait cycle in seconds 2 and 120

CONCLUSIONS

According to the simulation data, the maximum reduction in muscle capability is seen in vastus lateralis muscle which is the largest muscle of quadriceps muscles. This muscle directly opposes vastus medialis on the inner portion of thigh. The vastus medialis muscle is the most affected muscle in contusion. This shows the fatigue in vastus lateralis decrease its supporting action and hence leaves the other muscles more susceptible to injuries.

INTRODUCTION

In classical dance (ballet), most of the vertical and horizontal jumps are performed with an increased external rotation position of the lower limb (turnout). To obtain the amount of turnout that is considered to be aesthetically acceptable in theory, which is about 140 degrees, some ballet dancers use the knee, ankle and feet to increase the amplitude between both feet. These compensation mechanisms have been reported as risk factors for the increased incidence of knee, ankle and foot musculoskeletal injuries in dancers [1]. Vertical jumps are constant motor actions that take part in dance choreographies. Jumps occur with different initial conditions and lower limb positions, being the tournout position a recurrent one. The purpose of the present study was to investigate the effect of turn out position on the lower limb muscle forces during vertical jumps performed by classical ballet dancers from the Portuguese National Ballet Company.

METHODS

As a work in progress, one professional classical ballet dancer from the Portuguese National Ballet Company was recruited to perform this pilot study. An informed consent was previously signed by the participant. Motion capture was performed using a markerless camera system (8 Qualisys Miqus, 3-megapixel resolution video cameras), sampling at 85 Hz. Two Bertec Force Plates collected the ground reaction force (GRF) data with a frequency of 1000 Hz. The subject performed a sequence of vertical jumps starting from the following lower limb initial conditions: 1st position (A- with an externally rotated hip joint position and B- with both feet parallel in neutral position), 2nd position (A and B) and 4th position (A and B).
Markerless motion capture video data were processed using Theia3D (v2021.1.0.1450), from which 4x4 pose matrices of each body segment were exported for analysis in Visual3D (C-Motion, USA). An Opensim generic musculoskeletal model with 19 degrees of freedom and actuated by 92 Hill-type muscle-tendon units was scaled to match the anthropometric characteristics of the subject [2]. Residuals reduction was performed to compensate for dynamic inconsistencies between the measured kinematics and GRF. Individual muscle forces were estimated using computed muscle control algorithm during the braking and propulsion phases of the jump.

RESULTS AND DISCUSSION

For this preliminary analysis, data from two jumps (one in neutral position and the other in turnout position) are presented. The subject was a female with 50kg of mass and 1.62m of height.

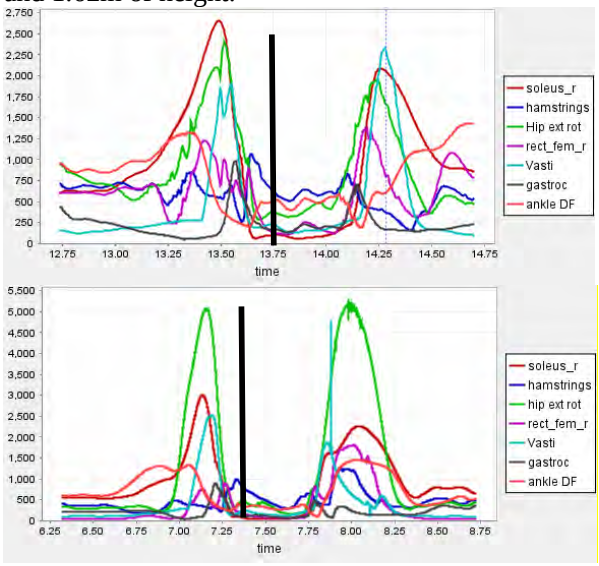

Figure 1 Muscle forces during 1st position (top) and 1st parallel position (bottom) vertical jumps. Vertical line is the take off instant

CONCLUSIONS

In the parallel jump, the subject uses more the hip external rotator muscles when compared with the regular 1st position. Both soleus and vasti muscles are the main force producers but with greater intensity in the parallel jump. Probably due to the different and less used technique.

INTRODUCTION

Modern computational models can accurately quantify anterior cruciate ligament (ACL) loads during dynamic tasks in the laboratory [1,2]. These models use body motion, ground reaction forces (GRF), and electromyograms (EMG). However, acquiring EMG and GRF outside the laboratory, i.e., sports fields or medical clinic, is challenging due to instrument costs, setup time, and skills to acquire and interpret data. Limiting EMG and GRF data, while maintaining model prediction accuracy, would be practically valuable for translation of ACL modelling technology outside the laboratory. We examined the consequences of limiting EMG and GRF on fidelity of model-predicted ACL loads.

METHODS

Twenty-three healthy females (mean (±standard deviation) age, mass, and height of 19.7 (±4.0) years, 59.7 (±9.5) kg, and 1.65 (±0.06) m, respectively) performed a standardized drop-land-jump task, while body motion, GRF, and surface EMG were acquired. Data were used in four neuromuscular models: EMG-informed and static optimization, each with three dimensional (3D) and exclusively vertical GRF. For each model, external biomechanics, lower limb muscle forces, and knee contact forces were computed, and subsequently used to estimate ACL force [1,2]. The ACL force across stance and rank-order of participants based on their peak ACL force were compared across models using one-way repeated measures ANOVA and *post hoc* t-tests via statistical parametric mapping and Kendall's rank correlation, respectively.

RESULTS AND DISCUSSION

Compared to EMG-informed + 3D GRF, both EMG-informed and static optimization methods using only vertical GRF generated significantly higher ACL force (mean differences, 205.5 N and 253.8 N, respectively) for most of stance. When 3D GRF were used, differences between EMG-informed and static optimization were observed only within the final 20% of stance (mean differences, 116.4 N). Compared with static optimization + 3D GRF, both EMG-informed and static optimization combined with only vertical GRF generated significantly higher ACL force (mean differences, 89.1 N and 137.4 N, respectively) for most of stance (Figure 1). No statistically significant correlations in rank-order of participants were found between EMG-informed + 3D GRF and the other models (Table 1), meaning model configuration affects both absolute and relative magnitude of ACL forces. Although, vertical GRF is readily measured in-field using commercially available instruments, this study demonstrated using only vertical GRF substantially overestimated ACL loads. Simplifying the neural model to static optimization overestimated ACL loading even when modelling used 3D GRF.

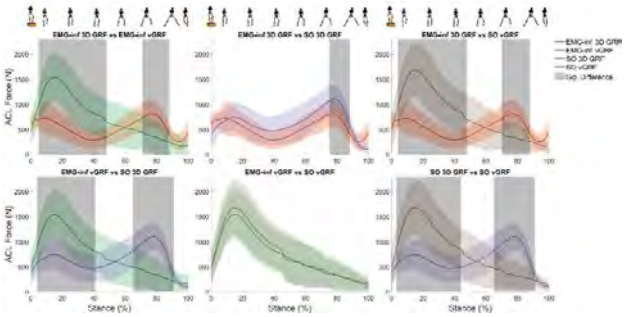

Figure 1. Pairwise comparisons of ACL force (±1 standard deviation) over stance of drop-land-jump estimated via four modelling approaches.

CONCLUSIONS

Simplifying requirement for experimental measures of muscle activation patterns via static optimization and/or reducing GRF from 3D to only vertical force resulted in spurious model estimates of ACL loading. Compared to modelling with 3D GRF, using only vertical GRF resulted in much larger ACL forces due to a lack of a posteriorly directed GRF during landing. The consequence of neglecting EMG in favour of static optimization was more complex. Individual responses were highly variable, but resulted in a small but significant increase in ACL loading for the cohort studied. Finally, rank order of participants based on their peak ACL loading could not be preserved under any simplified modelling approach used in this study. Findings indicate both EMG and 3D GRF should be included to model ACL loading during dynamic tasks.

ACTIVITY OF SUPERFICIAL TRUNK MUSCLES IN PATIENTS WITH STROKE DURING GAIT: A CASE SERIES

Cruz, Christopher[1], Chiong-Maya, Arlene[1], Tiuseco, Archelle Jane[1], Alcantara, Loraine[1], Bieren, Arieane Christie[1], Javier, Victorio Luis Gabriel[1], Maban, Marissa, Joanna[1], Partin, Dorothy Gayl[1]e, Sison, Krizia Mariel[1], Velez, Jacinto III[1], and Young, Har-li[1]

[1] College of Rehabilitation Sciences, University of Santo Tomas, Manila, Philippines.
Email: cgcruz@ust.edu.ph

INTRODUCTION

One of the common sequelae of stroke is difficulty walking, which is strongly attributed to the affectation of the activity of the lower extremity and trunk muscles [1]. Rectus abdominis (RA) and external obliques (EO) muscles provide pelvic stabilization needed for proper leg movements to occur during walking [2]. Most of the studies available have analyzed different activities of the lower extremity muscles [3] and no studies have been found to analyze the activity of RA and EO or the superficial trunk muscles as a whole. The aim of this study is to describe the activity of superficial trunk muscles in terms of peak amplitude and duration using EMG in the gait of patients with stroke.

METHODS

This descriptive case series study will utilize an electromyogram to measure the amplitude of superficial trunk muscle activation during the gait of patients who have had a stroke for the first time and are in Brunnstrom Stage 3 of motor recovery.

RESULTS AND DISCUSSION

Observation made with the use of EMG showed that both the right and left RA and EO of all participants were active all throughout the gait cycle with their peak activity variably seen during loading response, midstance, and terminal stance of the reference leg (right leg), with 70% observed to peak in activity during midstance.

The pattern of muscle activity of RA and EO in the study may be caused by the demands of gait in maintaining minimal displacement of the center of gravity (COG) in relation to positional changes undergone by the body, as well as by the compensations made by the RA and EO for the loss of function of the lower extremities brought about by stroke. This may be taken into account in planning rehabilitation for patients with stroke, which may focus on these muscles when addressing ambulation ability.

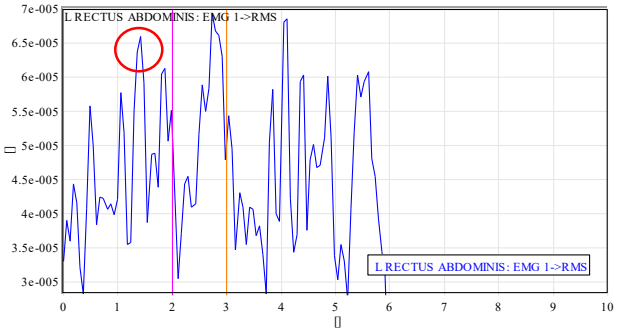

Figure 1 Muscle activity of left rectus abdominis during gait of participant 1. The peak muscle activity of this muscle was obtained during the midstance of the reference leg.

CONCLUSIONS

The superficial trunk muscles- RA and EO- assessed in this study were active all throughout the gait of the participants, with 70% observed to peak in activity during midstance. These observations are assumed to have been brought by the high work demand to the superficial trunk muscles in maintaining minimal displacement of the COG during midstance and/or to be a manifestation of compensation for the weakness of the lower extremity muscles directly brought about by stroke. Further studies are needed to provide concrete evidence of such assumptions.

INTRODUCTION

Parkinson's disease (PD) is one of the neurodegenerative diseases; motor impairments of people with PD start on the unilateral predominance throughout the progression of the disease and present bilateral impairments at a later stage. However, determining the severity of motor symptoms in people with PD relies on subjective diagnosis by neurologists. Furthermore, objective measurement needs to be studied to identify and classify body segments according to disease severity in people with PD. Therefore, this study aims to classify people with PD and healthy controls based on imaging of time-series data using objective and in-depth turning tasks for directions toward the more affected side of people with PD. In addition, there is to present objective factors that may determine the severity of the disease, and its accuracy is to confirm.

METHODS

The participants were 30 people with PD and 30 age-matched healthy controls. People with PD performed the 360° turning task at their preferred speed toward the directions of the inner step of the more affected side in the "Off" state of medication, and the healthy controls performed the task toward the left side. To analyze the time-series data, the position and acceleration data of a total of 40 body segments marker trajectories, including the center of mass, were used, which were converted into new imaging and then trained with a convolutional neural network (CNN) algorithm technique (Figure 1). The performance of the two-group classification model was evaluated using accuracy.

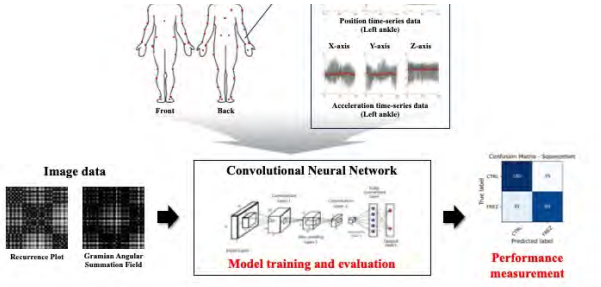

Figure 1 Flow chart for the proposed method.

RESULTS AND DISCUSSION

The body segments classified in the people with PD and the healthy controls were the left (82%) and right (81%) elbows and the left (80%) and right (80%) shoulders in the position time-series data. In addition, they were left (84%) and right (81%) heels, right toe (81%), left ankle (81%), left posterior superior iliac spine (84%), and left wrist (83%) in the acceleration time-series data. In previous studies, the classification accuracy of people with PD and healthy controls during straight gait using wearable sensors was reported to be 87.2% through the distal segments' upper and lower limbs symmetry [1]. The asymmetric characteristics of upper and lower limb segments are most pronounced during disease progression [2]. Therefore, our results identified body segments with bilateral coordination problems of the upper and lower limbs of people with PD based on whole-body segments during turning.

CONCLUSIONS

We identified symptom-affected body segments using full body segments during 360° turning for directions toward the more affected side of people with PD, and suggest that the CNN technique, a deep learning algorithm analysis based on time-series data imaging of identified body segments, may contribute to improving disease severity discrimination and classification of people with PD in the clinical environment.

INTRODUCTION

Foot biomechanics studies in relation to flatfoot deformity have shown that peritalar subluxation at the transverse tarsal joints, particularly increasing abduction of the talonavicular joints, needs to be assessed in the clinical setting. However, the foot movement assess without footwear such as socks and shoes, although the footwear influences for foot movement. Sakamoto and Kudo had shown that the stretch strain sensor (STR) could assess forefoot inversion and dorsiflexion in relation to the hindfoot with footwear[1], however, abduction of the talonavicular joint could not be assessed. The purpose of this study was to develop assessment methods using the STR for abduction of the talonavicular joint.

METHODS

The 14 feet of 14 normal male volunteers (age 44.6±8.0 years old, height 1.72±0.06 m, weight 73.4±13.4 kg) participated in this study. This study was performed after obtaining ethical review approval from our institution.

The difference in talonavicular coverage angle using radiographs between sitting and quiet standing was defined as talonavicular coverage angle excursion (TNCA-E) as the abduction of the talonavicular joint. Foot strain in both sitting and quiet standing was assessed using the STR sensor attached to the medial side of the foot in four patterns. Pattern 1 positioned between the navicular and the sustentaculum tali, pattern 2 between the medial cuneiform and the sustentaculum tali, pattern 3 between the navicular and the medial malleolus and pattern 4 between the medial cuneiform and the medial malleolus. In addition, the STR sensor is inclined for as long as possible to rotate approximately 40 degrees upward from the transverse plane in patterns 1 and 2 and approximately 50 degrees downward from the transverse plane in patterns 3 and 4 (Figure 1).

The change in foot strain between quiet standing and sitting was calculated from four patterns. The difference between four patterns was evaluated using Freedman's test with Bonferroni test. And the correlation coefficient between four patterns of strain change and TNCA-E was assessed using Spearman's coefficient.

RESULTS AND DISCUSSION

The foot strain using pattern3 (median;1.05 (25%-75%;1.04-1.07)) was significantly greater than that using pattern1 (1.03 (1.01-1.06)) and pattern2 (1.03 (1.01-1.04)), and the foot strain using pattern4 (1.05 (1.03-1.06)) was significantly greater than that using pattern1. In addition, the TNCA-E have a significant correlation coefficient with the medial side of the foot strain in pattern3 (r=0.60, p=0.02, power=0.73), and other patterns did not show the significant correlation coefficient.

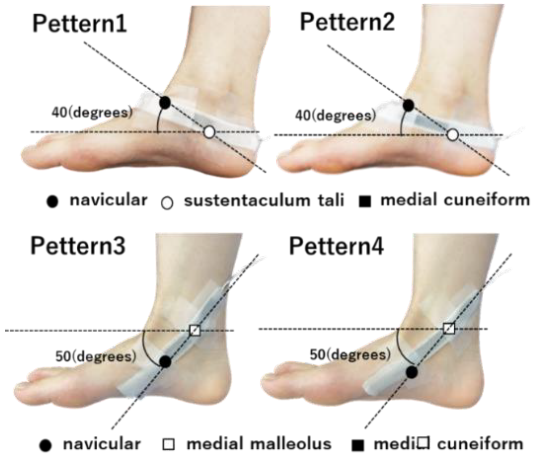

Figure 1 Four mounted patterns of STR sensor

The axis of motion of the talonavicular joint is inclined dorsally by approximately 40 degrees from the transverse plane [2]. The STR in pattern3 and 4 were mounted on the skin perpendicular to this axis, therefore the STR mounted on pattern3 could reflect the abduction of the navicular relative to the talus. And pattern4 was mounted from the medial malleolus to the medial cuneiform, so it might not be difficult to maintain it perpendicular to the axis of motion of the talonavicular joint. The STR in Pattern3 may have the capability to assess the abduction/adduction of the talonavicular joint with footwear conditions.

CONCLUSIONS

The abduction of the talonavicular joint with footwear can be assessed using STR mounted between medial malleolus and navicular.

INTRODUCTION

For patients with hip osteoarthritis (OA), the hip extension limitation is considered a risk factor for disease progression [1]. When considering a rehabilitation approach to prevent disease progression, it is important to know whether the hip flexion-extension movement can be controlled. Recently, researchers have focused on the inter-trial variability of the task variable formed by whole-body movements as an index of the task-specific stability [2]. If the hip angle is sufficiently controlled, the inter-trial variability is reduced and the hip angle is stabilized. This study aimed to investigate a hip movement strategy during gait at the point where the inter-trial variability is produced by whole-body movements.

METHODS

A public gait dataset comprising 106 patients with unilateral hip OA (hip OA group) and 80 asymptomatic participants (asymptomatic group) [3-6] was used. Data were recorded using a motion capture instrument, and twelve stance phase data were extracted from each participant. Using the joint position, the head, neck, upper trunk, lower trunk, knee, and shank angles (supported leg) in the sagittal plane (elemental variables) were calculated, as well as the hip joint angle formed from the elemental variables (task variable). An uncontrolled manifold analysis (which quantifies the contribution of the elementary variables in the stabilization of the task variable) was then performed, and the synergy index ΔV was calculated. The variances of the elemental variables that did not affect the task variable (V_{UCM}) and those that affected (V_{ORT}) them were also calculated, along with the value of the task variable (angle) and its standard deviation (std). Subsequently, statistical parametric mapping (SPM) was performed using a one-sample t-test if the ΔV was more than 0 (whether stabilizing), followed by two-sample t-test to compare the group differences in all variables.

RESULTS AND DISCUSSION

The ΔV in both groups is significantly higher than 0 throughout the stance phase ($p < 0.001$), indicating that the hip angle is stabilized throughout the stance phase. The degree of synergy for stabilization is similar in both groups with respect to the ΔV and V_{UCM} (Figure 1 A, B). However, the V_{ORT} and std beyond 70% of the stance phase (Figure 1 C, E) are slightly higher. Prior to this, the hip angle beyond 20% of the stance phase (Figure 1 D) varies, and the hip angle in the hip OA group is slowly extended within a limited range. This indicates that the gait strategy in the hip OA group can be changed earlier in the stance phase to avoid the need for external stabilization in the sagittal plane during gait.

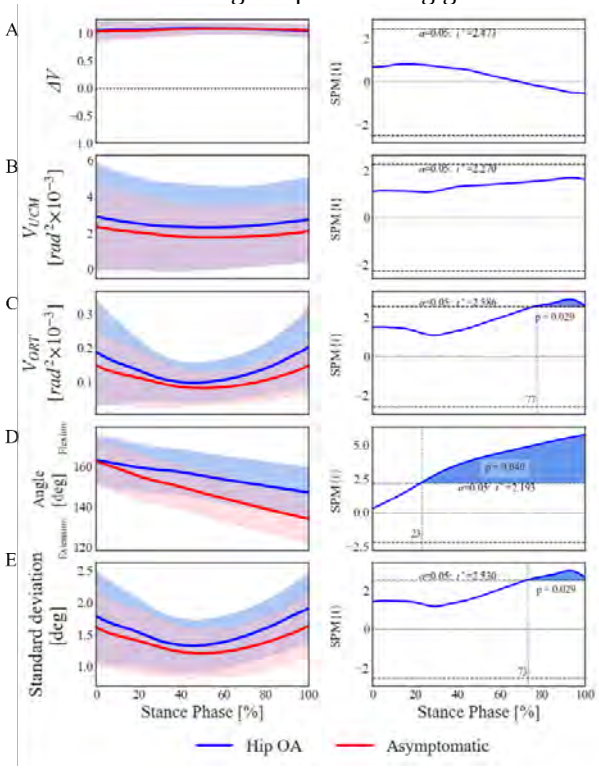

Figure 1 Results of the SPM two-sample t-test of the ΔV, V_{UCM}, V_{ORT}, angle, and std. The mean, standard deviation (left panel), and t value calculated from the SPM (right panel) are shown.

CONCLUSIONS

In this study, patients with hip OA were able to sufficiently stabilize their hip angles during the stance phase by changing their strategy in the early stance phase. Therefore, it is important to consider the reasons for changing the strategy during rehabilitation.

Biomechanical Analysis of Contralateral Cane Use

Hyeoun-Soo Shin[1], Min-Jae Kim[1], Gwang-Moon Eom[1]
[1] Biomedical Engineering, Konkuk University, Chungju , Korea.
Email: kkurehab@naver.com

INTRODUCTION

Osteoarthritis (OA) in knee, especially at the medial tibiofemoral compartment, is a leading cause of disability in elderly people [1,2]. Increase in the knee adduction moment (KAM) was associated with the risk of progression of medial knee osteoarthritis and chronic knee pain [3,4]. Contralateral cane use, but not the ipsilateral one, resulted in significant reduction of KAM [5-7]. However, the mechanism how the contralateral cane use reduces KAM is still unclear. Therefore, the purpose of this study was to identify the mechanism of the reduction.

METHODS

Sixteen healthy young male subjects with no history of lower limbs disease were included in this study. A T-shape cane was used by the right hand which is contralateral to the left (ipsilateral) leg. Subjects were instructed to make the tapping timing of the contralateral cane close to that of the ipsilateral foot contact.

Subjects walked on a 5 m walkway, in the middle of which three force plates were instrumented. Two plates along the progression of subjects were used for legs and the other for the cane. Seven motion capture cameras (Motion Analysis Inc., CA.) were used for kinematic measurement with Helen-Hayes full marker set. Subjects wore tight Mocap suits, hat, and foot covers on barefoot exclusively designed for motion capture, on which reflective markers were placed. No-cane and two cane loading conditions (5 and 10 % Body Weight(BW)) were designed. For the cane loading practice, subjects were requested to match the peak cane load presented by a force platform with the designated loading. Three measurements were made for each loading condition after enough practice.

Kinetic data (KAM, ground reaction force: GRF, and its lever arm) and kinematic data (knee joint center, center of mass: COM, and center of pressure: COP) on the frontal plane during stance phase of ipsilateral leg were extracted from the measured data by using Cortex 8 program (Motion Analysis Inc.) and custom-made Matlab program. The lever arm was calculated on the frontal plane of the knee joint axis. From the GRF on the frontal plane, two instants of peaks in the first and second half of stance phase (1st and 2nd peak instants hereafter) were determined. Kinetic and kinematic data at peak instants were designated as variables for further analysis.

RESULTS AND DISCUSSION

The reduction of KAM in response to the cane loading was correlated far more with the lever arm than with the magnitude of GRF.

Fig.1 shows how the lever arm is altered by cane loadings, i.e., how COM, knee joint center, and GRF change their location and direction. It is noted that the medial shift in response to the increase in cane loading was dramatic for the knee joint center, however the change in GRF direction was not significant. The results suggest that the reduction of KAM was mainly due to the medical shift of knee joint center rather than the change of GRF direction.

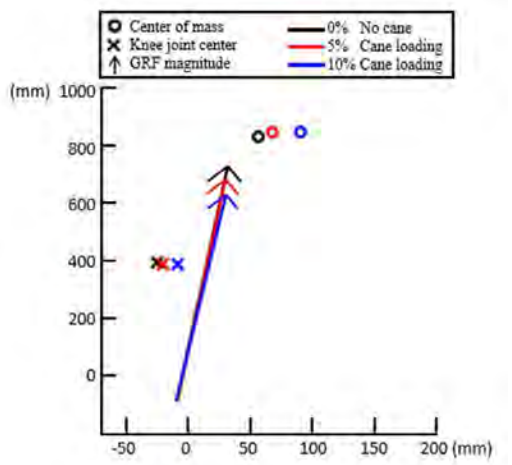

Figure 1 GRF, knee joint center, and COM on the frontal plane at the 1st peak of GRF. For the comparison of different cane loadings, the ankle joint position was set to be at the origin.

CONCLUSIONS

Lever arm had dramatic effect in reducing knee adduction moment rather than GRF magnitude. Lever arm was reduced by medial shift of knee joint center rather than tilting of GRF.

INTRODUCTION

It is known that the co-contraction of dynamic and antagonist muscles increases during gait in the elderly, limiting smooth locomotion[1]. Miyashita et al. estimated ankle power using an IMU sensor, and the establishment of a gait analysis method using an IMU sensor is highly needed in gait analysis research[2]. Therefore, the aim of this study is to investigate whether the co-contraction rate can be estimated using IMU sensors.

METHODS

The participants were 11 outpatients orthopaedic clinic (73.7 ± 6.8 yrs,1.56 ± 0.9 m, 53.3 ± 9.7 kg). An IMU (Cometa, Milano, Italia, 143Hz) was attached to the fibular head of the lower leg (three axes; Ax: vertical, Ay: anterior-posterior, Az: mediolateral axes). Surface electromyography (EMG) was measured from the anterior tibialis (TA: area A), lateral gastrocnemius muscles (GL: area B) using the Wave COMETA EMG system (2000Hz). EMG signals were processed using a Butterworth bandpass fourth order filter of 20 – 400Hz, full-wave rectification, and then a Butterworth lowpass fourth order filter of 6Hz. The muscle co-contraction uses formula (1). (Figure 1) [2]. The measurement task performed comfortable and maximum gait speed. The calculated jerk in each direction was reported as Ax', Ay', Az', and the jerk in the three-axis direction was condensed into one value as the instantaneous magnitude of the vector using the formula (2) [3]. The calculated percent co-contraction and jerk for one gait cycle was divided into stance phase, loading response (LR), mid stance (MSt), terminal stance (TSt), and pre-swing (PSw). The peak jerk value was calculated for each phase and the mean value was calculated from five gait cycles. The variables were investigated age, sex, height, weight, gait speed (comfortable, maximum), percent co-contraction (%), jerk, and estimated ankle joint power (formula (3)). The Spearman's rank correlation coefficient were used to examine the correlation between percent co-contraction and jerk.

・$Percent\ contraction(\%) = 2 \times \frac{common\ area\ A\&B}{area\ A + area\ B} \times 100$ (1)

・$m = \sqrt{Ax'^2 + Ay'^2 + Az'^2}$ (2)

・$Estimated\ ankle\ power(W) = -4.869 + 0.269 \times Ay + 0.104 \times Body\ Weight$ (3)

RESULTS AND DISCUSSION

The dorsiflexors of the ankle are activated during LR, however, an insufficient response to the load occurs with increasing activity of the plantarflexors. The jerk, which represents the instantaneous change in acceleration, is also greater when the change in force is greater. Therefore, jerk is expected to increase when the load responding is sufficient. The negative correlation between the co-contraction and the jerk of the LR in the current study indicates that the changes in force during the load response phase were less due to the co-contraction.

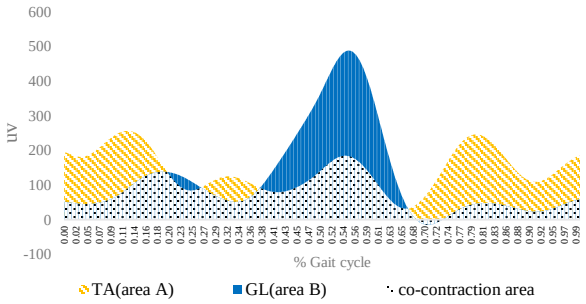

Figure 1 lower leg muscle co-contraction in the gait cycle.

CONCLUSIONS

There is possibility that an IMU can be reflect muscle co-contraction of lower leg muscle from jerk of lower leg during LR phase.

INTRODUCTION

Mobility impairments remain a major concern for people with stroke, impacting their quality of life and limiting community participation. Clinical interventions for gait impairments aim to improve gait quality and reduce compensatory movements. Current clinical practice in gait analysis relies heavily on visual observation which is subjective and dependent on clinical experience. Hence, there is a need to objectively measure gait abnormality and identify its precise location within the gait cycle. We proposed an innovative precision measurement method to assess post-stroke gait impairment clinically using movement analytics powered by SPM1D [1], while at the same time studying the feasibility and patient tolerance.

METHODS

A total of 15 stroke participants (*M* age = 53.73 years old, *SD* = 12.20, 4 females) who fulfilled the following criteria were recruited: (1) unilateral hemiparesis, (2) > 6 months post-stroke; (3) ambulant with at most contact guard/standby supervision with/without walking aid during the study, (4) 10m Walk Test score ≥ 0.2m/s; (5) distance of ≥ 50m for the 6 min Walk Test without rest stop; (6) with Functional Ambulation Category of ≥4 and AMT>6/10. They were excluded if they had psychological and cognitive problems and uncontrolled or unstable medical conditions. The participants were asked to perform a list of lower-limb tasks as outlined in our previous work [2]. All movements were recorded with a 2-megapixel Miqus M3 motion capture system (Qualisys AB, Sweden) using a modified CAST marker set. The markers datasets were first preprocessed and joint angle trajectories (hip, knee, and ankle) were modelled and extracted using Visual3D (C-Motion Inc., USA). Gait cycle segmentation was done using a custom-made code in Python. Time-normalised joint trajectories for each participant during walking were averaged across different repetitions to obtain the subject-level dataset. Joint trajectories of the affected and unaffected lower limbs were compared using a paired *t*-test function in SPM1d.

RESULTS AND DISCUSSION

All stroke participants successfully completed the tasks. Only the results of the walking task are reported. Compared to the normal hip (Figure 1), the affected hip shows reduced flexion during initial contact and terminal swing. During the swing phase, the paretic knee is more extended, and with increased ankle adduction.

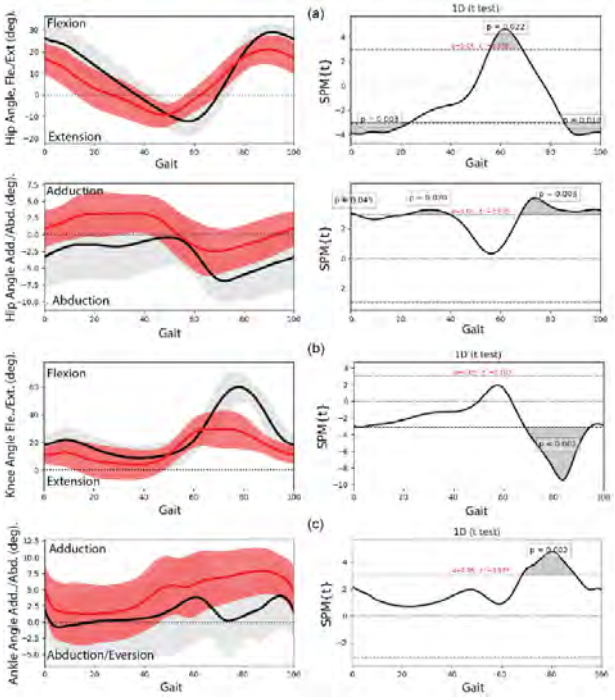

Figure 1. Outputs from the SPM1d analysis comparing affected (**red**) and unaffected (**black**), (a) hip joints, (b) knee joints, and (c) ankle joints during walking. The X-axis represents the full gait cycle. Data are taken from all 15 participants. Significant deviations ($p < 0.05$) are indicated in shaded grey.

CONCLUSIONS

This study shows that SPM1d can specifically identify asymmetry in the gait cycle during walking, where significant abnormalities lie. Future analyses will examine stroke-induced compensatory patterns during walking. This method will potentially be useful clinically as an objective tool to add precision to treatment evaluation.

INTRODUCTION

A medical use of insoles aims to treat, reduce pains and improve the function of those who have disability or abnormality with their lower limbs. In comparison, healthy people use insoles to prevent injuries and pain in the lower limbs and to improve feeling of walking [1]. People use insoles made of different materials depending on their purposes. For the variety of foot shapes of individuals, the author hypothesized that 3D scanning and 3D printers would be beneficial for fabricating insoles for each demand. This research aimed to investigate the effectiveness of the 3D scanned/printed insoles for normal gait for healthy adults.

METHODS

Twenty adult males with normal feet with an arch height ratio of 11-15 % were recruited for our study. The insoles were fabricated using eLabo (Rapithela Corp.) based on digital data of the 3D-scanned participant's soleprint. The insoles were made of EPU41, a UV-curable urethane elastomer. The thickness of the insole was 5 mm. We conducted the experiment under three conditions: bare feet, experimental shoes, and experimental shoes with the 3D-printed insole. Participants walked on the circular path in the following procedure : (1st) walking two laps, (2nd) walking 5 minutes, (3rd) walking 1 minute, (4th) walking two laps. We measured the center of pressure (COP) trajectory using a 9.042m large-scaled foot pressure sensor mat (Nissha Corp.) during (1st) and (4th). Also, expired gas was obtained during (3rd) with douglas bag. Then, the oxygen consumption ($\dot{V}O_2$) was calculated. The maximum lateral amplitude of the COP trajectory of 16 participants was identified, except for participants whose expired gas was leaked.

RESULTS AND DISCUSSION

The median of the $\dot{V}O_2$ for 16 participants with 3D-printed insole condition was smaller than those of the experimental shoes condition (Table 1). Fig. 1 shows the boxplot of the maximum lateral amplitude of the COP related to the foot width for 16 participants with barefoot, experimental shoes, and 3D-printed insoles. The median of the maximum amplitude of the COP trajectory with the 3D-printed insole condition was the smallest for those of the other conditions (Fig. 1). However, the maximum amplitude of the COP trajectory with the 3D-printed insole condition for some participants was not smaller than those of the experimental shoes condition. The maximum amplitude of the COP trajectory was reported to be a barometer of gait stability [2]. Therefore, it was suggested that 3D-printed insoles reduced COP fluctuations for some participants and improved gait stability.

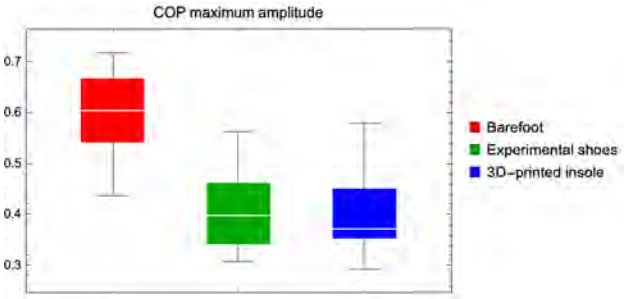

Figure 1 Ratio of COP maximum amplitude related to the foot width with barefoot, experimental shoes, and 3D-printed insoles.

CONCLUSIONS

The results of improved gait stability due to decreased COP maximum fluctuations and reduced oxygen consumption with 3D-printed insole condition suggested that the 3D-printed insole based on the 3D-scanned participant's soleprint could reduce the physical load in a walking motion. However, there were still variations between individuals in the effect of the 3D-printed insole based on the 3D-scanned participants' soleprints.

COMPARISONS OF ENERGY EXPENDITURES AMONG CHILDREN DIAGNOSED WITH IDIOPATHIC TOE WALKING AND TYPICAL CHILDREN USING INERTIAL SENSORS

INTRODUCTION

Children diagnosed with Idiopathic Toe Walking (ITW) walk on their toes and are liable to leg pain and fall injuries. It is crucial to understand how toe walking affects energy expenditure in these children compared to typical children of the same age. In this study, we utilized an inertial measurement unit (IMU) attached at the low back to evaluate the number of steps and energy expenditure in the child's natural setting for three days. Twenty participants were instructed to wear a sensor on their low back for three days, and their activities of daily living (ADL) were objectively quantified during weekdays and weekends in their natural settings. We found energy expenditure was higher among children diagnosed with ITW compared to typical controls. We also found the children diagnosed with ITW took shorter and more steps than age-matched controls. A future investigation into biomechanics and new gait interventions is needed to improve gait efficiency and energy expenditure among children diagnosed with ITW.

METHODS

Ten healthy controls and ten children diagnosed with ITW were recruited in this study. The participants were age matched and consisted of 15 males and 5 females (Age: 8.85 ± 3.45 years, Height:52.96 ± 9.52 cm, Weight: 75.28 ± 40.52 lbs). The study was approved by Chapman University Institutional Review Board (IRB 20-219). To understand energy expenditure in natural settings McRoberts sensor (Dynaport, McRoberts, The Netherlands) was wore by children at their low back for three days after their initial visit to the lab.

RESULTS AND DISCUSSION

For total energy expenditure, ITW subjects took 73.7% more steps on weekdays and 36.8% more steps on weekends than healthy subjects. For the relative total energy expenditure lying percentage, ITW subjects had a 14.3% higher value than healthy subjects on weekdays and a 2.8% higher value than healthy subjects on weekends. For the relative total energy expenditure sitting percentage, ITW subjects had a 4.3% higher value than healthy subjects on weekdays and a 6.4% higher value than healthy subjects on weekends. For the relative total energy expenditure walking percentage, ITW subjects had a 30% higher value than healthy subjects on weekdays and a 7.2% lower value than healthy subjects on weekends. Idiopathic toe walking (ITW) certainly affects daily activities and the quality of life.

Previously researchers have reported that children with cerebral palsy had lower physical activity levels and, as a result, lower total energy expenditure (TEE) values [1]. An investigation on children treated with home parenteral nutrition reported that children undergoing home parenteral nutrition programs had similar levels of TEE as the healthy control children analyzed in the study [2]. As per our knowledge, there has been no investigation on energy expenditure and activities of daily living in children diagnosed with ITW. Our preliminary data shows that ITW children took more steps than healthy children on both weekends and weekdays. This may be due to their shorter step lengths compared to controls. Additionally, children diagnosed with ITW had a more significant relative TEE percentage for lying, sitting, walking, and stair walking on weekends and weekdays.

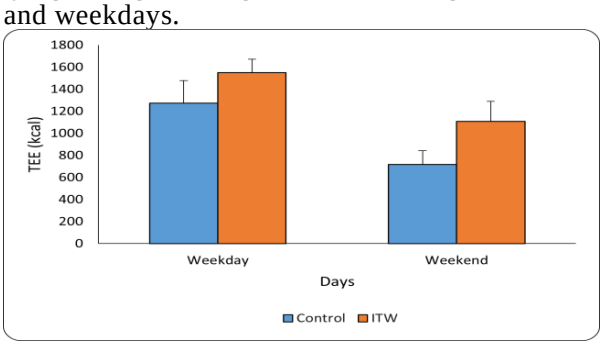

Figure 1 Total Energy Expenditure (TEE) for healthy controls and ITW participants during weekdays and weekends.

CONCLUSIONS

Using advanced technologies like accelerometers our team collected data that could reveal some of the adverse effects of ITW on daily activities and energy expenditures. All questions about the conference should be addressed to soangra@chapman.edu.

INTRODUCTION

Patients with Parkinson's disease (PD) are at high fall risk. Falls prevention requires an easily accessible and objective tool to screen for fall risk. Recently, marker-less motion capture systems have been used for convenient assessment of gait kinematics. We hypothesized that differences in the fall risk would reflect in the gait kinematics in patients with PD. This study aimed to investigate whether gait kinematics obtained with marker-less motion capture are associated with fall risk.

METHODS

Patients with PD hospitalized at the Center for Neuromodulation at Kurashiki Heisei Hospital from January to February 2023, who were able to walk without physical assistance or aids, were included in this study. The Microsoft Kinect V2 sensor (Microsoft Corp.) was used as a marker-less motion capture system. Data obtained from measurements were processed using Mobile Motion Visualizer AKIRA (MMV AKIRA, System Friend Inc.). Participants walked along a 5m path toward the Kinect sensor at a comfortable and fast gait, each once. Using the skeletal coordinate data recorded by MMV AKIRA, walking speed, stride length and time, cadence, and step width were calculated as spatiotemporal variables of gait. The maximum trunk forward lean, bilateral shoulder flexion, extension and abduction, hip flexion and extension, and knee flexion and extension angles during one gait cycle were also calculated. These variables were calculated using MATLAB R2022b (MathWorks Inc.). The fall risk for participants was evaluated using the Mini-Balance Evaluation Systems test (Mini-BESTest). We defined the Mini-BESTest score <19 points as a high-risk group and ≥19 points as a low-risk group, based on a cut-off for high fall risk [1]. Spatiotemporal and joint angle variables of gait were compared between the high-risk and low-risk groups using the Mann-Whitney U test. Statistical analysis was performed using R ver. 4.1.2, with a significance level of 5%. Additionally, *r*-values were calculated as effect size.

RESULTS AND DISCUSSION

A total of 9 patients (5 in the high-risk group and 4 in the low-risk group) were included in the study. In the comfortable gait, there were no significant differences between the high-risk and low-risk groups in all variables. However, the high-risk group tended to have a larger trunk forward lean and left hip flexion angle ($p = 0.111$, $r = 0.531$). In the fast gait, the stride length was significantly shorter in the high-risk group (Table 1). Furthermore, bilateral hip flexion angles were larger, and walking speed tended to be lower in the high-risk group (Table 1).

CONCLUSIONS

The feature of gait kinematics obtained with the marker-less motion capture system differed between the high-risk and low-risk groups for falls. Those differences in fast gait were greater than comfortable gait.

TRUNK MOVEMENT DURING NORDIC WALKING EVALUATED USING A GYROSCOPE IN PATIENTS WITH HIP OSTEOARTHRITIS

Chiho Fukusaki[1,2], Taisuke Nakamichi[2]
[1] School of Health and Sport Sciences, Chukyo University, Toyota, Japan.
[2] Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Japan.
Email: fukusaki@sass.chukyo-u.ac.jp

INTRODUCTION

Patients with hip osteoarthritis (hip OA) frequently show a large movement of the trunk during walking, which has found to be a major risk factor for falling [1]. Nordic walking (NW), which is walking with two poles, is one of the exercises for patients with hip OA [2] and acts as a walking aid in their daily life. It has been observed that NW reduces the vertical contact force in patients with knee OA [3] and improves gait asymmetry in patients with knee and hip OA [4]. This study aimed to investigate whether NW reduced trunk movement during walking in patients with hip OA.

Inertial sensors are used for gait analysis, especially in clinical settings, as they can easily measure gait parameters and do not disturb the patients' usual walking. This study used a gyroscope to evaluate the trunk movements during walking.

METHODS

Participants: Twelve female patients with hip OA who were familiar with NW participated in this study. This study was approved by the Research Ethics Committee of the University of Tokyo and written informed consent was obtained from all participants prior to participation.
Protocol: Participants were instructed to walk along a 15-m level walkway first without poles (normal walking) and then with poles (NW) at a preferred speed. They wore a triaxial gyroscope at the level of the xiphoid process to evaluate the trunk movement. Two triaxial gyroscopes were positioned above the lateral malleolus of each leg to determine the heel contact. The sampling rate of the gyroscopes was 100 Hz.
Signal analysis: Ten steps in the middle of the 15-m walkway were determined and cadence (steps/s) during the interval was calculated. The root mean square (RMS) of the angular velocity around each of the three axes at the xiphoid process was calculated during the 10 steps.
Statistical analysis: Changes in cadence affect the angular velocity of the trunk. To evaluate trunk movement without the effect of cadence, we calculated and compared the following two parameters:
RMS ratio = RMS of angular velocity during NW / RMS of angular velocity during normal walking.
Cadence ratio = Cadence during NW / Cadence during normal walking.

A paired *t*-test was used to compare RMS ratio to cadence ratio. P-values less than 0.05 were considered to be statistically significant.

RESULTS AND DISCUSSION

Table 1 shows the cadence and RMS values of triaxial angular velocity during normal walking and NW. The RMS ratio of the yaw angular velocity was significantly larger than the cadence ratio ($p < 0.01$). There was no significant difference between the RMS ratio of the pitch angular velocity and the cadence ratio. The RMS ratio of the roll angular velocity was significantly smaller than the cadence ratio ($p < 0.001$).

These results suggest that patients with hip OA showed larger yaw rotation and smaller roll rotation of the trunk during NW than during normal walking. A smaller roll rotation implies a smaller lateral sway, indicating a reduced risk of falling during NW. A large yaw rotation during NW would relate to the arm movements needed to move the poles forward and backward.

Table 1 Cadence and RMS values during normal waking and NW.

	Normal walking	NW	Cadence ratio RMS ratio
Cadence (step/s)	1.82 ± 0.12	1.66 ± 0.14	0.916 ± 0.074
RMS-yaw (dps)	20.1 ± 5.7	21.9 ± 6.4	1.099 ± 0.197 *
RMS-pitch (dps)	18.0 ± 7.9	16.3 ± 7.3	0.906 ± 0.111
RMS-roll (dps)	11.5 ± 3.5	8.6 ± 2.5	0.759 ± 0.104 *

*Significant difference between cadence ratio and RMS ratio.

CONCLUSIONS

Using a gyroscope, this study showed that NW reduced lateral trunk movement and increased horizontal trunk rotation during walking in patients with hip OA.

INTRODUCTION

Vision is known as the most important sensory input system for the interpretation of the inner body state and outer environmental circumstances. Aging and its related ocular diseases may cause rapid or chronic descent of the vision, with cataract being one of the most common eye diseases in the elderly, accounting for about 88% of the elderly suffering from vaired degrees of cataract [1]. However, there is no research to date that have investigated how decreased vision affect the whole-body balance control during obstructed gait. This study aimed to quantify the visual impact on the end-point control in healthy elders when performing obstacle-crossing with monocular or binocular vision.

METHODS

Sixteen healthy older adults walked at a self-selected pace on an 8-meter walkway and performed obstacle-crossing with three different obstacle heights (i.e., 10%, 20% and 30% of the subject's leg length) under two visual conditions (i.e., binocular and monocular vision) (Fig. 1). Thirty-nine infrared retroreflective markers placed on anatomical landmarks commonly used in human motion analysis were used to track the motions of the body segments using an 8-camera motion analysis system. For the three obstacle-crossing heights and two visual conditions, a counterbalanced measures design was used, while the sequence of the obstacle and visual conditions were based on a pre-generated random number table.

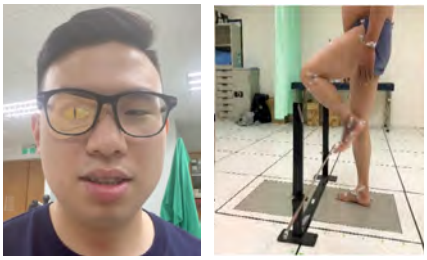

Fig. 1 Subjects crossed a height-adjustable obstacle with binocular and monocular visions.

The marker data were used to calculate endpoint variables. Crossing speed was calculated as the average speed of the whole body's center of mass in the direction of progression over the crossing cycle [2]. A two-way mixed-design analysis of variance (ANOVA) with one between-subject factor (vision) and one within-subject factor (obstacle height) was performed to analyse the spatiotemporal parameters, namely crossing speed, stride length, toe-obstacle distance, heel-obstacle distance, and toe-obstacle clearance.

RESULTS AND DISCUSSION

Subjects showed significantly greater leading and trailing toe-obstacle clearances but lower crossing speed with monocular vision during obstacle-crossing when compared to those with binocular vision (Table 1). No significant between-vision differences were found in stride length, toe-obstacle and heel-obstacle distances (Table 1). No significant height effects were found for any spatiotemporal parameters.

Table 1: Means (standard deviations, SD) of the crossing speed, stride length, and toe-obstacle and heel-obstacle distances with the binocular and monocular visions when crossing obstacles at 20% leg length (LL).

	monocular	binocular	Vision effect
Crossing speed (m/s)	0.78 (0.09)	0.76 (0.09)	$p = 0.01$*
Stride length (%LL)	132.6 (6.9)	132.1 (9.4)	$p = 0.06$
Horizontal distance (%LL)			
Toe-obstacle	27.68 (4.5)	26.50 (3.7)	$p = 0.67$
Heel-obstacle	18.46 (4.7)	19.10 (6.1)	$p = 0.53$
Vertical clearance (%LL)			
Leading-toe	28.93 (5.9)	24.37 (4.6)	$p = 0.01$*
Trailing-toe	25.88 (5.6)	21.62 (8.2)	$p = 0.01$*

CONCLUSIONS

Healthy older adults with monocular vision displayed an obstacle-crossing technique that aimed to produce a lesser risk of tripping control. More studies are needed to assess the fall risk in subjects with visual impairment in older adults.

ALIGNING LOCAL SEGMENT FRAMES BASED ON DIFFERENT OPTIMISATION CRITERIA TO STANDARDISE KINEMATIC SIGNALS

Adrian Sauer[1,2], Ariana Ortigas Vásquez[1,2], Barbara Postolka[3], Pascal Schütz[3], Allan Maas[1,2], Michael Utz[1], Matthias Woiczinski[2], Thomas M. Grupp[1,2], William R. Taylor[3]

INTRODUCTION

Clinical gait analysis involves deriving signals from raw kinematic data to characterise the movement between joint segments. In spite of previous attempts to ensure the reporting of kinematics is standardised, disagreement among the approaches used to define joint coordinate frames and thereby determine kinematic signals prevails. The exact alignment of segment frames has been clearly demonstrated to considerably affect the estimated values of joint kinematics [1,2]. Consequently, tackling these differences in local coordinate frames is essential to allowing the consistent interpretation of joint movement patterns. The REference FRame Alignment MEthod, an extension of the Frame Orientation Optimisation Method [2], specifically accounts for these differences by optimising a selected parameter characterising the studied signal. Here, we investigate the effects of using different statistical parameters to define the underlying objective function to be optimised.

METHODS

REFRAME realigns local segment frames to minimise the values of user-selected optimisation criteria. This study considered a healthy subject's rotational knee kinematics (based on a transepicondylar flexion axis approach), previously captured *in vivo* using dynamic videofluoroscopy during a stair descent trial [1]. Five different REFRAME implementations were applied to the flexion/extension, ab/adduction and int/external rotation signals, where each implementation minimised one of the following statistical parameters of ab/adduction: sum of absolute values, root-mean-square error (RMSE) vs. 0, variance, maximum absolute value, range of motion, and RMSE vs. a reference curve.

RESULTS AND DISCUSSION

Frame transformations produced by REFRAME led to noticeable changes in the magnitude and characteristics of the optimised kinematic signals, both in ab/adduction, as well as flexion/extension and int/external rotation. Changes in ab/adduction were visibly associated with the underlying statistical parameter used to formulate the objective function (Fig. 1). Although previous work demonstrated consistent frame alignment across datasets could be achieved using different implementations of REFRAME [2], the results presented here clearly highlight the importance of considering the exact objective function being optimised before attempting to make any clinical interpretations of the optimised kinematic signals.

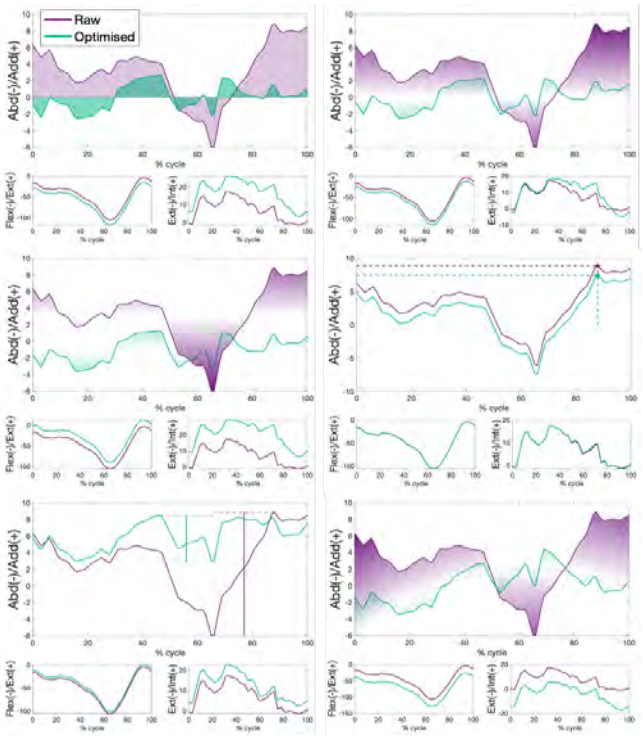

Figure 1 Knee kinematics [°] (tibia relative to femur) for a sample subject stair descent trial before (raw) and after (optimised) REFRAME implementations with different objective criteria (from top to bottom, left: sum of absolute values, variance, range of motion; right: RMSE vs. 0, maximum absolute value, and RMSE vs. a reference curve).

CONCLUSIONS

While REFRAME has the potential to address differences in the local frame alignment of kinematic datasets, the implications of the underlying objective function should be critically considered, especially when attempting to interpret the clinical significance of the optimised kinematic signals.

CENTRE OF PRESSURE DISPLACEMENT AND VELOCITY DURING GAIT IN SUBJECTS WITH LOW BACK PAIN

Clara Leyh[1,2,3] and Véronique Feipel[1,2]

INTRODUCTION

Few studies have investigated the excursion and velocity of the center of pressure (COP) during gait in subjects with low back pain [1-2] although postural instability [3], modified ground reaction forces and plantar pressures [4,5] as well as planus feet [2,6] have been observed in these patients.
The aim of this study was therefore to study center of pressure displacement and velocity during gait at different velocities in patients with low back pain and to compare those with healthy subjects.

METHODS

78 healthy controls (CG) and 146 subjects with low back pain (LBP) walked barefoot three times at three different self-selected speeds (slow, preferred, fast) over a 6-m long walkway, the GAITRite (CIR Systems) or the ZENO (ProtoKinetics). The order of gait speeds was randomized. A 2-m lead-up and follow-through distance was completed to avoid acceleration and deceleration bias. From GAITRite raw contact data and extracted ZENO COP parameters, average values over three trials were computed for posterior-anterior, medial–lateral and resultant displacements (COP*x*, COP*y*, COP*xy*) and velocities (V*x*COP, V*y*COP, V*xy*COP).
Normality, homoscedasticity and linearity assumptions of COP data as well as covariate (age) and independent variable (group) independency were verified to explore differences in COP parameters between three gait velocities (dependant variable) after controlling for age (mixed-model ANCOVA). Mauchly tests explored sphericity assumptions and, where necessary, adjusted p-values were assessed. Tukey HSD test were computed to explore interactions between velocities and independent variables (group).

RESULTS AND DISCUSSION

Mixed-model ANCOVA assumptions (homoscedasticity, linearity, independency covariable-independent factor and homogeneity of regression slopes) were met.
Except for COP*y* that was not influenced by gait velocity after controlling for age (p=0.15), COP*x* as well as all COP velocity parameters increased with increasing gait speed (adj. p<0.001). COP*xy* presented instead a concave U-shaped variation from slow to fast speed (adj. p<0.001).
Between groups, V*x*COP and V*xy*COP did not differ at slow and preferred speeds (p≥0.11) but, at fast speed, subjects with LBP presented significantly lower V*x*COP and V*xy*COP than controls (p<0.001) (figure 1). Moreover, in subjects with LBP, COP velocity differences between gait speeds tended to be smaller than in controls (|Preferred-Slow|=5.5±2.5 cm/s versus 7.0±3.2 cm/s and |Fast-Preferred|=7.3±3.4 cm/s versus 9.1±3.7 cm/s, respectively), reflecting potentially the increased gait velocity of controls, especially at fast speed. Indeed, at fast velocity, controls walked significantly faster with a greater cadence than subjects with LBP (185±0.29 cm/s and 0.21±0.31 steps/s versus 166±0.30 cm/s and 2.10±0.31 steps/s, respectively). In contrast, no differences between groups in COP displacements and V*y*COP were observed after controlling for age.

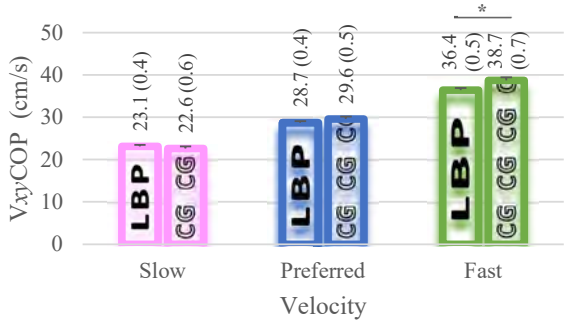

Figure 1 Group-Velocity Interaction for total COP velocity (VxyCOP) at slow (pink), preferred (blue) and fast (green) speeds in subjects with low back pain (LBP) and controls (CG). Adjusted averages and standard errors (vertical bars) are reported for their covariates at their means (Age=38.1 yrs). Asterisks denote the statistically significant differences between groups within gait velocities.

CONCLUSIONS

This study indicates an effect of velocity on mean posterior-anterior and total COP displacement, in agreement with reported anteriorization and posteriorization of the COP at fast speed at 65-90% of stance phase and at heel strike, respectively [7]. The effect of low back pain on mean posterior-anterior and total COP velocities was present only at fast speed but further studies should deepen this finding by controlling gait speed between groups.

INTRODUCTION

A multi-segment spine modelling approach offers a detailed understanding on the complex movement of the scoliotic spine during gait. However, there are several models proposed that utilise difference kinematic modeling approaches [1,2]. Therefore, it is important to compare the segment angles from these models if the associated data will inform clinical management strategies. This study compared the angle outputs from two multi-segment spine models during gait in patients with AIS.

METHODS

Following ethical approval, eight participants (6 female; 15±2 years, 1.7±5.7 m, 59.2±8.7 kg) with scoliosis (S) and four (3 female; 15±1.3 years, 1.64±6.4 m, 55.6±8.8 kg) non-pathological participants (NP) were recruited. Marker trajectory data was collected at 100 Hz using a 10-camera motion capture system (Vicon, Oxford, UK). Reflective markers were attached to the spine and back in accordance with Model 1 (M1) [1] and Model 2 (M2) [2]. Participants were required to walk barefoot at their preferred walking speed (S: 1.08±0.15 m/s; NP: 1.22±0.06 m/s) and fast walking speed (S: 1.44±0.12 m/s; NP: 1.49±0.13 m/s). Segment angle data from 5 trials were time scaled and normalised to 100% of the gait cycle. Upper thoracic, lower thoracic, upper lumbar and lower lumbar segment angles were analysed using ROM and time-series waveforms.

RESULTS AND DISCUSSION

Differences in the ROM and time-series waveforms for the spine segments were apparent both between and within the participant groups, and across kinematic modelling approaches at different walking speeds. For example, the mean lower lumbar segment transverse plane ROM in general was greater for M1 in comparison to M2 (Figure A, B, C, and D). Greater ROM for M1 could be attributed to greater relative movement between reflective markers on the back surface and those attached over the spinous processes. This contrasts with M2 that utilises a 3D cluster approach which negates relative movement between markers, since they are in a fixed position.

Opposing ROM findings were seen across participants, with ROM increasing for some and decreasing for others for both models across different walking speeds. Potentially, both modelling approaches may be influenced by surface topography and lumbar morphology characteristics such as soft tissue artefact, muscle definition, skin elasticity and body composition which affect angle outputs [3].

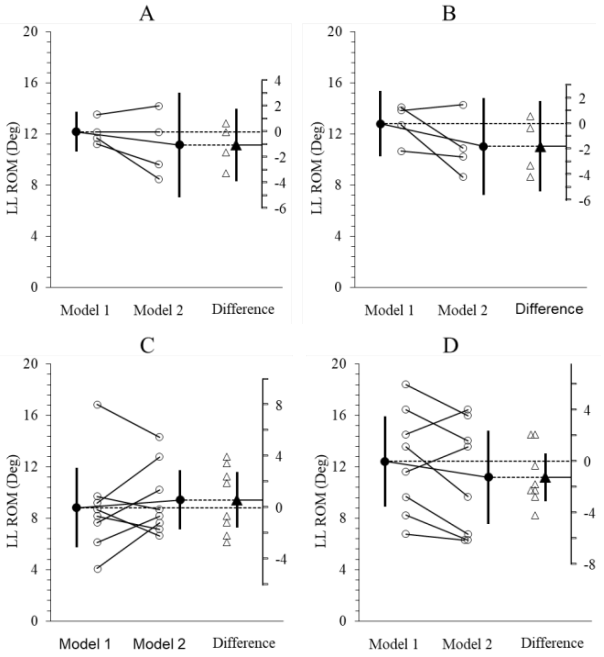

Figure 1 Mean (black circle) and individual (white circle) gait cycle range of motion (A non-pathological PWS and B non-pathological FWS / C scoliosis PWS and D scoliosis FWS) for lower lumbar segment transverse plane angle for Model 1 and Model 2.

CONCLUSIONS

Understanding back surface topography and morphological factors combined with single-subject analysis is vital for understanding and interpreting reported angles from different kinematic modelling approaches. This will contribute to effective clinical management.

MULTI-SEGMENT SPINE MOVEMENT IN ADOLESCENCE IDIOPATHIC SCOLIOSIS AND EFFECT OF WALKING SPEED

Aoife Healy[1], Robert Needham[1], Filip Lazic[2], Nikola Jevtic[2], and Nachiappan Chockalingam[1]
[1] Centre for Biomechanics and Rehabilitation Technologies, Staffordshire University, Stoke on Trent, UK.

INTRODUCTION

Research has shown that walking speed affects the amplitude of lower limb joint kinematics in non-pathological children, with most values decreasing at slower speeds and increasing at faster speeds [1]. An understanding of the effect of walking speed on multi-segment spine movement and in children with scoliosis is required. This study aims to evaluate the impact of scoliosis and walking speed on joint range of motion (ROM) and time-series waveforms.

METHODS

Following ethical approval, eight participants (6 female; 15±2 years, 1.7±5.7 m, 59.2±8.7 kg) with scoliosis (S) and five (4 female; 15±1 years, 1.62±7.0 m, 52.6±10.0 kg) non-pathological participants (NP) were recruited. A 10-camera motion capture system (Vicon, Oxford, UK) collected marker trajectory data at 100 Hz. Reflective markers were attached to the spine, back, pelvis and lower limbs [2,3]. Participants were required to walk barefoot at their preferred walking speed (S: 1.08±0.15 m/s; NP: 1.22±0.06 m/s) and fast walking speed (S: 1.44±0.12 m/s; NP: 1.49±0.13 m/s). Data from 5 trials were time-scaled and normalised to 100% of the gait cycle. Upper thoracic, lower thoracic, upper lumbar and lower lumbar segment angles were analysed using time-series waveforms and ROM.

RESULTS AND DISCUSSION

In line with previous findings for lower limb joint kinematics an increase in the mean amplitude of spinal kinematics was seen at the faster walking speed in both groups. However, differences in ROM and time-series waveforms for the spine segments were evident both between and within the participant groups, and across the different walking speeds. For example, the mean lower lumbar segment transverse plane ROM was higher for NP than S, but differences were evident between individuals within the groups (Figure 1A and B). There was greater variability in the time-series waveforms across S (Figure 1C, D, E and F). These observations highlight differences between the groups and that at different walking speeds participants utilised individual compensatory movements. The variability across S may be attributed to variations in Schroth classifications within the group [4].

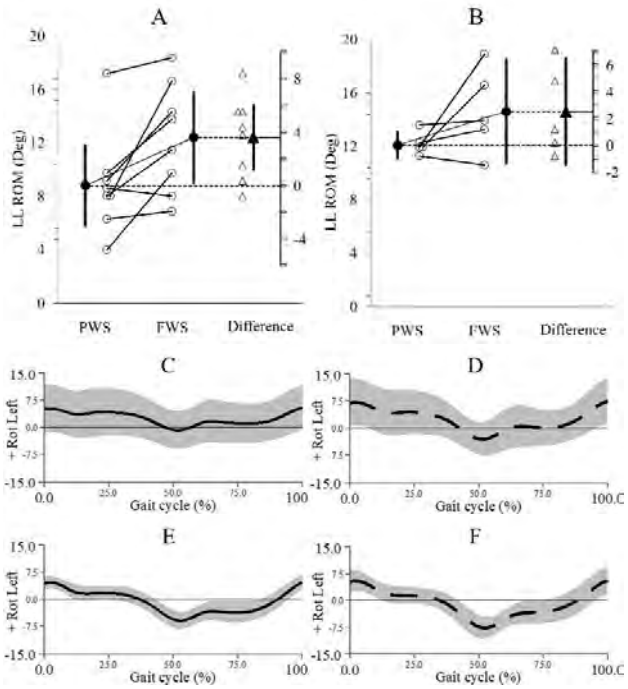

Figure 1 Mean (black circle) and individual (white circle) gait cycle range of motion (A scoliosis and B non-pathological) for lower lumbar segment transverse plane angle for preferred walking speed (PWS) and fast walking speed (FWS). Lower lumbar segment transverse plane angle for PWS (C scoliosis and E non-pathological) and FWS (D scoliosis and F non-pathological).

CONCLUSIONS

Both having scoliosis and walking at varying speeds were found to impact spine segment ROM and time-series waveforms. Results highlight that single-subject analysis should accompany group analysis to aid understanding and support the development of effective patient-specific treatment interventions.

Instrumented Assessment of Falls Risk in Subjects with Mild Parkinson's Disease

Yen-Chun Lin, Sai-Wei Yang
Department of Biomedical Engineering
National YangMing ChiaoTung University, Taipei, Taiwan
Email: swyang@nycu.edu.tw

INTRODUCTION

Parkinson's disease (PD) mainly affects the motor nervous system, and common clinical symptoms include resting tremors, muscle stiffness, motor impairment, slow movement, poor posture control, and unstable gait. Motion disorders lead to an increased risk of falls in patients with Parkinson's disease (Galna etal., 2010; Stegemoller etal., 2012). Clinical scales are mostly used to evaluate the risk of falls, such as: The unified Parkinson's disease rating scale (The unified Parkinson's disease rating scale, MDS-UPDRS) part 3 - motor examination, Berger scale (Berg Balance Scale (BBS), Tinetti Performance Oriented Mobility Assessment (POMA), but most of the assessment methods are based on observation (Kegelmeyer et al., 2007). The purpose of this study was to investigate the characteristic differences in muscle activation and gait ability between PD patients with Hoehn & Yahr grading stage (H & Y Stage) 2 ~ 3 and healthy elderly people of the same age, and using instrumented biomechanical parameters, to score each item of the POMA scale, and comparing the instrumental score and the observation scale score.

METHODS

The experiment recruited 4 PD patients, all onset on the left side, age: 63.5±4.72; H & Y Stage: 2.25 ± 0.25; POMA: 21.00 ± 3.96; MDS-UPDRS - motor function test: 19.5 ± 8.20; BBS: 51.00 ± 2.94 and 6 normal subjects, age: 66.16±3.3; POMA: 28.00±0.00; BBS: 55.00±0.82. After explaining the purpose and procedure of the experiment, and asking the subjects to fill out the consent form, a basic measurement and questionnaires were performed. CTSIB balance tests were conducted.

RESULTS AND DISCUSSION

The results showed that in the PD sit-to-stand test, because the lower activation of the left lower limb muscles, the ability to adjust the postural balance during the sit-to-stand process was low. In the walking test, it was found that the left footstep width of PD was 14% wider, the stride frequency was 28% smaller, and the pace was 18% slower than that of the healthy elderly of the same age(Fig 1). When crossing obstacles, due to the lack of muscle strength of the left lower limb, the center of pressure (CoP) showed larger excursion, and affected the center of mass (CoM)sloshing and significant changes in the CoM-CoP incline angle. The Sensory Integration and Balance Clinical Test (CTSIB) found that the vestibular and proprioceptive balance of PM was low. There are differences between POMA scale observation and instrumental scoring, particularly significant difference in the balance evaluation, but, there is no statistically significant difference between the balance observation scores but the gait assessment in comparison with normal subjects. Although there is no statistical difference between the PD gait and the total score and the instrumental evaluation, compared with normal people who had a full score of 16 for balance and a full score of 12 for gait, the instrumental evaluation can better reveal the stability and prediction of PD dynamic posture the likelihood of its fall occurring.

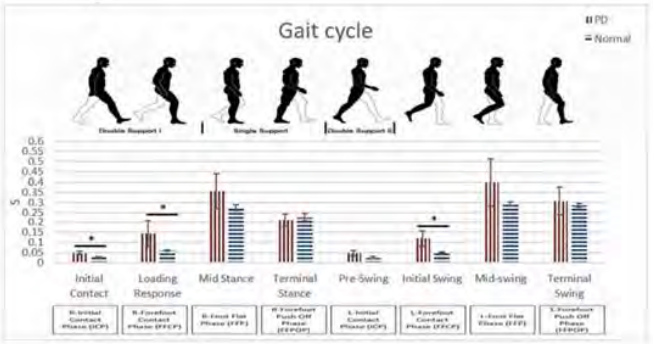

Figure 1 *Time spent on each gait cycle phase*

CONCLUSIONS

Based on the four PD participants who had a consistent left limb onset symptom occurring, the study concluded that due to the lack of strength of the left lower limbs, and the degradation of the vestibular and body balance mechanisms, resulted in unstable posture balance ability in sitting to standing, walking, crossing obstacles, and static balance tests. The instrumental evaluation of POMA scale can scientifically predict the risk factors of falls in patients with mild PD by using biomechanical parameters.

MACHINE LEARNING CLASSIFICATION OF GAIT IN LEPROSY PATIENTS WITH FOOT DROP

Adriane Mara de Souza Muniz[1,2], Jose Carlos Cohen[3], Henrique Lelis Clemente de Oliveira[1], Maria Katia Gomes[3], Luciano Menegaldo[1]

[1] Programa de Engenharia Biomédica (PEB/COPPE), Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [2] Escola de Educação Física do Exército (EsEFEx), Rio de Janeiro, Brazil, [3]Hospital Universitário – Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.
Email: lmeneg@peb.ufrj.br

INTRODUCTION

Leprosy (Hansen's disease) is a neglected tropical chronic infectious condition, with around 200,000 new cases reported yearly worldwide. Common peroneal nerve injury frequently occurs, causing foot drop [1]. The resulting altered gait pattern has not been previously described using 3D gait analysis or classified with machine learning. This study uses logistic regression (LR) and random forest (RF) techniques for discriminating normal gait from foot drop gait caused by leprosy.

METHODS

Gait kinematics and dynamics were analyzed from 12 patients with unilateral drop foot caused by leprosy (8 men; 44.7±10.8 years; 1.7±8.2 m; 82.6±20kg) and 15 healthy controls (12 men; 37.6±15.6 years; 1.7±6.1 m; 74.5±18.6kg). Each subject could walk independently at their self-selected speed along a 10 m walkway for five successful trials. Helen Hayes markers protocol was used to reconstruct gait using the hardware (8 cameras, two force platforms) and software from a BTS (Milan, Italy) system. Fifteen parametric gait variables were evaluated from the patient's affected limb and control's dominant limb and used as classifiers' independent variables: Stance: ankle at initial contact (A_IC); maximal plantar flexion (PFA); maximal knee flexion (KFA); maximal knee adduction (HAA); ground reaction force first (FPF) and second peak (SPF) of force; maximal plantarflexion torque (PFT); maximal knee extension torque (KET); maximal hip flexion (HFT) and extension (HET) torque. Balance: maximal dorsiflexion (Dorsi_B); maximal knee flexion (KFB); maximal hip flexion (HF_B). Gait cycle: pelvic tilt range (PTR) and gait speed. The outcome binary variable was to belong to the patients' (1) or controls' group (0), with a 0.5 cutting point.

For the LR model, the stepwise approach based on the Akaike information criterion (AIC) was used for variables selection, followed by the χ^2 test to contrast with a complete model or with subsets of variables. The selection of variables is made automatically in the RF.

The classifiers' performance was assessed using k-fold cross-validation because our sample size is small. Performance metrics (accuracy, sensitivity, specificity and AUC) were averaged from 5 folds. Class balance was performed in the training group using a bootstrap-based technique (random over-sampling examples - ROSE) with 100 samples. Processing was made in R 4.2.1(R Core Team, 2022).

RESULTS AND DISCUSSION

RF performed better than LR, although not statistically significant (Table 1), similar to [2]. The LR stepwise selection identified A_IC, PFA, Dorsi_B, KFA, HAA and HET as relevant variables. For RF, the most relevant variables were Dorsi_B, PTR, A_IC and HFT (Figure 1).

Table 1: Models performance metrics.

	Accuracy	Sensitivity	Specificity	AUR
LR	0.73 ± 0.19	0.62 ± 0.44	0.81 ± 0.37	0.86 ± 0.22
RF	0.86 ± 0.20	0.81 ± 0.37	0.87 ± 0.35	0.95 ± 0.22
p-value	0.084	0.260	0.500	0.207

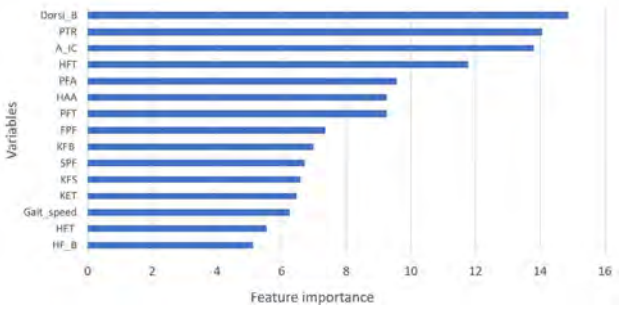

Figure 1 RF feature importance.

CONCLUSIONS

Random forest outperformed logistic regression. For both classifiers, sagittal ankle motion and hip torque were the more important features that classify gait with leprosy foot drop. These results might help guide patients' treatments and follow-up of rehabilitation programs.

INTRODUCTION

The chance and extent of gait instability increases with age [1]. More recently, nonlinear dynamic analysis (NLD) has been used to understand changes in gait as a function of ageing [2]. NLD methods provide the opportunity to study inner structure, regularity, complexity and stability of gait represented by a recorded time series in a more direct way and has presented strong evidence of identifying risk of falling [3]. A recent systematic review indicated that Lyapunov Exponent and Multiscale Entropy are the most commonly used nonlinear dynamic analysis methods in the study of falls in older adults [4]. However, further investigation is needed to determine which method is better suited for distinguishing fallers from non-fallers.

METHODS

The study included 34 healthy female participants aged over 60 years (17 with history of falling and 17 without history of falling in the last year) with a mean age of 73 years (SD = 5.3) and a mean body mass index of 23.4 kg/m2 (SD = 2.7). Whole-body marker trajectories were recorded at 220Hz using an automated 3D motion capture system with a 12 camera motion capture system (Miqus M3, Qualisys AB, Gothenburg, Sweden). Each participant completed four trials of 2-minute treadmill walking at preferred speed (PS), as well as at -20% (slow) and +20% (fast) of PS. The first 2 minutes of each experimental session was used as a warm-up/treadmill adaptation period. The collected data were filtered using a 4th-order Butterworth 14Hz low-pass filter. Short- (SLyE) and long-term (LLyE) LyE using Rosenstein's method, largest LyE (LyE) using Wolf's method and Multiscale Entropy (MSE) using were calculated for joint angles in Sagittal (S), Frontal (F) and Transvers (T) planes, and CoM position in three Medio lateral (ML), Anterior posterior (AP) and Vertical (V) directions. Principal component regressions (PCR) analysis and multiple t-test performed to analysis data.

RESULTS AND DISCUSSION

Results from the stepwise logistic regression on rotated principal components revealed that, across all three different speeds, the Multiscale Entropy (MSE) of the ankle joint in the frontal plane was a significant predictor for distinguishing fallers from non-fallers among the study participants. Specifically, a one-unit increase in MSE of the ankle angle in the frontal plane was associated with a 0.36 decrease in the odds of falling at preferred walking speed (OR = 0.64, 95% CI [0.45-0.92], p <0.001), a 0.26 decrease in the odds of falling at slow speed (OR = 0.74, 95% CI [0.49-0.92], p <0.001), and a 0.38 decrease in the odds of falling at fast speed (OR = 0.62, 95% CI [0.45-0.92], p <0.001). Table 1 presents the p-values of multiple t-test obtained from the output of PCR at three different speeds. These results suggest that MSE of the ankle angle in the frontal plane can be a useful tool for predicting fall risk in older adults at different walking speeds. Further research is needed to determine the effectiveness of MSE in other populations and settings, and to explore the potential of other NLD methods for fall risk assessment.

CONCLUSIONS

In conclusion, our findings suggest that analysing the Multiscale Entropy (MSE) of the ankle angle in the frontal plane may provide valuable information for assessing fall risk in older adults. Specifically, higher MSE values in the frontal plane of the ankle joint were found to be associated with a decreased risk of falling, even after controlling for other variables. These results were consistent across all three different walking speeds and the four different nonlinear dynamic (NLD) methods mostly used in the literature. Therefore, clinicians and researchers may consider using MSE of the ankle angle in the frontal plane as a simple and effective tool for fall risk assessment in older adults.

INTRODUCTION

In clinical practice, the evaluation and treatment of tibial rotation function is performed in patients with osteoarthritis and ACL injuries. There are numerous opportunities to focus on the tibial rotation function during step movements associated with the change of direction, particulary in high performers, including patients with ACL injuries (crossover step, side step, etc.). Alternatively, when driving a car (automatic transmission) with a paralyzed lower limb, there is an opportunity to focus on the pedaling motion by tibial rotation. Despite its importance in evaluating tibial rotation function, the development of a simple measurement method and a reference range of motion are yet to be established. [2]

The goal of this study was to determine the intrarater reliability and range-of-motion (ROM) characteristics of a tibial rotation ROM instrument that was made by the author (Figure 1).

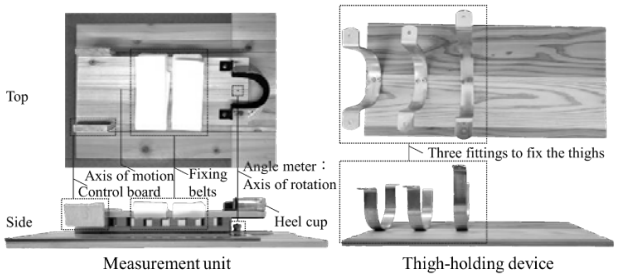

Figure 1 Instrument to measure tibial rotation range of motion.

METHODS

This study included forty healthy adults (23 males, mean age 20.7 ± 1.9 years, 80 legs). None of them had a history of knee problems. The measuring instrument was self-made and comprised a measuring unit and a thigh-holding device. A protractor and a control board that applies force and guides motion compromise the measuring unit. The structure is intended to fix the plate on which the sole of the foot is placed (plantar plate) on the protractor's axis of movement and allow it to rotate freely. The thigh-holding device is made up of three U-shaped metal fittings that are fastened to a board and can be adjusted.

The passive tibial rotation ROM was measured in a sitting position with knee flexion 90° using a self-made instrument. Other movements were used to measure ROM, with the second toe as the axis of movement. The μTas-MT1 (ANIMA) control board was fixed and loaded with the previously discovered resistance value of 4.8 Nm. [3] For the lower extremity, the measurement conditions were two conditions (left/right) and three measurement repetitions.

R software, version 4.0.4 was used for statistical analysis. This was a one-tester intrarater reliability study. The values of the ICC can range from 0 to 1, with a higher value indicating better reliability. ICC less than 0.20 was considered as slight; 0.41-0.60 as moderate; 0.61-0.80 as substantial, and 0.81-1.00 as almost perfect. Normality distribution was confirmed with a prior Shapero–Wilk test for intrarater reliability on the measurements. Furthermore, gender differences in tibial internal and external rotation ROM were examined. A t-test was performed following the Shapiro–Wilk test. Furthermore, the level of significance was set at 5%.

RESULTS

In the estimation of intrarater reliability in tibial internal rotation ROM, high values were obtained ($ICC_{1,3}$= 0.996; 95%CI = 0.994-0.997). Similarly, high values in tibial external rotation ROM ($ICC_{1,3}$ = 0.997; 95%CI = 0.995-0.998) were obtained. Male tibia of external and internal rotation ranges were 50.5 ± 7.6° and 34.1 ± 9.6°, respectively. Females, alternatively, had a range of external and internal rotation of the tibia of 61.1 ± 7.8° and 43.4 ± 8.9°, respectively. Females had a considerably greater range of tibial external and internal rotation motion in than male ($p < 0.001$).

CONCLUSIONS

In measuring tibial external and internal rotation ROM, self-made instrumentation demonstrated high reliability. The measurement is done while sitting, and the structure allows for the application of objective resistance values, indicating the possibility of high versatility for use in clinical practices. There may be gender differences in tibial rotational ROM, and basic data on tibial rotation ROM is necessary for developing a scientifically based physical therapy evaluation and treatment program.

DOES THE LOWER EXTREMITY MUSCULAR FUNCTION SYMMETRY EXIST IN ATHLETES WITH ACLR?

Ning Chu[1], Yin-Ju Chen[1], Yu-Ting Tzeng[1] and Heng-Ju Lee [1]
[1] Department of Physical Education and Sport Sciences, National Taiwan Normal University, Taipei, Taiwan
Email: hjlee@ntnu.edu.tw

INTRODUCTION

The secondary injury of the anterior cruciate ligament (ACL) has attracted more attention in many studies. The incidence of ACL injury on the non-injury side is even twice that of the ACL injury on the injured side (Grassi, 2020). Lower limb asymmetry is one of the risks of injuries. The functional Y-Balance Test (YBT) composite value <94% bilateral symmetry is associated with a greater risk of injury (Plisky, 2006). In muscle strength, a lower H:Q ratio was associated with an increased risk of recurrent ACL graft rupture. Studies also showed that after passing the return to sport tests, the asymmetry of the limbs still exists or gradually develops toward the trend of asymmetry, which leads to secondary ACL injuries. Therefore, this study aims to assess the asymmetry in YBT and bilateral muscle strength after ACL reconstruction.

METHODS

Participants: Ten ACLR and five healthy athletes were recruited to participate in this study. The conditions of ACLR acceptance were: unilateral and one ACL reconstructed surgery; all athletes have completed the rehabilitation and returned to sports. All participants were without lower limbs musculoskeletal injury within six months.

Procedures: Participants performed the function test with the method of YBT. Both legs were tested separately in 3 directions (anterior, posteromedial, and posterolateral). The maximal reach distance of 3 trials was recorded for analysis. The concentric strength of the quadriceps (Qcon), the concentric strength of the hamstring (Hcon) and the eccentric strength of the hamstring (Hecc) of the participants were measured by Biodex isokinetic dynamometer, and the angular velocity was set at 60°/s. One set of 3 repetitions with maximum effort was executed. Both legs were tested separately, and each trial was initiated with the non-injured limb.

Statistics: All the variables were compared between groups using independent-sample *t*-tests. The symmetry index = injury side/non-injury side*100% for ACLR group, and the symmetry index = L side/R side*100% for the healthy group. Significant level was set at $\alpha \leq .05$.

RESULTS AND DISCUSSION

The participants' characteristic data are in Table 1. The reconstructed grafts were all semitendinosus for ACLR. The symmetry index of all the variables (Figure 1.) showed that ACLR's hamstring concentric and eccentric strength symmetry indexes were lower than the healthy group. These variables of the injury leg were lower than the non-injury leg in the ACLR group. The role of the hamstring is to counteract the forward shear force exerted by the quadriceps on the tibia to reduce the stimulation of ligaments and joints. It is important to reduce and prevent secondary ACL injuries. The YBT index, quadriceps concentric strength, and traditional and functional H:Q ratio were not significantly different

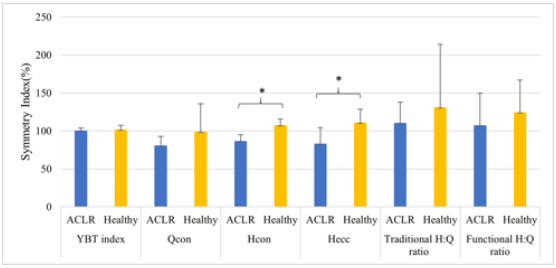

Figure 1 The symmetry index of variables, *p<.05

CONCLUSIONS

Although the athletes have returned to sport over two years, and the results of their YBT are symmetrical, the hamstring's concentric and eccentric strength may still be asymmetry. This might lead to a higher risk of secondary ACL injury.

Analyses of Lower Limb Asymmetry in Division I Women Basketball Players: A Pilot Study

Pin-Chun Tseng, Hui-Wen Hsiao, Heng-Ju Lee
Department of Physical Education and Sport Sciences, National Taiwan Normal University, Taipei, Taiwan
Email: hjlee@ntnu.edu.tw

INTRODUCTION

In basketball, lower limb injuries are the most likely to occur. More than 60% of lower limb injuries occur during practice or competition, and the proportion of injuries to female athletes is more significant than that of male athletes [1]. Since basketball is a sport with unilateral dominance, it may cause asymmetry of lower limb balance and strength between the dominant and non-dominant sides. In jumping and landing tasks, if the difference between the two sides of the lower limbs is too significant, it will increase the incidence of non-contact lower limb injuries, such as injury of the anterior cruciate ligament (ACL). For sports that use the single leg, single leg drop jump is more suitable as an assessment method [2]. Therefore, this study aimed to analyze the Reactive Strength Index (RSI) and Dynamic Postural Stability Index (DPSI) differences between the dominant and non-dominant sides of female basketball players through single-leg drop jumps.

METHODS

Seven Division I female basketball athletes were recruited in this study (age:23.86 ± 1.46 years old; height:174 ± 5.95 cm; weight:67.71 ± 8.48 kg). Subjects had no severe head and lower extremity injuries or surgery within half a year. Within three months before the start of the experiment, subjects are without acute lower extremity injuries. This study defines the dominant side, which players subjectively think of as the foot they use to kick the ball.

In the experiment, a force plate (Kistler, 9260AA6, Winterthur, Switzerland, 1000Hz) was used to collect the ground reaction force parameters for data analysis during the single leg drop jump, including Jump height, RSI, Impact force, and DPSI. Using paired t-test to compare the differences between RSI, Jump height, landing impact force, and DPSI of the dominant and non-dominant side.

RESULTS AND DISCUSSION

The results of this study show (Table 1) that the dominant side is significantly larger than the non-dominant side in the RSI of single-leg drop jump, but there were no significant differences in jumping height, impact force, and DPSI. All seven subjects in this study's dominant side are right sides. However, there was no significant difference in jumping height between the dominant and non-dominant sides. The difference in RSI showed that the dominant side could reach the same jump height with a shorter movement time, which may be related to specific movements of basketball pattern to explain, such as unilateral jumping. Jumping injuries are common in basketball, especially when landing on a single leg. Past research has also shown that jumping and landing in an asymmetric pattern has a higher probability of non-contact injuries [3].

CONCLUSIONS

The symmetry of the lower limbs helps improve and reduce the risk of injury [4]. The difference in the RSI between the dominant and non-dominant side of the women's basketball players in Division I may be one of the potential injury risks. It is still needed to determine whether the RSI can be used as an effective indicator for predicting athletes' lower limb injuries. There are currently only seven subjects in this study, and the experiment will continue in the future. After enough subjects, the results will be more convincing.

INTRODUCTION

Anterior cruciate ligament (ACL) injuries usually occur in non-contact sports that require repeated jumps, landings, and postural changes, and previous studies have shown that the incidence of ACL injuries is higher in female athletes, about 2-6 times higher than in males. In another epidemiological study on ACL injury in badminton, female badminton players had a higher incidence of ACL than males [1]. Investigating gender differences in muscle activity in badminton players during the pre-landing preparation phase of high-risk single-leg landing tasks and incorporating gender differences in kinematic data would better help badminton coaches, players, and rehabilitators understand the potential risk mechanisms that may contribute to the high incidence of non-contact ACL injuries in females.

METHODS

Sixteen badminton players (8 male, 8 female) performed a single-legged badminton landing task, and kinematic data and muscle activity data of the lower extremity were recorded for each subject. Gender differences in lower limb kinematic data, mean values of lower limb muscle activity, and co-contraction values during the landing preparation phase were compared using an independent samples t-test.

RESULTS AND DISCUSSION

In the badminton landing task, the knee valgus angle was greater in females than in males (6.27 ± 2.75 vs. 1.72 ± 3.20) in the pre-landing preparation position （Table 1）. During the pre-landing preparation phase (100mms before initial contact). prospective studies in athletes have shown that a large knee valgus angle predicts a potentially high risk of subsequent ACL injury. The mean and standard deviation of lower limb muscle activity during the landing preparation phase of a single leg landing task after a backhand side overhead stroke in badminton, as shown in Figure 2.

Compared to male badminton players, females exhibited greater gluteus maximus (44.92±18.00 vs 20.34±11.64), rectus femoris (41.56±9.84 vs 26.14±10.46), and medial gastrocnemius (37.39±17.31 vs 19.11±11.17) lateral gastrocnemius (36.86±17.82 vs 13.59±2.71) muscle activity. This may be due to the large gluteus maximus, rectus femoris, and gastrocnemius muscles associated with large ACL loads [2].

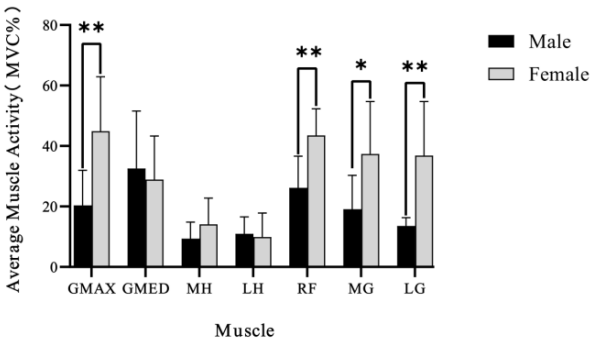

Figure 1 Mean and standard deviation of lower limb muscle activity during the preparation phase before landing for the single-leg landing task in badminton. * and ** represent statistically significant differences ($p<0.05$) and highly significant differences ($p<0.01$), respectively.

CONCLUSIONS

During the landing preparation phase of the badminton single-leg landing task, there were significant gender differences in neuromuscular control (muscle activity patterns, movement patterns) between badminton players. Female badminton players exhibit neuromuscular control strategies that may be inadequate for ACL protection and a potential risk factor for a high incidence of ACL injury. In the future, when developing programs to prevent ACL injuries in female badminton players could consider targeting the optimization of neuromuscular control during the pre-landing preparation phase.

INTRODUCTION

Reliably predicting post-surgery walking function can help inform better designs of surgical treatments and reconstructive implants for pelvic sarcoma patients. One key task is to predict the muscle activations during post-surgery walking. Muscle synergies have been used to represent muscle activations in lower dimensionality via the combination of time-varying synergy activations and vectors of muscle weightings, defined as the synergy vectors [1]. A previous study predicted post-surgery walking while assuming synergy vectors remain constant pre and post surgery [2]. We explore in this study the methods of using pre-surgery muscle synergies to predict post-surgery muscle activations.

METHODS

Experimental gait data of a pelvic sarcoma patient were collected before the internal hemipelvectomy surgery and 12 months after the surgery. A subject-specific musculoskeletal model was developed in OpenSim, to simulate and analyze the gait motions of each sessions [3]. We calibrated an EMG-driven model using 15-16 channels of EMG data for each of the operated and the non-operated leg pre and post-surgery and obtained muscle activations [4]. The pre-surgery muscle activations of each leg were decomposed into muscle synergies using non-negative matrix factorization from which the synergy vectors were set constant while synergy activations varied cycle-to-cycle. We subsequently investigated: 1). if the pre-surgery muscle synergy vectors, or 2). if the pre-surgery muscle synergy activations (mean), can reconstruct the post-surgery activations at a high level of "variability accounted for" (VAF). The post-surgery synergy parameters were solved via a non-negative least square problem of the pre-surgery muscle synergy parameters and post-surgery muscle activations. The percent variability accounted for (VAF) was used to evaluate both cases.

RESULTS AND DISCUSSION

The reconstruction of post-surgery muscle activations was at VAF<20% in Case 1, whereas at VAF>90% when ≥6 synergies were used in Case 2 (Figure1).

CONCLUSIONS

Using pre-surgery synergy activations combined with minimally changed synergy vectors may be the more reliable way to predict post-surgery walking given the high VAF in reconstructing muscle activations.

EFFECT OF SHOE SOLE THICKNESS ON THE EXTERNAL ANKLE JOINT INVERSION MOMENT DURING DROP LANDINGS ON A TILTED SURFACE

Nahoko Sato[1], Yasuo Ikegami[2]
[1] Faculty of Rehabilitation Science, Nagoya Gakuin University, Nagoya, Japan.
[2] Research Centre of Health, Physical Fitness and Sports, Nagoya University, Nagoya, Japan.
Email: nsato@ngu.ac.jp

INTRODUCTION

Many shoe companies utilise damping materials, such as gel, air, or springs, in the midsole to prevent injuries and improve performance, resulting in the development of many shoes with thicker midsoles, particularly for running. Thick-soled shoes have also been developed for other sports, such as basketball, where the foot is often exposed to horizontal ground reaction force (GRF), such as cutting movements. When the foot is exposed to horizontal forces during landing, the external ankle inversion/eversion moments that the foot undergoes depend on the positions of the centre of pressure and ankle joint centre [1]. Thus, if the position of the ankle joint centre become higher because of thick soles, these moments generated by the horizontal GRF would become larger. Although there have been many studies on the effect of shoe sole thickness on running movement, the effect of sole thickness on foot kinetics exposed to horizontal GRF has not been clarified.

This study aimed to investigate the effect of different sole thicknesses on foot kinetics during landing movements on a tilted surface exerting horizontal inward GRF on the foot. It was hypothesised that the thickness of the sole increases the distance between the ground and centre of the ankle joint, resulting in a larger moment arm of the horizontal GRF, which generates a larger inversion moment.

METHODS

Twenty healthy men (age: 20.6 [standard deviation (SD) 1.7] years; height: 171.1 [SD 1.8] cm; and mass: 63.0 [SD 8.6] kg). The Nagoya Gakuin University Research Ethics Committee approved the experimental procedure, and written informed consent was obtained from each participant before commencement of the experiment.

In this study, three conditions with different shoe midsole thicknesses were used; the same shoe model (Stan Smith, Adidas) was used for all three conditions, and the thickness of the midsole was adjusted to provide 25 mm (control condition), 35 mm (+10 mm condition), and 45 mm (+20 mm condition) from the outsole to the insole, respectively. The shoes used in each condition had the same upper cup, heel cup, and outsole.

Spherical markers were attached to nine landmarks on the right lower leg and foot. Participants were asked to drop land with right leg onto a tilted force platform (Kistler instruments) at 25° from 0.3 m above the force platform for the aim of exerting a constant horizontal inward force on the foot. Their motions were captured using a 10-camera motion capture system (Vicon Motion Capture Systems), sampling at 500 Hz. This motion capture system was electronically synchronised to the force platform, which was sampled at 1,000 Hz. The three conditions were randomised, and five trials were conducted for each condition.

The time from the toe contact to the first peak of the horizontal component of the GRF (Fy) was defined as the initial landing phase. During the initial landing phase, the external ankle inversion moment due to Fy and its moment arm were calculated. All the parameters were averaged over five trials for each participant. Variables from the three conditions were analysed using one-way repeated-measures analysis of variance, followed by the Tukey's post hoc test for multiple comparisons. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

The inversion moment at the time of peak Fy was largest in the +20 mm condition (0.20 [SD 0.03] Nm/BW), followed by the +10 mm (0.18 [SD 0.03] Nm/BW), and then the control (0.16 [SD 0.02] Nm/BW), with significant differences among the three conditions ($p < 0.05$). The moment arm of inversion moment at that time also showed the largest value in the +20 mm condition, although there was no significant difference in the value of Fy among the three conditions. These results support our hypotheses.

Although materials with poor cushioning were used to adjust the midsole thickness in this study, it has been reported that a shoe with high cushioning reduces the peak value of the GRF during running [2]. Thus, a material with higher shock absorption should be used in the thick-soled shoes to minimise the disadvantage of the increased moment arm owing to thick-soled shoes.

CONCLUSIONS

When the foot is exposed to horizontal GRF, the external ankle inversion moment would increase with a thicker sole. This is caused by the thicker sole increasing the moment arm of the horizontal GRF. Cutting movements with thick-soled shoes are considered to increase the risk of ankle sprains.

INTRODUCTION

Slope walking is inevitable activity during daily life, and the risk of falling in the elderly is increased due to increased challenges to balance control during slope walking [1]. Up to 453% hip powers increase required in young adults when incline walking [2], but little is known about the elderly, even though muscle strength decreases with aging [3]. Therefore, this abstract aims to quantify the total work done in the 3D hip joint.

METHODS

Twenty healthy male adults (Ten young: 23.7±1.1yrs, 67.5±5.0kg, 174.8±4.6cm. Ten elderly: 64.8±2.4yrs, 68.1±7.4kg, 170.4±5.6cm) were fitted with 29 retroreflective markers (Helen Hayes Marker Set). Participants were habituated to the walkway area and then performed at least three walking trials at each of the three grades (+6°, 0°, -6°). Each participant walked at a self-selected speed. Each subject took at least two steps on the slope before and after contacting the force platform. The GRF data and kinematic data were captured with a mounted force platform (Kistler 9286B, Switzerland) and a 6-camera 3D Optical Capture system (Motion Analysis Raptor-4, USA). Each foot's major gait events (heel strike and toe-off) were visually identified. GRF data were filtered using a fourth-order zero-lag Butterworth filter of 15 Hz. Positive (P) and negative (N) work were calculated in each trial by integrating the power curves over one stride. Two-way repeated measures ANOVA($\alpha \geqslant 0.05$) was used to assess slope effect, with Tukey post hoc tests.

RESULTS AND DISCUSSION

Significant changes in 3D hip joint work are presented in Figure 1. Positive and negative work were compared with 0° in the top and middle planes. Elderly hip work was compared with the young at the bottom. In the sagittal plane, a significant interaction effect of aging and gradient was found on the positive work ($p<0.01$), a significant interaction effect of aging and gradient was found on the negative work ($p<0.01$). In the frontal plane, aging significantly affected positive work ($p<0.01$), a significant interaction effect of aging and gradient was found on the negative work ($p<0.01$). In the transverse plane, aging significantly affected positive work ($p<0.01$). Negative work was affected by aging ($p<0.01$) and gradient ($p=0.01$) (Figure 1). For the young, the largest changes were observed in the frontal plane with up to 198% increase in work relative to level gait. For the elderly, the largest changes were observed in the sagittal plane with up to 197% increase in work relative to level gait. Compared with the young group, aging has led to more than five times power increase in the transverse plane.

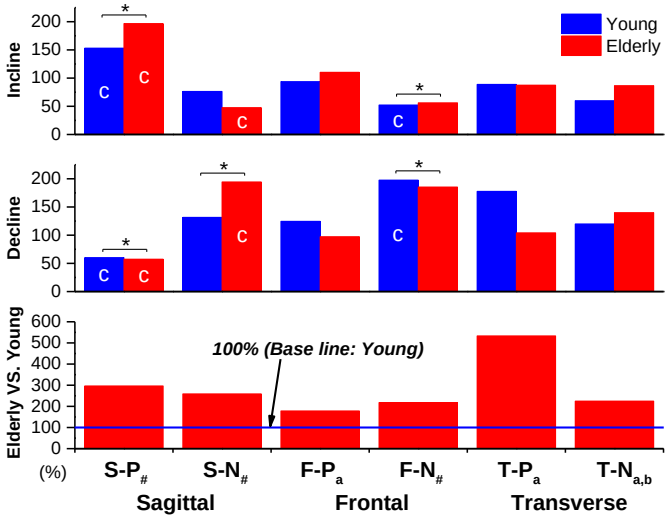

Figure 1 Hip joint work percentage during incline walking (top), decline walking (middle) relative to level walking, and the elderly hip joint work relative to the young during level walking(bottom). P=positive work, N=negative work, S=sagittal, F=frontal, T=transverse. Blue bars indicate young participants, red bars indicate elderly participants. Pound (#) indicates significant interaction of aging and slope. a and b indicate significant main effects of aging and slope, respectively. c indicates a significant slope effect with level walking, and asterisk (*) indicates a significant aging effect.

CONCLUSIONS

During slope walking, older people generate more positive and negative work than young people to accommodate inclines and declines. It required up to five times work increased. These results provide insight into the reasons for environmental barriers [4] and may shed light on a higher risk of falls for slope walking.

INTRODUCTION

The effects of proprioceptive neuromuscular facilitation stretching (PNF) on falls risk factors in older adults is unknown due to insufficient and low quality data. While flexibility training is recommended to older adults with a history of falling, static stretching has been associated with diminished lower limb voluntary activation (VA) [1,2] - a factor detrimental to balance [3]. Caution regarding pre-exercise static stretching has been advised [4]. Suitability of PNF for older adult populations remains unknown, yet some chronic strength gains are reported in young adults [5]. The purpose of this study was to compare acute effects of PNF on percentage VA (%VA) of the plantarflexor muscles between older and younger healthy adults. It was hypothesised that reductions in %VA would be reported after PNF, with greater effect in older adults.

METHODS

Two age groups: older group (3 females and 5 males (mean ± SD): age, 63 ± 2 years; height, 1721 ± 85 mm; weight, 74 ± 10 kg) and younger group (5 females and 4 males (mean ± SD): age, 26 ± 2 years; height, 1746 ± 86 mm; weight, 45 ± 13 kg). Cross-over design, all participants completed three laboratory visits in 10-14 days. Visit 1: familiarisation, Visits 2 and 3: randomised experimental condition - PNF (3 repetitions of a 10 second (s) isometric contraction at ~65% self-reported effort followed by 5-10 s rest) or control (active ankle ROM). Isometric maximal voluntary contractions (MVC) of plantar-flexor muscles followed each condition, with ≧1 minute rest. All participants completed both conditions (right leg only). Six MVC trials immediately followed experimental conditions, alternating between MVC *with* and MVC *without* doublet using the interpolated twitch technique (ITT) (1.5 s into MVC (superimposed) and 5 s after MVC (potentiated)) via two cutaneous electrodes (one each over the proximal and distal ends of the gastrocnemius muscle). During each trial participants viewed visual feedback of isometric plantarflexor torque data collected via Biodex III dynamometer, Biodex Medical Systems, Shirley, NY; 85° hip, and 0° knee flexion, with ankle 0° plantarflexion). %VA was calculated as:

$$\left[1 - \left(\frac{\text{superimposed doublet}}{\text{potentiated doublet}}\right)\right] \times 100.$$

RESULTS AND DISCUSSION

Paired t-tests and three-way repeated measures analysis of variance (ANOVA) showed no significant effect for age or condition in %VA: (mean ± SD) younger group: control = 82 (0.2)% and PNF = 75% (0.2); older group: control = 87 (0.1)% and PNF = 87 (0.2)%, where $p > 0.05$ (see Figure 1).

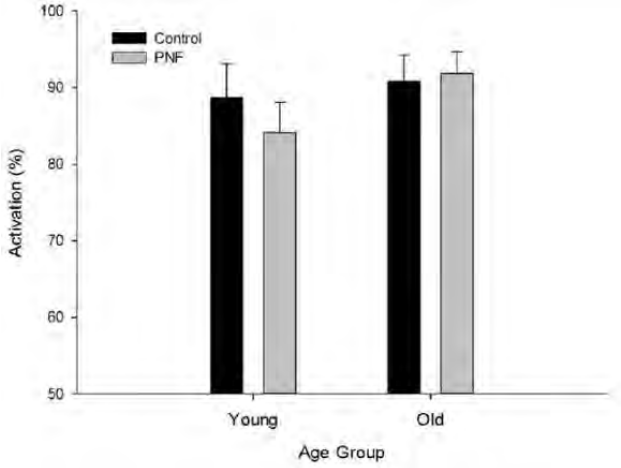

Figure 1 No significant effect for age or experimental conditions was found b three-way repeated measures ANOVA.

CONCLUSIONS

PNF showed no significant reduction in plantarflexor %VA or MVC torque in older adults. It may be a suitable alternative to static stretching. Future studies should investigate chronic effect on flexibility and %VA.

INTRODUCTION

Multiple studies have examined biomechanical changes to crank arm length in healthy adult athletes [1,2,3]. However, these studies only implemented symmetric and bilateral changes of crank arm length. Asymmetric crank arms may have clinical applications in individuals with physiologic asymmetries. The purpose of this pilot study was to examine the kinematic changes during cycling with asymmetric crank arm lengths in a healthy population. It was hypothesized that sagittal plane range of motion (ROM) in lower extremity joints would decrease as the crank arm length decreased.

METHODS

Seven recreationally active and healthy young adults (4 males, Age: 25.0±4.0 years, BMI: 24.4±3.4 kg/m^2) were included in this study. They cycled on a cycle ergometer (Excalibur Sport, Lode, Groningen, Netherlands) at seven different crank arm lengths on the right limb while the left crank arm was fixed at 170 mm (standard crank arm length). The participants started with the standard 170 mm crank arm length on both sides. In the remaining six test conditions, the right crank arm length was randomly adjusted from 130 – 190 mm at 10 mm increments using a custom adjustable crank arm. The workrate was fixed at 100 Watts and the cadence at 80 revolutions per minute. A 13-camera motion analysis system (240 Hz; Vicon Motion Analysis Inc., Oxford, UK) was used for 3-dimensional kinematic data collection. A 2 (side) x 7 (crank length) mixed model analysis of variance was performed to detect differences of ROMs between the two sides and crank arm length conditions for the hip, knee, and ankle ROMs ($\alpha = 0.05$).

RESULTS AND DISCUSSION

There were significant interactions for all ROMs ($p < 0.001$). The post hoc comparison results for the right side with different crank arm lengths showed that hip extension ROM decreased with each decrease of crank arm length from 190 mm (all $p \leq 0.017$), except for the comparison of 180 vs. 190 mm (Table 1). The knee extension ROM also decreased with each decrease of crank arm length from 190 mm (all $p \leq 0.002$). This pattern continued at the ankle with decreased ankle plantarflexion ROM with each decrease of crank arm length from 190 mm (all $p \leq 0.031$), except for the comparison of 180 vs. 190 mm, 160 vs. 170 mm, and the 140 vs. 150 mm conditions. As expected, there were no significant differences on the left side (the fixed crank arm length) between all comparisons. There were no significant differences from the left and the right limb during the symmetric crank arm condition.

Our hypothesis that sagittal plane ROM of hip, knee, and ankle joints would decrease as the crank arm decreased was mostly supported. Crank arm length has the greatest impact on the knee joint with 4 –6° of change for every 10 mm change in crank arm length while the hip and the ankle joints showed a 2 – 4° change for the same adjustments to the crank arm length.

CONCLUSIONS

The results of this study provide the first evidence of lower extremity joint ROM changes with asymmetric adjustments to crank arm lengths. It is still unknown of joint kinetic changes with such adjustments. Future research should investigate the impact of crank asymmetry in individuals with a physical asymmetry.

INTRODUCTION

Electrical muscle stimulation (EMS) training is often used in sports rehabilitation and strength training, most of the EMS training to the quadriceps as the main target, but the calf muscle electrical stimulation training is often ignored, it is one of the main power muscles of sprint and jump. The purpose of this study was to examine whether the addition of EMS to a regular calf muscle training regimen resulted in changes in muscle strength that resulted in greater benefits for sprint and jump performance.

METHODS

Twenty healthy athletes were divided into two groups (regular calf training and calf training combined with EMS). The main training target are calf gastrocnemius muscles. All athletes train for 4 weeks. 30m sprint time, jump height and muscle activation characteristics were assessed before and after training. Bidirectional (group x time) factorial analysis of variance was performed for repeated measurements, with $\alpha = 0.05$ to determine whether there was a significant effect.

RESULTS AND DISCUSSION

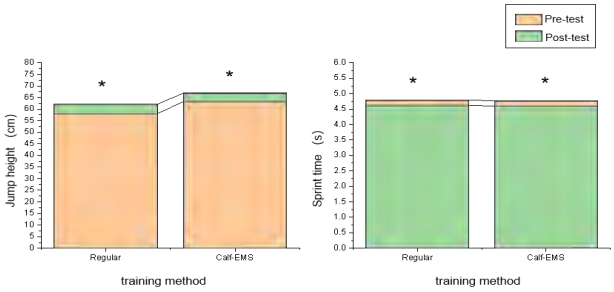

Figure 1 Comparison of pre-test and post-test exercise performance results (* represents a significant difference between Pre- and Post-test)

Both regular and Calf-EMS groups showed increased jump height and faster sprint time after training ($P < 0.001$). Compared with calf training with or without the assistance of EMS, there was no improvement in the results of training and EMG (Figure 1, Table 1).

The current findings do not support our original hypothesis, which suggested that electrical muscle stimulation (EMS) has been recognized as an effective method leading to significant improvements in explosive strength and athletic performances [1]. One plausible explanation would be due to the short training duration (a total of 11 sessions in four weeks) and constant EMS intensity over the training sessions. Previous studies found that EMS training can significantly improve countermovement jump performance by 17% (8 weeks) and drop jump by 6.6% (12 week) [2], respectively, while only increment of 5.5% was evident in our four-week training.

CONCLUSIONS

Calf-EMS training can significantly improve sprint and jump performance, but there is no obvious advantage over conventional training. Future training should consider electrical stimulation of different muscles or longer training sessions.

INTRODUCTION

The tendon transfers the force generated by the muscle and stores and reuses the elastic energy through the muscle-tendon unit (MTU) interaction. Aging changes tendon compliance and the capacity to reuse elastic energy. Elderly individuals showed shorter fascicle length behavior and less tendon shortening during locomotion, which led to increased muscle activity and less elastic energy reusability [1].
It was noted that the Achilles tendon (AT)'s mechanical characteristics changed dramatically with age at around 46 years, but that the 40s and 20s were similar [2]. Therefore, we aimed to investigate the mechanical property of the AT and its behavior during walking in the 50s.

METHODS

Eight healthy males with middle-aged (50s, height: 174.9 ± 6.8cm, weight: 74.0 ± 10.7kg, age: 55.9 ± 2.2yr, walking speed: 1.18 ± 0.2) and eight young adults (20s, height: 175.6 ± 5.8cm, weight: 79.0 ± 9.8kg, age: 27.1 ± 1.2yr, walking speed: 1.15 ± 0.2) were recruited.
An isometric plantar flexion was conducted using a dynamometer to measure muscular force and AT elasticity. Muscle-tendon junction (MTJ) in medial gastrocnemius (MG) was captured using B-mode ultrasound. Also, their walking at the preferred speed was captured with motion capture systems, ground reaction force (GRF), Electromyography (EMG), and ultrasound.

RESULTS AND DISCUSSION

The 50s showed lower muscle force and compliant characteristics in AT. Reduced mechanical properties were similar to an aged tendon in the elder.
Furthermore, the 50s walked with flexed joints of their lower extremities. However, they do not differ in MTU behavior. Although the 50s had less capacity to use AT, their joint strategy might permit them to perform MTU interaction like the 20s [3].

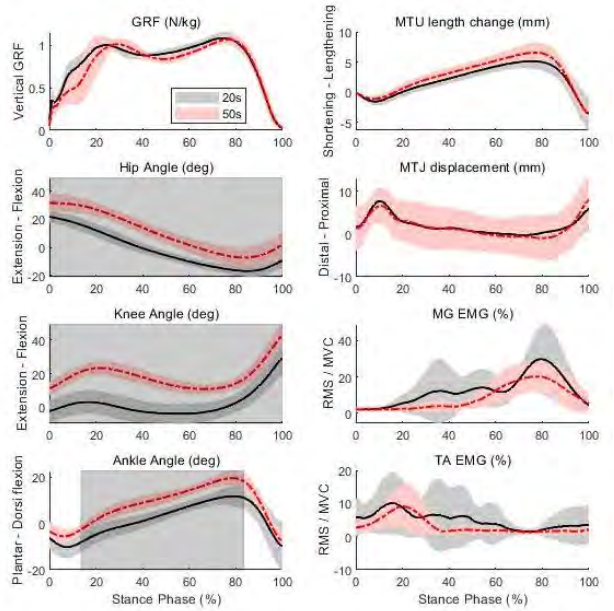

Figure 1 Joint angles and MTJ displacement during the stance phase. The movement was compared using SPM1D, and the shaded area shows a significant difference.

CONCLUSIONS

Middle-aged people demonstrated the deteriorated mechanical characteristics of the AT, which were less effective in transferring force and reusing elastic energy. Our results showed that the changed joints' strategy seems to enable MTU behavior in the 50s. In conclusion, aging impacts the gait and architecture of the 50s; they need to train for health and prepare for aging.

Comparison of Differences in Lower Extremity EMG According to Foot Angle during Self-Weight Squat in Adult Women with Genu Valgum

Chanki Kim[2,5], Jiyoung Kim[2,5], Haeryang Jo[1,5] and Kyoungkyu Jeon[1,2,3,4,5]

[5] Functional Rehabilitation Biomechanics Laboratory, Incheon National University, Incheon, South Korea
Email: kimchangi96@inu.ac.kr

INTRODUCTION

Genu valgum is a condition in which one or both knees are deviated toward the centerline [1]. As the TFA (tibiofemoral angle) increases, the pressure applied to the patellofemoral joint increases and anterior knee pain occurs, which tends to increase knee instability [2]. As such, physical malalignment is a major cause of musculoskeletal injury [3]. It was reported that the squat with medial knee displacement showed a decrease in the vastus lateralis muscle EMG and an increase in the gastrocnemius EMG compared to a squat in which the knee was correctly aligned [4-5]. Therefore, the purpose of this study is to compare and analyse whether there is a difference in muscle activity according to the condition of the foot angle during self-weight squat in adult women with genu valgum.

METHODS

15 adult women in their twenties with genu valgum participated in this study. In order to measure EMG of the lower extremities according to foot angle during self-weight squat, two-foot angle (0º, 30º) were performed. A paired *t*-test was used to compare and analyse the difference between the two-foot angle conditions. All statistical analysis was performed using SPSS 26.0 (IBM, USA), and all variables were calculated as mean and standard deviation. The statistical significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

As a result of this study, there was a significant difference in lower limb EMG between the two conditions (0º, 30º) in the left VMO (t_{14}=2.344, p=.034), right VLO (t_{14}=2.303, p=.037), left VLO (t_{14}=2.488, p=.026), left RF (t_{14}=2.704, p=.017), right GAS (t_{14}=-3.595, p=.003), left GAS (t_{14}=-2.871, p=.012) during self-weight squat. In the case of medial knee deviation during squats, a pattern of decreased vastus lateralis muscle activity and increased gastrocnemius activity appears [5-7]. According to the results of this study, compared to the case where the EMG is 0º, when the foot angle is 30º, when the vastus lateralis muscle decreases and the gastrocnemius muscle increases, from the EMG point of view, and when the angle is set to 30º during self-weight squats, medial knee deviation may occur.

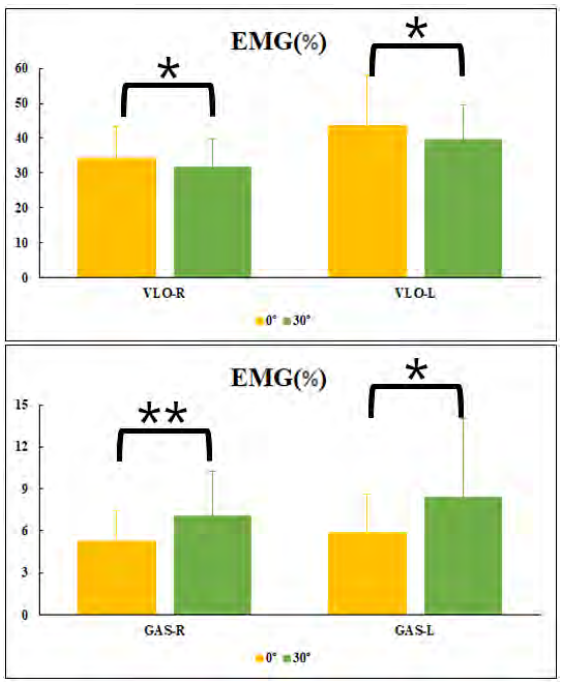

Figure 1. Results of lower extremity EMG according to foot angle during self-weight squat.
Note: data are mean ± standard deviation. *p<.05, **p<.01.
Abbreviation: EMG: electromyography; VLO: vastus lateralis; GAS: gastrocnemius R: right leg; L: left leg

CONCLUSIONS

The results of this study showed a decrease in the activity of the vastus lateralis muscle and an increase in the activity of the gastrocnemius muscle compared to the foot angle of 30º to 0º, which means medial knee deviation may occur during self-weight squats. Therefore, it is thought that adult women with genu valgum will be able to perform squats with a less risk of injury than when the foot angle is 0º during self-weight squats.

ECCENTRIC PRELOAD INCREASES WORK DURING SHORTENING BY COUNTERACTING RESIDUAL FORCE DEPRESSION

Tobias Göcking[1], Denis Holzer[2] and Wolfgang Seiberl[1]
[1] Department of Human Sciences, Bundeswehr University Munich, Neubiberg, Germany.
[2] Technische Universität München, Munich, Germany.
Email: wolfgang.seiberl@unibe.de

INTRODUCTION

Residual Force depression (rFD) is defined as a decrease in steady-state isometric force following active shortening compared to a purely isometric contraction at identical muscle length and activation. It is generally accepted that the magnitude of rFD depends on the amount of work performed during the active shortening phase. Despite this, Seiberl et al. [1] showed that the work performed during the shortening phase of stretch-shortening cycles (SSC) was greater compared to pure shortening controls, yet the resulting rFD was smaller. This contradicts some accepted ideas about rFD mechanisms related to stress-induced inhibition of cross-bridge attachments associated with the amount of work performed during the shortening [2]. This study aimed to add understanding about the influence of stretch-induced performance enhancement on shortening work and rFD after SSCs. By controlling the amount of eccentric and isometric preload prior to shortening, we focused on shortening work, rFD and the rate of force-redevelopment after shortening.

METHODS

Electrically stimulated ankle plantar flexor torque was measured during preloaded shortening and SSC contractions (range 25° at 40°/s). Three different protocols were used: 1) preloaded shortening with constant low intensity (*SHO*); 2) shortening with high stimulation intensity during preload and low stimulation intensity during the shortening phase (*SHO-matched*); 3) SSC with constant low intensity (SSC). Low intensity was referred to stimulations evoking ~30% of the maximum voluntary torque. The second stimulation intensity (high) is used to reach identical preload torque values as measured at the end of stretch in SSCs in order to match identical preload before shortening. Repeated-measures ANOVA was used to analyze parameters of interest (force/torque, work, rFD, rate of force redevelopment (RFrD) across conditions during and after shortening (α=.05).

RESULTS AND DISCUSSION

Despite identical preload (p=1.00), shortening work during *SSC* was 1.2 ± 0.2 times higher than during *SHO-matched. SSC* and *SHO-matched* showed 1.8 ± 0.5 and 1.6 ± 0.4 times higher work compared to *SHO,* respectively. During steady-states after shortening, *SHO-matched* resulted in greatest rFD (23.9 ± 11,8%), compared to *SHO* (16.3 ± 13.4%) and *SSC* (8.2 ± 10.1%). RFrD was comparable after *SSC* and *SHO-matched,* and *SHO*.

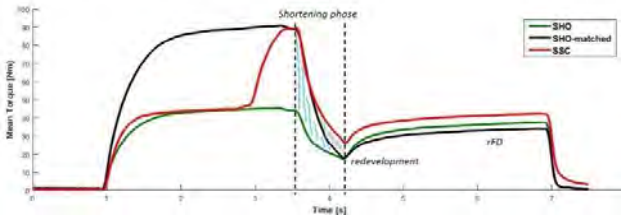

Figure 1 Torque for shortening (*SHO*) *vs* shortening with high preload (*SHO-matched*) *vs* SSC with constant low intensity (SSC).

CONCLUSIONS

Data of *SHO-machted* and *SSC* clearly show that the amount of preload makes the primary contribution to performance enhancement in muscle shortening. However, the type of preload still makes a difference, and eccentric preload outperforms torque-matched isometric preload especially towards the end of the shortening, resulting in less depressed torque/force. Therefore, eccentric preload in SSCs also positively influences force generating readiness of muscles after the shortening phase by reducing the amount of rFD during and after shortening. Interestingly, the rate of force redevelopment was not different after the shortening; yet redevelopment started from a higher level after *SSC* condition (Figure 1). Recent theories favor titin related mechanisms responsible for increased forces during stretch and reduced force depression during shortening [3]. Thus, the increased force generating readiness for following muscle actions after SSCs might also be explained by titin related mechanisms. Further research on different structural levels should focus also on the phase of force redevelopment after SSCs.

INTRODUCTION

Pilates is one of the most popular exercise. For increased pilates populations, it's important to know bionmechanical functions of Pilates, which muscles are used. Through this learning, people can be informed of the purpose of exercise. However, there are not enough researches on Pilates. In other words, It needs additional studies in terms of biomechanics. In this study, we focused on analyzing footwork, one of the most representative exercises of Pilates. The purpose of this study was to analyze the impact of spring tensions on muscle activities of the lower limbs during footwork motion.

METHODS

Eight female Pilates instructors participated this experiment. All participants performed footwork movements on the reformer. There were three types of movement intensity: Low (L), Mid (M) and High (H). Each movement was performed 6 times at the same speed (15bpm) at each intensity. Five surface EMG sensors (Delsys, Massachusetts, USA) were utilized to obtain muscle activity signals, and the sensors were attached to the biceps femoris (BF), semitendinosus (ST), rectus femoris (RF), vastus lateralis (VL) and vastus medialis (VM). The measured EMG signals were normalized to the resting state (%RVC). The footwork movement was divided into extension phase and flexion phase. The iEMG was used to calculate muscle usage, and time was normalised to each phase to analyze the pattern of muscle activity affected by knee angle.

RESULTS AND DISCUSSION

During footwork movements, a pattern of increasing muscle activity was observed as knee angle increased in BF, ST, VL and VM (Figure 1). These results suggest that the load on the spring influenced the muscle activity pattern. Spring is a form of elastic resistance. These results are consistent with Hooke's law, which states that the elastic resistance of a spring increases as the spring length increases [1]. In the iEMG data (Table 1), VL and VM showed statistically significant differences in spring loads ($p < 0.000$). In contrast, there were no significant differences in BF, ST and RF. The VL and VM are monoarticular muscles, while the other muscles are biarticular muscles. According to the previous research, monoarticular muscles acted as mobilizers, whereas biarticular muscles acted as stabilizers [2]. And footwork motion has a consistent trajectory of movement, and it is less affected by gravity due to the reformer carriage. These reasons seem the latent considerations of the iEMG results. The iEMG results suggest that the footwork movement affects the monoarticular muscles more.

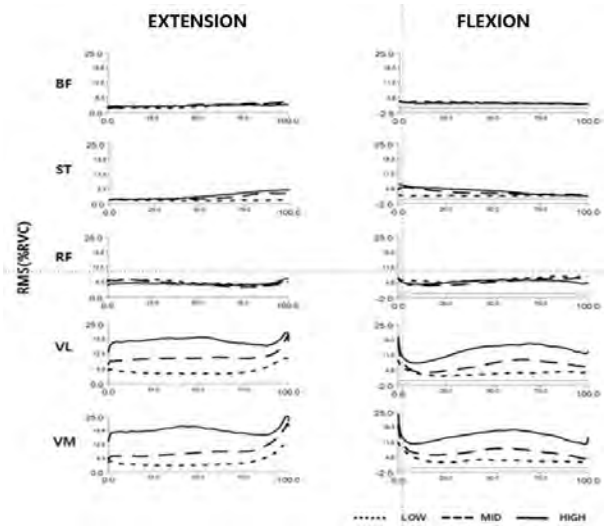

Figure 1 Muscle activation pattern according to the knee angle.

CONCLUSIONS

The EMG results showed that as spring tension increased, iEMG of the VL and VM also increased during footwork movements. However, there were no differences in BF, ST and RF. As a result, this suggests that the footwork motion may be better consideration to training monoarticular muscles rather than biarticular muscles.

INTRODUCTION

Modern shoes are used not only for functional purposes but also as an element of fashion. Women wear high heels to emphasize their individuality and fashion, but choose low heels for comfort. However, the higher the heel of the shoe, the higher the probability of falling when walking on stairs, which can be a risk factor for injury (Tencer et al., 2004). Therefore, in this study, we compared and analyzed the kinematic variables of the lower extremities according to the height of the heel when an adult woman ascended stairs wearing three types of shoes with different heel heights.

METHODS

The subjects of this study were 24 healthy adult women who had no lower extremities injury within 3 months (age: 22.08±1.28, height: 160.43±4.30, weight: 54.10±6.39, foot size : 232.29±2.54). In this study, the model staircase consisted of 9 infrared cameras (sampling rate: 200fps) and 3 layers, and the ground reaction force measuring machine (sampling rate: 1000Hz) was built in the middle layer.
The subjects wore shoes (1cm, 5cm, 7cm) in random order, and collected variables for the range of motion(ROM) of the lower extremities in the stance phase by distinguishing the initial contact (IC) and toe off (TO) times when the dominant foot landed on the measuring instrument. All data were analyzed by calculating the average value of three stair ascends.

RESULTS AND DISCUSSION

For both shoe conditions, the main differences in ROM between the three types of shoes occur at the hip and ankle joints (Table 1). In addition, the lower the heel, the greater the ROM of the ankle joint in the sagittal, frontal, and lateral planes than the higher heel.
These results are judged to be for limiting excessive movement of the ankle, as the higher the heel, the more plantar flexion of the ankle (Gu et al., 2013). However, there was no difference in heel height in the ROM in the three planes of the knee joint. Finally, a higher heel at the hip joint has a smaller anterior plane ROM than a lower heel. This is confirmed by the fact that the variability according to the gait style among the subjects was not controlled because the speed was not controlled(Opila-Correia, 1990).

CONCLUSIONS

As a result of this study, the lower the heel, the greater the range of motion of the ankle joint, and the ROM the hip joint in the frontal plane than high the heel. These results indicate that the lower the heel was more stable and resulting in a greater ROM. However, It was confirmed that the difference in gait pattern between the subjects due to not controlling the speed.
Thus, follow-up research is needed to derive accurate results on the effect of heel height differences on the body by controlling the speed so that subjects can measure at a constant speed in the future.

Kinematic analysis of metatarsophalangeal joint during level and slope walking

Sang Woo Jung[1], Pankwon Kim[1], Jiyoung Jeong[1] and Choongsoo Shin [1]
[1] Department of Mechanical Engineering, Sogang University, Seoul, Republic of Korea.
Email: cshin@sogang.ac.kr

INTRODUCTION

Powered prosthesis can improve the walking performance of the amputees [1]. Although metatarsophalangeal (MTP) joint contributes important roles in push off and double support phase during walking [2,3], few studies on powered prostheses including MTP joint have been performed [4]. In addition, previous studies have reported the MTP joint kinematics during level walking [5-7] but kinematic data during slope walking have not been reported. Actual outdoor ground surfaces often include uphill or downhill. Therefore, the aim of this study was to investigate the MTP joint sagittal kinematics during uphill/downhill walking and compare them with during level walking.

METHODS

Nine healthy male subjects (age: 23.3±0.78 years, height: 171.8±3.92 cm, mass: 69.7±6.12 kg) participated in this study. To measure the MTP joint kinematics, 30 retro-reflective markers were placed on the lower limb. The kinematic data were recorded at 400Hz using a motion analysis system equipped with ten infrared cameras. Each gait cycle was defined as the period between the initial heel strike and subsequent heel strike of the same foot. Since the obtained data were not normally distributed, Mann-Whiney U-test was performed at a significance level of 0.05.

RESULTS AND DISCUSSION

Both initial contact and maximum value of MTP joint angle in downhill walking was significantly smaller than level walking ($P<.05$, $P<.01$) (Table 1). Additionally, MTP joint maximum dorsiflexion was significantly greater in uphill than downhill walking ($P<.01$ Table 1). The maximum MTP dorsiflexion appeared in the late stance phase in all three conditions (Figure 1, Table 1). There were no kinematic parameters indicate significant difference between during level and uphill walking.

Maximum MTP joint dorsiflexion was 40.4° and stance phase covered 60% of one gait cycle during level walking, which are similar with previously reported values as 45° and 63% [5,7]. In addition, MTP joint maximum dorsiflexion condition was 42.9° during 15° slope uphill walking. Our results can be utilized as a design guideline for powered prosthesis with MTP joint.

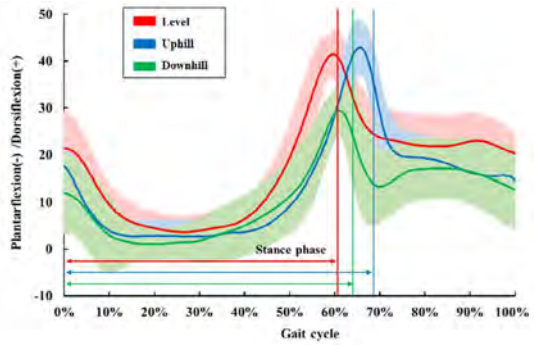

Figure 1 MTP joint kinematics during level, uphill, and downhill walking

CONCLUSIONS

Both initial contact angle and maximum MTP dorsiflexion in downhill walking were smaller than in level walking, whereas no differences were found in uphill walking compared to level walking.

INTRODUCTION

The main challenge of bone anchoring devices is early pull-out of implant, causing loosening of tightened suture. This phenomenon is especially found in osteoporotic patient, due to decreased bone content to cling on.[1] The aim of this study was to propose a hybrid suture anchor with axis-symmetry expandable barbs that can outspread to enhance holding power inside osteoporotic bone. Biomechanical evaluation of anchor stability was performed by static/dynamic pull-out test inside normal/osteoporotic bone samples.

METHODS

A 5.5mm in diameter hybrid suture anchor with axis-symmetry barb mechanism at middle was designed and manufactured to compare the biomechanical stability with a standard suture anchor (control group). The barb mechanism of the hybrid suture anchor can expand by pushing down the inner core to according to enhance the holding power of the surrounding bone according to the situation of bone osteoporosis (Figure 1) [2]. Total of 20 blocks of proximal swine humerus were prepared, and randomly divided into 10 normal and 10 osteoporotic samples which were decalcified with 0.5M EDTA solution for 8 weeks [3]. Hybrid and standard anchors were inserted into the bone blocks at 45°angle to mimic the real clinical situation (received horizontal and vertical pull-out forces). The barbed mechanism was pressed to full-expand in osteoporotic group to enhance the holding power but not in the normal bone. Each bone block was clamped onto the testing machine and the suture was hooked through a SMC knot at the other end (Figure 1C) Static pullout and after dynamic 150-cyclic load pullout tests were performed (n=5). The pull out forces in dynamic tests were set at 150N and 70.2N for normal and osteoporotic bone, respectively, and the frequency was set at 0.5Hz.

RESULTS AND DISCUSSION

The result of all pull out strength tests were shown in Table 1. One barbed anchor in normal bone and two in osteoporotic bone failed during dynamic loading. All the fiber-wires were torn during dynamic tests of control group anchor inside normal bone, indicating strength value surpass its average tensile strength, which lies around 265N in our previous tests. The results have shown 1.66 fold increase in strength of barbed anchor inside osteoporotic bone after dynamic loading. This could result from the barb mechanism tightening up surrounding bone matrix during dynamic cycling. The hybrid anchor without barbs expand showed no difference (p=0.81) with control group in static strength inside normal bone. Although there is a 1.55 fold difference in static strength inside osteoporotic group, no significant difference was found (p=0.02).

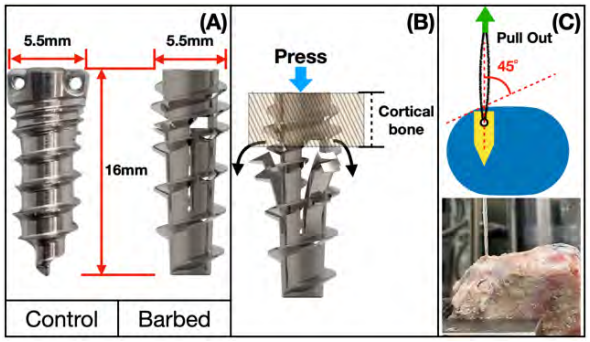

Figure 1 (A)Design parameter of hybrid anchors, (B)Expanding mechanism; (C)Setup of pull-out strength test

CONCLUSIONS

The new hybrid suture anchor with barbed design can improve the stability after dynamic cyclic loading.

INTRODUCTION

Surgical treatment with anterior tension band wiring (used K-wires directly or cannulated lag screws) for the transverse patella fracture usually rises clinical complications included failure of fixation, migration and skin irritation. Although bilateral fixed-angle plate was introduced to provide greater stiffness and lower fracture gap dehiscence for transverse patella fractures [1]. However, problems were emerged with inaccurate pre-bending and alignment, interference of bone screws, and lack of holding power for bone fragments. The aim of this study was to develop a titanium 3D printed anatomical contour bone plate with hook mechanisms and size adjustable assembly thin bone plates (AATBP) for patella fracture fixation. Cyclic loading test was performed to evaluate the biomechanical stability between this osteosynthesis system specifically designed and tradition anterior tension band wiring for use on the transverse patella fracture.

METHODS

Two thin bone plates were contoured anatomically and can be assembled by ratchet to adjust the assembled plate size to fit the corresponding patella anterior surface. Two-pair hooks on the proximal and distal edges of the assembled plate that can grip the fractured fragments of the patella were also designed. The thin bone plates were fabricated by a metal 3D printer (AM400, Renishaw, Gloucestershire, UK) using titanium alloy powder and cleaned using ultrasonic oscillations. Six identical left patellae made from 3D printed ABS material (ABS-P430; Stratasys, Ltd., Minnesota, USA) with transverse fractures for fixation with anterior tension band wiring approach featured two stainless steel K-wires and AATBP securing with 2.4mm inter-crossing locking screws were prepared for biomechanical testing. The specimens were mounted on the a specially designed testing platform to simulate 90 ° angle knee flexion using an artificial femur condyle as a pivot point [2]. The medial, lateral fracture gaps and maximum pull force detected by load cell were measured using digital ruler after cyclic test with 300 cycles under 150N applied on the model.

RESULTS AND DISCUSSION

The AATBP can effectively fine-tune the proper fixing position according to the transverse patella fracture situation through the ratchet design and the superior and inferior hooks can grip on the proximal and distal edges of the patella to generate holding power to tighten the fracture fragments. However, thin bone plates with complex geometry needed to take a lot of efforts and time consuming by using traditional manufacturing processes and desired to adopt the metal 3D printing manufacturing. The maximum patellofemoral forces during knee flexion tests were found at 60 degrees and consistent with the physiologic locomotion and indicated the rationality of the testing platform. The cyclic loading tests showed that the average maximum patellofemoral force of using AATBP was lower than that of tension band wiring. The fracture gap at the medial and lateral sides of the assemble thin-plates were 0.027±0.06mm and 0.067±0.03mm and significantly smaller than those of the tension band wiring were 1.965±0.63mm and 2.343±0.32mm, respectively.

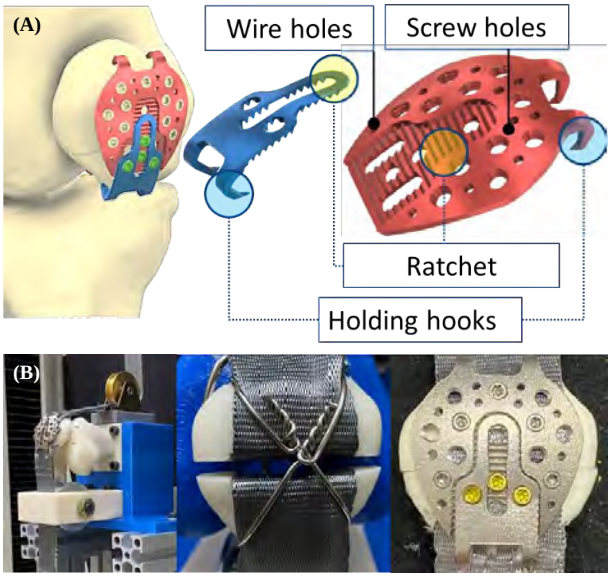

Figure 1 (A)CAD model of AATBP; (B)Testing platform and specimens (middle: tension band wiring and right: AATBP).

CONCLUSIONS

This in vitro biomechanical cyclic loading test implied that used of the titanium 3D printed AATBP can effectively maintain stability for transverse patella fracture.

PULLOUT EVALUATION OF A NOVEL PEDICLE SCREW WITH A PROXIMAL PEDICLE SLEEVE AUGMENTATION

Ting-Shuo Hsu[1,2], Hsuan-Wen Wang[1] and Chun-Li Lin[1]

[1] Biomechanical Engineering, National Yang Ming Chiao Tung University, Taipei City, Taiwan.
[2] Department of Orthopaedic Surgery, Shuang Ho Hospital, Taipei Medical University, New Taipei City, Taiwan
Email: B101093048@tmu.edu.tw

INTRODUCTION

Pedicle screw fixation is the mainstay technique for lumbar spine stabilization in various spine disorder. However, insufficient fixation strength wound cause screw loosening which caused failure of pedicle screw fixation. Previous study has shown the cortical bone of pedicle provides almost 60% of the pullout strength and provides more than 80% of the cranio-caudal stiffness [1]. The stabilizing effect over the vertebral body is relative not as important.

The geometry of the pedicle isthmus is an ovoid cross-section, we designed a novel pedicle screw with an elliptical pedicle sleeve to enhance the squeezing (compact pedicle) effect within the pedicle isthmus area. We hypothesized the pedicle screw fixation strength could be enhanced by the novel pedicle screw.

METHODS

Determining the pullout out strength of designed screws is essential. In this study, geometry of pedicle screws for the novel screw have been modified to improve their pull-out performance. The geometric feature of the novel screw was showed (Figure 1). The different pitches between the pedicle isthmus(proximal) and vertebral core(distal) provided a advancing and compression effect of pedicle sleeve during screw insertion. The novel screw with a size of 6.0 mm X 45 mm were used. In conventional screw group, the polyaxial screws (Baui Biotech, Co., Ltd., Taiwan) with a size of 6.0 mm × 45 mm were inserted.

Pullout strength test have been conducted in accordance with ASTM F543 Annex 3. A pilot hole with a diameter of 5.0mm was predrilled. The screw was inserted to 60% and 100% length in each group, respectively. A commercially available synthetic bone with a density of 0.32 g/cm3 (20PCF, Pacific Research Laboratory, Inc., Vashon Island, WA, USA) was used. Axial tensile force was applied at a rate of 5mm/min until the screw pullout out of block or fails. Load versus displacement curve with max load was recorded. These experiments were conducted in three trials for each group. The independent t-test was employed to analyze the data of the two groups.

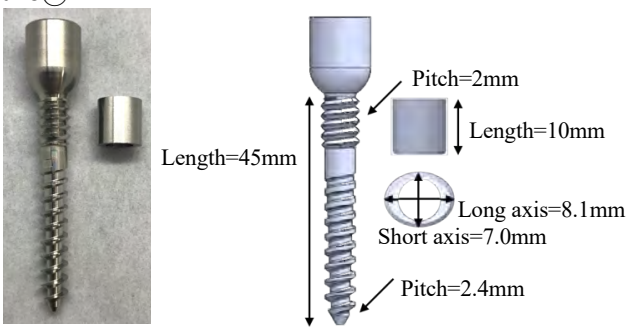

Figure 1 The novel pedicle screw with a proximal pedicle sleeve augmentation (left). The geometric feature of the novel screw (right).

RESULTS AND DISCUSSION

The results of pullout strength were showed (Table 1). In the condition of full-length insertion, the pullout strength of the novel pedicle screws was 1865.7 ± 97.6 N, whereas the pullout strength of the conventional screws was 1723.3 ± 13.9 N. The pullout force of the novel screw was significant increased.

Previous study also reported the similar findings. Tsuang et al [2] found that proximal 1/3 unthreaded screws provide higher pullout strength compared to full threaded screws. We suggested that the effect of squeezing (compact cancellous bone) within proximal pedicle isthmus portion increased the fixation strength. Further study is necessary to evaluate the biomechanical properties of the novel screw in the animal and human spine models.

CONCLUSIONS

A modified geometry of pedicle part of the pedicle screw influences the stability of pedicle screw fixation strength. This study concludes the novel pedicle screw augmented with a proximal pedicle sleeve leads to a significant increased pullout strength compared to a standard pedicle screw.

INTRODUCTION

The lateral abdominal muscles play a role in stabilizing the trunk during anticipatory postural control [1]. It has been suggested that mediVR Kagura (mediVR, Inc., Japan), which performs virtual reality-guided reaching exercises in a seated position, may improve trunk movement during walking [2]. We hypothesized that one of the factors by which Kagura improves gait function may be the activation of the lateral abdominal muscles by the reaching motion. Therefore, the purpose of this study was to clarify the changes in muscle thickness of the lateral abdominal muscles that occur during virtual reality-guided and normal reaching exercises.

METHODS

Twenty-two healthy adults (mean height,170.2 ± 4.6 cm; mean weight, 59.7 ± 5.9 kg; mean age, 21.2 ± 2.3 years) were randomly assigned to the Kagura group, which performed the reaching exercise in a seated position using Kagura, and the Control group, which performed reaching without VR, 11 subjects each. In both groups, six directions of reaching were used.
The target point of reaching in each direction was 90% of the maximum reaching position. The reaching exercise was performed for 20 minutes. The muscle thickness of the right lateral abdominal muscles (external oblique (EO), internal oblique (IO), and transversus abdominis (TrA)) were measured before and after each intervention using an ultrasound imaging system (US) in a resting sitting position and in six reaching position (reaching with the right upper limb; 1. ipsilateral forward, 2. ipsilateral diagonally forward, 3. ipsilateral lateral, reaching with the left upper limb; 4. contralateral forward, 5.contralateral diagonally forward, 6. contralateral lateral). The probe was placed 3 cm medial to the intersection of the perpendicular line from the right axilla and the height of the umbilicus, and EO, IO, and TrA were imaged. The change in muscle thickness was calculated by subtracting the thickness of the muscle when reaching from the thickness of the muscle in the resting sitting posture. Differences in the amount of change in muscle thickness in the above six postures between groups were tested using either an unpaired t-test or a Mann-Whitney u-test. The significance level was set at less than 5%.

RESULTS

No significant differences were found between groups before the intervention for all muscle thickness changes. After intervention, the muscle thickness changes of TrA was significantly greater in the Kagura group than in the Control group in ipsilateral 3-way reaching position (Figure 1).

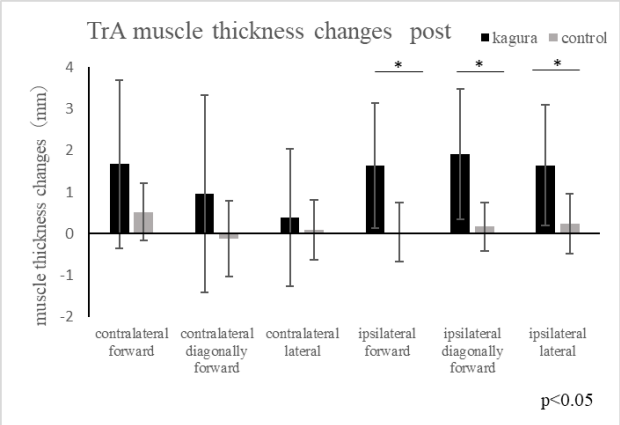

Figure 1 Change in the thickness of transversus abdominis muscle after intervention.

In this study, TrA, one of the lateral abdominal muscles, was activated in the VR reach exercise compared to the normal reach exercise.
In the normal reaching exercise, the positional information of the target point and his/her own body are perceived using visual and proprioceptive feedback [3]. On the other hand, the virtual reality-guided reaching exercises may have trained postural control based on prediction, since the subject could not visually perceive his/her own body on the VR.

CONCLUSIONS

The results suggest that Kagura may have an effect to activate TrA during the reaching motion.

OPTIMISATION OF THE ELECTRODE CONFIGURATION OF A SEMG SENSOR SYSTEM TO BE USED IN REHABILITATION SETTINGS

Elmar Junker[1], Elisa Romero Avila[1], Catherine Disselhorst-Klug[1]
[1] Department of Rehabilitation and Prevention Engineering, RWTH-Aachen, Aachen, Germany.
Email: junker@ame.rwth-aachen.de

INTRODUCTION

The use of wearable devices to monitor a person's movement performance has increased in recent years in the field of rehabilitation. These devices provide healthcare professionals with information regarding the status of the patient and considerations for their therapy [1]. If the recording of the muscular activation through surface electromyography (sEMG) were considered in these devices, a more reliable monitoring and a greater understanding about the patient's condition would be obtained. To this end, a 16-channel sEMG sensor system has been developed with a design that allows an autonomous use by the user [2]. However, to ensure an adequate and reliable recording of sEMG signal quality, the material, type, and configuration of the electrodes should be considered according to the purpose of the sEMG sensor system and the guidelines for sEMG recording [3]. The aim of this work is to stablish an appropriate dry electrode arrangement by analyzing the effect of inter-electrode distance (IED) and electrode diameter on the sEMG signal energy and quality and to incorporated the findings into the sEMG sensor system which is to be used during dynamic tasks.

METHODS

Optimization of electrode-size and IED

For this, two linear electrode arrays with a 10 mm IED were considered. Each array consisted of six, dome-shaped gold-plated electrodes with a diameter of either 5 mm or 8 mm. The electrode arrays were assessed during isometric contraction of the biceps brachii. Influence of electrode size and IED on signal energy, signal-to-noise-ratio and reproducibility were analysed.
When using dry electrodes in a bipolar configuration IEDs between 10 and 20 mm are the best compromise between high signal energy, a high reproducibility and with a small risk of crosstalk. Regarding the electrode size, no effect between both sizes was observed during long-term measurements. However, it was found that the 8 mm diameter electrode required more time to stabilize and provide less consistent measurements compared to the 5 mm-diameter electrode.

Integration into the sEMG sensor system

Based on the previous results, 5 mm dome-shaped gold-plated electrodes were incorporated in the sEMG sensor system. Seven electrodes were used to form an electrode array with an IED of 15 mm (Figure 1). Three electrodes formed a bipolar configuration to minimise the potential for incorrect localisation of the electrodes in the longitudinal direction of the muscle. Four electrodes arranged in a rectangular way were configured as reference electrode. To minimize transversal misalignment eight of these electrode arrays were arranged in the shape of an armband to form 16 sEMG channels (Figure 1). Additionally, in this way, the orientation of the bipolar leads was parallel to the muscle fibres. To evaluate the system during dynamic tasks with respect to the risk of crosstalk and movement artefacts, muscular activation of the biceps was recorded while performing flexion and extension of the elbow. Signal-to-noise ratio (SNR) and root mean square (RMS) values were computed.

RESULTS AND DISCUSSION

No motion artefacts were observed during the dynamic tasks. Furthermore, despite the fact that dry electrodes were considered, the sEMG signal was obtained with low noise as a result of the shape and size of the electrodes that allowed a constant contact with the skin surface. The selection of a bipolar configuration and IED of 20 mm ensured that a low SNR (28 dB) was obtained. The design of the sEMG sensor system allowed a parallel orientation of the electrode array to the muscle fibre. Moreover, it also prevented misplacement, regardless of the user's experience in locating the muscle. Ultimately, the sEMG sensor system enabled non-invasive recording of muscular activation with little assistance required or discomfort.

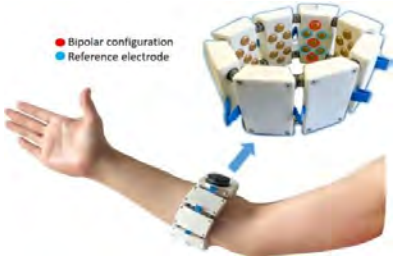

Figure 1 Design of the electrode array for an sEMG-sensor system

CONCLUSIONS

The proposed electrode array integrated in a user-friendly sEMG sensor system allowed the achievement of adequate and reliable sEMG signal quality with a low risk of crosstalk and movement artefacts even during dynamic tasks. Moreover, the design of the sEMG sensor system allows for positioning on the lower limbs, making it a device that can be easily and reliably used in a rehabilitation setting due to its design and features.

INTRODUCTION

The progression of blood flow restriction (BFR) training include the design of tourniquet cuffs with lower pressure gradients and the use of limb occlusion pressure (LOP). It is recommended that when using BFR equipment for training, the personal tourniquet pressure can be set according to the personalized LOP, which can reduce the risk of nerve damage and avoid the use of BFR potential complications[1].

Although there are currently commercially available instruments that can automatically measure personalized LOP based on measured LOP and set the degree of blood flow restriction during training, the cost of using the commercial instrument is expensive. On the other hand, the palm style aneroid sphygmomanometer is cheaper, it cannot determine the LOP so it is difficult to make personalized design blood flow restriction training program.

The purpose of our study will aim to overcome these problems by developing the innovative BFR training device. We use innovative BFR training device with a palm style aneroid sphygmomanometer and a commercially available BFR system, using Laser Doppler Flowmetry (LDF) as the gold standard. And we use palm style aneroid sphygmomanometer and a commercially available BFR system, PTS for BFR to conduct the reliability test and establish Intraclass correlation (ICC)[10].

METHODS

A total of 43 subjects participated in this study, 26 males and 17 females.The LDF probe was placed on the subject's index fingertip. Our study used two kinds of blood flow restriction, palm style aneroid sphygmomanometer (manual pressurization) and PTS for BFR (electrical pressurization). Two blood flow restriction systems were placed on the subject's left upper arm, and the order in which the systems are used is randomized.

Palm style aneroid sphygmomanometer (innovative BFR training device)

Skin blood perfusion was measured, we manually increased cuff pressure in 20-mmHg stepwise increments until the skin blood perfusion was no longer measured by LDF.

PTS for BFR (commercially available BFR system)

Easi-Fit BFR tourniquet cuffs (Delfi Medical, Vancouver, VC, Canada) and the instrument containing LOP calculation sensors and software werer used. The tourniquet cuff increases cuff pressure in 10-mmHg stepwise increments.

RESULTS AND DISCUSSION

Reliability test outcome

The ICC of PTS for BFR is 0.770 representing high correlation. And the ICC of palm style aneroid sphygmomanometer is 0.882 presenting high correlation.

Statical difference of LOP obtained by three different measurement methods

LOP obtained from three different measurement methods was showned in Table 1.

CONCLUSIONS

Both innovative BFR training device and commercially available BFR system were reliable, our innovative BFR training device seems to be more reliable. Using LDF as the gold standard, our innovative BFR training device is as accuraccy as commercially available BFR system.

INTRODUCTION

Marker-based motion capture is the "gold standard" method for acquiring the accurate 3D human motion. Recently, a markerless motion capture system was developed as an alternative method to overcome the shortcomings of the marker-based system, such as high price, time-consuming, et al. Markerless motion capture system estimated body joint centers and other anatomical landmark positions by a deep learning algorithm based on a training dataset[1], which overcomes the drawbacks of traditional systems and improved the efficiency of data collection. The previous study[2] tested the validation of kinematic measurements captured by markerless systems. As far as we know, no studies have tested the validation of inverse dynamics calculations using a markerless system. Devita[3] found that the kinematics of gait were not different in patients recovering from anterior cruciate ligament (ACL) injury and reconstruction surgery compared with healthy people, but joint moments are different. Certainly, it is crucial to acquire joint moments data from inverse dynamics calculations for gait analysis. This study aims to test the validation of inverse dynamics calculations for lower limbs during gait using a markerless motion capture system.

METHODS

16 healthy volunteers (28.2 ± 8.2 years age, 174.0 ± 6.2cm height, 69.3 ± 13.2kg weight) participated in this study. Participants wore tight-fitting, minimal clothes and the same type of running shoes. A 13-camera marker-based system (1200-megapixel, Nokov, China) and an 8-cameras markerless camera system (800-megapixel, Tsing-I, China) were positioned around a runway. Both systems recorded at 120 Hz. A force platform (Kistler, Switzerland) was embedded under the middle of the runway, which recorded the data at 1200Hz. 39 retroreflective markers were placed on each subject. The force platform and two motion capture systems collected data simultaneously.

RESULTS AND DISCUSSION

Compared with the marker-based system, the coefficient of multiple correlations (CMC) for the lower limb in the sagittal was $\geqslant 0.82$, and in the transverse planes was $\geqslant 0.75$ (Figure 1). We observed large inter-individual differences in joint moments between the two systems. Cation should be given when subjects' anthropometry data have a large deviation from that of the dataset. Increasing the size of the dataset or adding a manual correction procedure can help improve the accuracy of the joint center positions and further improve the validity of the joint moments calculation using the markerless motion capture system.

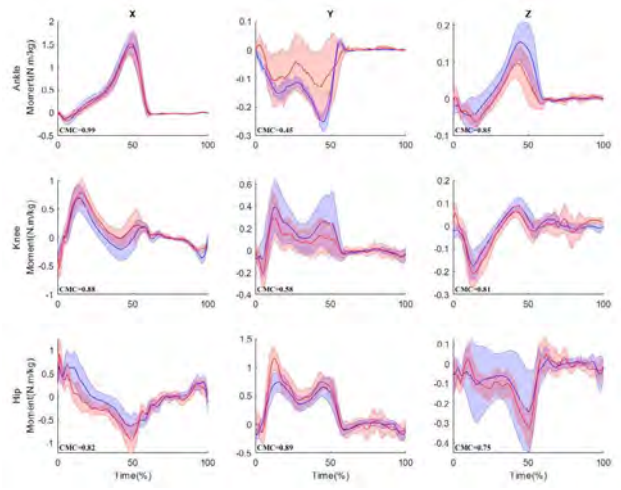

Figure 1: Lower limbs joint moment (Mean±SD) and CMC (blue: marker-based, red: markerless)

CONCLUSIONS

The markerless motion capture system can be used for lower limbs inverse dynamics calculations in the sagittal and transverse planes during gait.

INTRODUCTION

The Two-Step test is an index of gait ability in locomotive syndrome, evaluated by the distance travelled during the two steps [1]. The current two-step test only focuses on distance traveled, but obtaining kinematic data in the two-step test will allow us to understand the cause of gait ability decline. Three-dimension (3D) opto-electronic motion capture is considered the gold standard of kinematic analysis [2] , are seldom used in clinical settings. Then, smartphone based 3D movement analysis system, the OpenCap (Stanford University, CA, USA) , is proposed to be easily used in clinical settings to assess kinematics. The aim of this study is to confirm the reliability of kinematic measurements during the two-step test using OpenCap.

METHODS

We included 8 young, injury-free participants (age 21.5 ± 0.5 years; height 165.0 ± 0.1 cm; weight 54.5 ± 7.9 kg; male 3). Participants performed three trials of each two-step test from the right foot. OpenCap data were acquired at 60 Hz using two iPhones (Apple, CA, USA). The two iPhones were placed on a tripod 0.9 m positioned at a 40° angle to the participants. Three-dimensional motion analysis system data were acquired at 100 Hz using a ten-camera Vicon MX (Vicon Motion Systems, Oxford, UK). The reflective markers were attached to 35 landmarks according to the plug in gait model. The sagittal plane joint angles of the hip and knee joints were calculated from the acquired kinematic data, from which two peak values were extracted for each joint (Figure 1). To determine the OpenCap validity, the mean difference and 95% limits of agreement (LoA) between the OpenCap and Vicon were calculated for each angle peak using the Bland-Altman method. The 95% LoA were defined as the average difference ± 1.96 times the standard deviation of the difference. The correlation coefficient was obtained from the Bland-Altman plot, and the significance level was set at 5%. All data analysis was performed using Matlab (Mathworks, Inc. Natick, MA, USA).

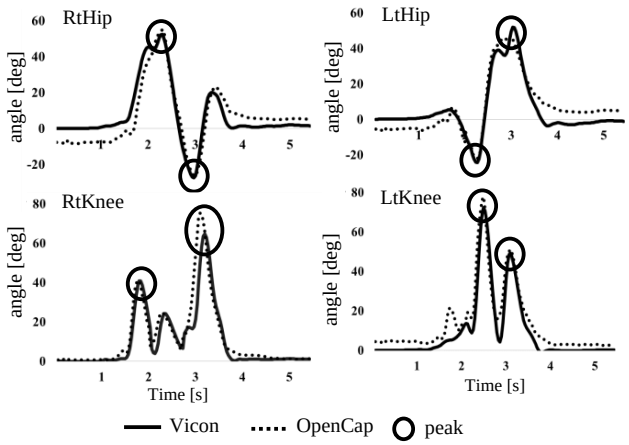

Figure 1: Joint angles of hip and knee in the sagittal plane

RESULTS AND DISCUSSION

The 95% LoA results indicated that OpenCap tended to underestimate hip and knee angles (Table 1). There were no significant errors in the RtHip 2nd peak and LtHip 1st peak, but these peak values were for movements with small angular changes. Furthermore, the correlation coefficient values suggest that OpenCap can measure movements with small angular changes with high accuracy, but the accuracy may decrease as the angular change increases.

CONCLUSIONS

OpenCap can be a reliable evaluation tool in the two-step test, but it is imperative to understand its characteristics of measurement accuracy of joint motions.

INTRODUCTION

Motion measurement is a fundamental biomechanical technique to understand the principle of the human movements. Especially, it is quite important to measure sports movements for improvement of performance and avoidance of sports injury. A markerless motion capture (MMC) technique is one of most useful method. Recently, an image recognition with a deep neural network or distance measurement with LiDAR have been used widely to capture human motion. On the other hand, MMC through visual hull (MMC-VH) [1] needs optical images only, and allows us to measure sports motion in many situations. However, the accuracy of the method depends strongly on camera resolution, and then it is difficult to measure minor or complicated joint motion, such as the knee axial rotation or adduction/abduction, with high accuracy. In this study, we have improved the accuracy, and compared with marker-based system.

METHODS

In this study, spin turn maneuver was measured for a healthy subject (1.74 m, 68 kg, 26 y/o). Motion images were captured using calibrated nine VGA (640 × 480 pixels) cameras at 120Hz. In MMC-VH, the accuracy of a visual hull expressing the three-dimensional subject volume decides the error of measurement. To improve the accuracy, in this study, silhouette images are extracted by k-nearest neighbor background subtraction. To make the contour clearly, accurate subpixel edge location was calculated at subpixel points [2]. Here, the contour line was expressed with point cloud data, and some point cloud data from all images were combined. The three-dimensional point cloud was used to construct the visual hull with ball-pivoting algorithm. The subject surface shape was obtained with a body scanner, and the body segments were matched to the visual hull. The relative postures between the matched segments were calculated as the joint angles. In this study, the joint angles were based on the ISB definition.
To validate and confirm the accuracy, in this study, optical marker-based motion capture (OMC) system was used simultaneously.

RESULTS AND DISCUSSION

Figure 1 shows the three-dimensional knee angles. In the Flexion, the double knee action is confirmed, and this study and OMC show a good agreement. The knee flexion is larger than the other knee motions, and then the shape around the knee joint should deform largely

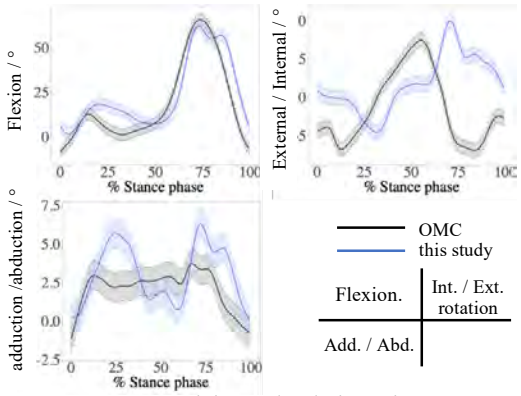

Figure 1 Knee joint angles during spin turn.

and the visual hull could agree with the actual deformation. In the adduction /abduction, this study and OMC have a moderate agreement less than 5°, but they are apart a little at 25 and 75% stance phase. At the time, the shank of swing phase approached to the other shank of the stance phase, and then the visual hull showed the shanks crossed. In the Internal/External rotation, this study and OMC were apart from each other after 75% stance phase. The I/E rotation is quite small compared with flexion. Also, the axial rotation does not make the distal end of the shank move largely or deform the surface of the knee joint. Thus, this study and OMC could not have a good agreement. Generally, the knee joint angles other than flexion are not large. Therefore, a special technique such as a point cluster method is required to measure small joint angles with high accuracy [3]. Even though our method did not completely correspond to OMC, the difference was quite small. Therefore, our method could be useful to improve the accuracy of MMC-VH.

CONCLUSIONS

We proposed a new method to improve MMC-VH, and measured spin turn maneuver with MMC-VH. For the three-dimensional knee movements, our method almost showed a good agreement with OMC.

Investigating the relationship between local and global gait stability

Ann-Kathrin Harsch[1], Daniel Koska[1] and Christian Maiwald[1]
[1] University of Technology Chemnitz, Institute of Human Movement Science and Health, Chemnitz, Germany
Email: ann-kathrin.harsch@hsw.tu-chemnitz.de

INTRODUCTION

Gait stability is differentiated between local dynamic and global stability. Local dynamic gait stability can be determined using the short-term maximal Lyapunov Exponent λ_s from the field of nonlinear dynamic methods and describes the sensitivity to small intrinsic perturbations. An increasing λ_s indicates greater instability [1]. The Margin of Stability (MOS) as a dynamic global stability parameter describes the response to external perturbations in gait. A negative MOS is associated with instability [2]. Both measures can distinguish different interventions (e.g., perturbations), but there is a lack of research evaluating whether there is a relationship between local and global stability [1].

METHODS

This study analyzed the data from Kopiske et al. [3]. 19 young adults participated in 5-minute walks on a split-belt treadmill. The first trial involved normal (unperturbed) walking at 1 m/s, while the second trial included a randomly occurring acceleration at one side of the split-belt treadmill to provoke slip-like events. Motion capture data was used to determine the respective foot position at ground contact, as well as the center of mass (COM) taken from the hip markers. $\lambda_{s,com}$ was calculated from the COM position in anterior-posterior direction, in which the perturbation occurs. $\lambda_{s,com}$ was taken from the middle 150 strides of the trial. The embedding dimension was set to 3, with a participant-specific time delay. $\lambda_{s,com}$ was then calculated as mean logarithmic short-term divergence from start to the first half stride. To quantify global stability, the continuous MOS was calculated by determining the shortest distance between the extrapolated position of the center of mass and the anterior Base of Support, calculated from current ground contact marker [4]. For perturbed gait, the differences between minimum and maximum MOS excursion within five strides after each slip event were averaged across all slips of one trial (MOS_{range}). MOS_{range} indicates more instability when increased.

RESULTS AND DISCUSSION

Both, MOS_{range} and $\lambda_{s,com}$ indicated more instability during perturbed gait vs. unperturbed gait. However, a consistent increase in MOS_{range} for perturbed gait is shown in Figure 1A, while $\lambda_{s,com}$ showed more interindividual variation (Figure 1B). Figure 1C suggests a negative correlation between the $\lambda_{s,com}$ from unperturbed gait and the MOS_{range} in response to perturbations. Hence, a more locally stable gait was associated with less global stability.

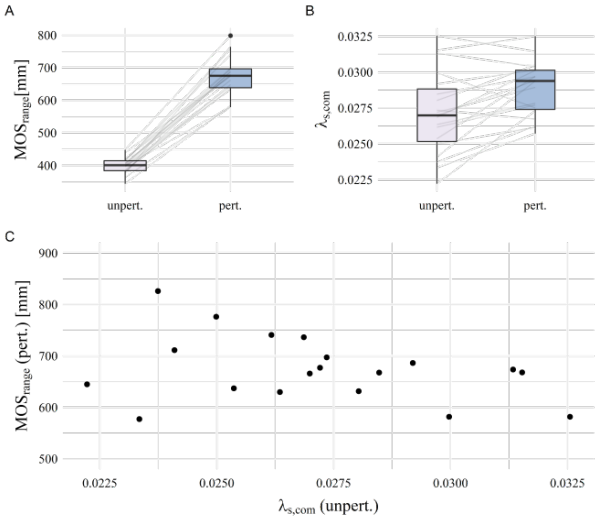

Figure 1. Effect of gait perturbations on **A:** global stability and **B:** local dynamic stability. **C:** Correlation of MOS_{range} and $\lambda_{s,com}$

These findings are contrary to the common assumption that less stable normal gait (higher $\lambda_{s,com}$) leads to a more pronounced response to external perturbations. However, this study design does not allow any causal inference. Furthermore, results need to be replicated, since they also may be attributed to the complex and abstract methodology of the parameters used. In particular, calculating $\lambda_{s,com}$ is intricate, with no established procedure, input signal or clear-cut outcome.

CONCLUSIONS

Our results indicate that individuals with less stable gait ($\lambda_{s,com}$) have a smaller response to external perturbations. Further research is needed to fully understand the underlying causes of these observations.

UNCOVERING CLUSTER STRUCTURES WITHIN EMG SIGNATURES OF GESTURES

Jonas Große Sundrup[1], Katja Mombaur[1]
[1]Canada Excellence Research Chair Human-Centred Robotics and Machine Intelligence, Systems Design Engineering and Mechanical & Mechatronics Engineering, University of Waterloo, Waterloo, Canada
Email: jonas.grosse-sundrup@uwaterloo.ca, katja.mombaur@uwaterloo.ca

INTRODUCTION

Gesture recognition systems have gained traction and popularity for quite some time. However, often times the focus on pure performance leads to choosing methods with limited understandability. We investigate a gesture recognition approach based on muscle signatures that provides both competitive performance as well as intuitive functional understanding, allowing for applications both in application as well as in reseach and an informed extension to new applications and research questions. This both highly accurate gesture recognition as well as foundational insight into cluster structures.

METHODS

We used the Myo Armband, an 8-channel sEMG recording device surrounding the forearm, to obtain muscle signatures for 7 different gestures. 700 recordings over 7 gestures (snap, fist, conunt, open, wave, wave out, point) were obtained after instructing 2 participants in how to do them. The actual recordings, however, were unsupervised, using instructional software, close to a real-world application. We employ Dynamic Time Warping (DTW) [2] to account for the naturally emerging time variability in humen motion when assessing the similarity of different recorded muscle signatures of these gestures. Based on the distance measure this establishes, we also assess the relative distribution of signature clusters their separability relative to each other.

Based on this we implement a simple k-Nearest-Neighbours with DTW, similar to [1], and extend on this by establishing bounds on the need of reference data, rejection approaches to make this classifier suitable for arbitrary, non-gesture data, and explore condensing techniques based on barycenter averaging [3] to improve both performance and stability.

RESULTS

When employing this procedure, we find classification accuracies at 97% - 99%, depending on subject. To understand how this emerges, we compute the distribution of DTW-distances within a cluster, i.e. every element of that cluster to every other element in the same cluster, and the distribution of each element of one cluster to each element of another cluster, depicted in Figure 1), with bold depicting the pointwise distances within a cluster. We find a clear separation pattern between most of the gestures with exceptions only for “point” and “wave out”, which explains the strong accuracy results.

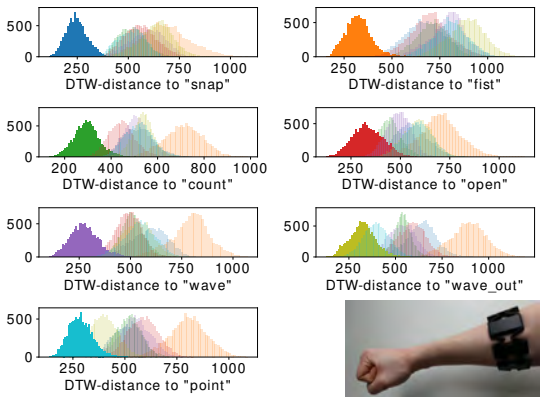

Figure 1: Pointwise cluster distance distributions for one subject.

It further shows the clustering structure of the underlying data, which in turn explains why the condensation techniques in play perform equally strong at lower computational cost as the exploit this clustering structure. The same structural findings can be exploited for an informed selection of gestures that favor cluster separability and as a consequence high classification accuracy. Based on this, we can show that three reference recordings over four days is enough for peak accuracy and we can also establish that d being the 50th percentile of the within-cluster distance distribution yields strong accuracy again above 97% - 99% while rejecting less than 10% of classifyable samples.

CONCLUSIONS

We have established a procedure to understand cluster distributions of EMG signals, allowing intuitive understanding of classification approaches, for which we established an bound on necessary data as an approach for live datastream classification. This insight allows to build onto this in a simple fashion to answer both emerging questions of research as well as practical challenges.

Prediction of the hip joint center position using statistical geometric transformation: validation in canine models

Cheng-Chung Lin[1], Hung-Ju Sun[2], and Ching-Ho Wu[2]
[1] Department of Electrical Engineering, Fu Jen Catholic University, New Taipei City, Taiwan.

INTRODUCTION

The hip joint center (HJC) position, often utilized for determining the femoral anatomical reference frame, is crucial for musculoskeletal modeling and kinematics and kinetics analysis. In scenarios where medical images are not available, predictive methods using linear regressions were commonly used, but none of them was universally acknowledged to outperform others. The functional methods were shown to surpass predictive methods in prediction accuracy and reliability [1] at the expense of additionally specific motion tasks for subjects. The study aimed to propose a new predictive method for HJC position via statistical geometric transformation. The new approach was trained/evaluated with a leave-one-out cross-validation scheme; and compared to those obtained from linear and nonlinear regressions.

METHODS

Twenty-six mature Taiwan dogs without detectable musculoskeletal abnormalities were recruited. Computed tomography (CT) scans were taken for each dog, from which the CT-derived pelvic and femoral models were reconstructed. Bilateral iliac crests and ischial tuberosities on the pelvic models and the greater trochanter, lateral femoral condyle, and HJC (taken as the femoral head centroid) on the femoral models were manually digitized. A deformable template of the above-mentioned bony landmarks was constructed in reference to the building process of the statistical shape model [2]. As a result, a new bony landmark configuration can be generated by superposing controllable deformations onto the averaged landmark configuration, and meanwhile, the template allows free rotation of the femoral landmarks about the HJC. The geometric transformation of the template was carried out by best-fitting the generated landmark configuration to landmarks (except for HJC) extracted from the target subject's bone models. The final landmark configuration gave the predicted HJC position. On the other hand, linear regression models and the nonlinear random forest regression were also built for HJC prediction, in which the inter-landmark distances were computed and taken as the model predictors. A leave-one-out cross-validation scheme was employed to train/evaluate the model performances.

RESULTS AND DISCUSSION

For the linear regression models, the most representative predictors in the prediction of HJC position in cranial/caudal (Cr/Cd), dorsal/ventral (D/V), and lateral/medial (L/M) directions were pelvic length (PL), iliac crests width (ICW), and both ICW and ischial tuberosities width (ITW), respectively. Both the linear and nonlinear regressions as well as the statistical geometric transformation procedure could yield predictions of HJC positions within the area of the acetabulum (Fig. 1). Among the three approaches, the statistical geometric transformation gave the most reliable HJC prediction as the correlation coefficients between the predicted and ground truth HJC positions were 0.96, 0.78 and 0.77 in C/C, D/V and L/M directions, respectively. The corresponding values for regressions were lower than 0.94, 0.29, and 0.67. The geometric transformation method also yielded predictions of HJC position with the lowest absolute errors in C/C and D/V directions. The means (standard deviations) of the absolute errors were 1.18 (1.19) mm and 1.96 (1.67) mm, respectively. The corresponding mean values for regressions were greater than 1.66 mm and 2.40 mm.

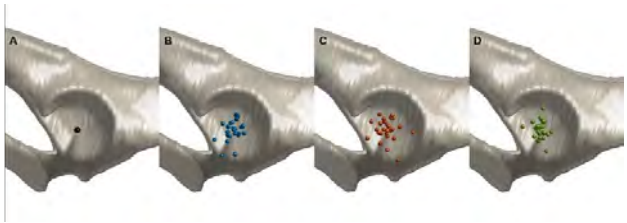

Figure 1 Schematic representation of (A) a ground truth HJC position and the predicted HJC position using (B) linear regression (C) random forest regression and (D) geometric transformation methods.

CONCLUSIONS

The present study developed a new geometric transformation method in conjunction with the deformable template of the bony landmarks for determining the HJC position. Instead of relying on limited geometric features of the bone as utilized in regression models, the new approach takes associated modes of deformation of bony landmark configuration on the pelvis and femur into account, which was demonstrated to yield a more accurate prediction of HJC position.

INTRODUCTION

Notably, kinematic data are essential to examine various aspects of the piano performance as "art," including the levels of individualized techniques by a professional pianist, etc. For relatively accurate data acquisition, the approach of marker-based capture is employed. However, missing data points during capturing and incorrect embedment of pre-defined body models during data processing seems to be inevitable drawbacks due to the nature of finger movements of piano performance. Therefore, we propose a specialized framework for cleaning hand motion data without an explicit hand model by applying general imputation and interpolation techniques.

METHODS

We captured 86 trials (about *20sec* each) of performances of a pianist. We attached 54 (4mm diameter) reflective markers to both hands and fingers (Figure 1). We used eight infrared cameras to record kinematic data at 120Hz. We separated 9 trials and randomly erased 10% of the data for the test. In addition, the velocity of each key depression is recorded with the recordable piano (Yamaha Disklavier C7). The average missing ratio was 19.6% for the fingertips and 14.6% for all data points. The imputation procedure consisted of four steps: 1) Points on the back of the hand are imputed with iterative linear imputation (MICE) [1], and we transform the all points according to the back of the local hand coordinate (Figure 1). 2) Outlier detection was performed. Points with longer or smaller than 20% of segment length or points with large covariance in Elliptic Envelope [2] were removed. 3) Spatial interpolation: For fingers, we iteratively applied radial basis function interpolation. We interpolated a point per step, and the orders were determined by considering the degree of freedom of the finger movement. 4) Temporal interpolation: Temporal cubic split interpolation were used to smooth the unwanted fluctuation.

We evaluated the reconstruction error of the missing points in mean square error (MSE) and the Pearson correlation between the vertical velocity of fingers and the recorded note velocity. The maximum velocity for 0.3*sec* before the key depression was used.

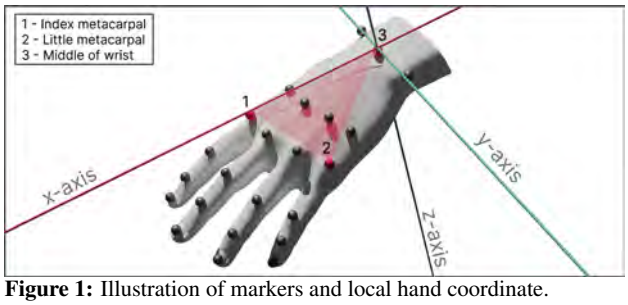

Figure 1: Illustration of markers and local hand coordinate.

RESULTS AND CONCLUSIONS

Our framework not only imputes all missing points, but also reduces reconstruction errors significantly as shown in Table 1. Although the velocity correlation in our framework is somewhat lower than that in the raw data, the imputed data preserve the natural movement of the keystrokes welgiven that it contains significantly more imputed keystrokes (260 additional imputed keystrokes). Our framework is generally applicable because it operates without a prior model and requires only a very small data set.

Steadiness of isometric plantarflexion is reduced when changing posture from supine to prone position

INTRODUCTION

When skeletal muscle is exposed to an artificial external loading, the force-generating capacity of muscle is mostly reduced due to the deformation of muscle [1]. As gravitational force, to which humans are regularly and unconsciously exposed, can also deform the soft tissues in humans [2], it is possible that muscle is deformed and consequently the force-generating capacity of muscle is affected by gravity. If this is true, muscle (motor unit) activity during contractions at a given force level would be altered by gravity, because motor unit (MU) activity is determined by its force-generating capacity.

The ability to perform a steady isometric contraction, so-called steadiness is determined by the variability of MU discharge frequency [3]. The purpose of the current study was to examine the effect of change in the orientation of the muscle relative to gravity on the steadiness of isometric contractions and the variability of MU discharge frequency, and whether these changes were dependent on contraction intensity.

METHODS

Healthy young men (n = 11) participated in this study. To change the orientation of the muscle with respect to gravity, participants lay in the prone and supine positions. Participants performed steady isometric plantarflexion at 20% and 40% of their maximal voluntary contraction (MVC) for 20 s with visual guidance with the right knee extended and the ankle in the 15° plantarflexion for both positions. To quantify the steadiness of the plantarflexion (amount of torque fluctuations), SD and CV of torque were calculated for the middle 8 s of the contraction.

High-density surface EMG was recorded from the medial gastrocnemius muscle during steady contractions according to standard procedures. High-density EMG signals were then decomposed with a convolutive kernel compensation method [4]. A single experienced investigator manually inspected all decomposition results with the specifically designed software for the decomposition of motor unit discharge (DEMUSE), retaining only those that were characterized based on a pulse-to-noise ratio [5]. To examine the effect of muscle orientation on motor unit activity, a motor unit successively discharging for both positions was extracted based on a cross-correlation analysis of the motor unit action potential extracted by spike-triggered averaging from high-density surface EMG. The mean, SD, and CV of discharge frequency of the extracted MUs were then calculated.

RESULTS AND DISCUSSION

In the steady contraction at 20% MVC, SD and CV of torque were 42% and 46% greater in the prone compared with the supine position ($P < 0.05$). The mean discharge frequency of ninety-nine trackable MUs across positions did not change, but SD and CV of discharge frequency were greater in prone than supine ($P < 0.05$).

In the steady contraction at 40% MVC, for the seven participants who had at least one MU tracked across positions, there was no difference in SD and CV of torque between positions. The mean discharge frequency of sixty-six trackable MUs was significantly ($P < 0.05$) but slightly greater (3.5%) in the prone position compared with the supine position, while SD and CV of MU discharge frequency were not different ($P > 0.05$). These results suggest that torque fluctuations during steady contractions at 20% MVC were greater in the prone position, accompanied by greater variability in MU discharge frequency.

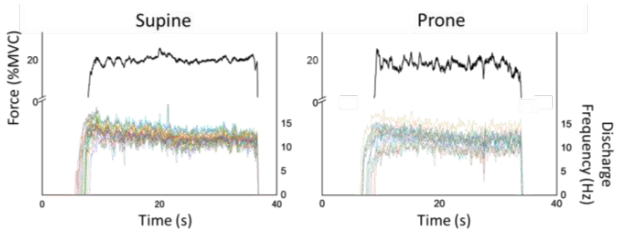

Figure 1 Representative signals of force and instantaneous discharge frequency of trackable MUs across supine (left) and prone (right) positions of a participant during steady contractions at 20% MVC.

CONCLUSION

Our results indicate that change in the orientation of the muscle with respect to gravity induced alterations in both the steadiness of isometric plantarflexion and variability of MU discharge frequency during steady contractions only at lower contraction intensities.

ENERGETICS, MECHANICS, AND MUSCLE: LOCOMOTOR ADAPTATIONS TO CHRONIC LIMB LOADING DURING DEVELOPMENT

INTRODUCTION

Humans and other animals adapt to expend the least amount of metabolic energy to complete a movement task, both over acute [1-3] and evolutionary timeframes [1,4]. Whether adaptations in locomotor economy occur in response to altered life history, especially during development (e.g. environmental fluctuations, or training in humans) remains less clear. Further, the mechanical underpinning to adaptations in locomotor economy that may occure during development have not been well explored.

We have previously demonstrated that chronic limb loading during development substantially alters locomotor economy; it was found that chronically limb-loaded animals (LL) cary additional limb mass remarkably more economically than control animal (CON) [5]. Here we test the hypothesis that a reduction in mechanical limb work contributes to the observed lower metabolic cost of carrying externally applied limb mass after chronic limb loading. Specifically, we hypothesize that (1) LL animals locomote with added limb mass using less mechanical power than CON animals, and (2) the increase in mechanical power between unweighted and weighted conditions will be smaller for LL animals than CON animals.

METHODS

To study the effect of load stimulus during development on locomotor mechanics, we applied an average load of 3.5% body mass unilaterally to the lower right limb of a group of guinea fowl, continuously from 1-16 weeks of age (limb-loaded group, LL; n = 10). CON birds were raised in the same conditions but with no external limb loading (n = 10). At 16 weeks old, half of the birds (N = 5 per group) were video recorded (100 Hz) walking on a treadmill in both unilaterally loaded and non-loaded conditions. An inverse dynamic formulation was used to analyse swing-phase kinetics. We compared mechanical data to previously collected metabolic data on the same animals in the same conditions [5].

RESULTS AND DISCUSSION

At 16-weeks old, LL animals used 24% less metabolic energy than CON animals to walk with 3.5% BM loading [5]. Our hypothesis that LL had lower mechanical power than CON was, however, refuted. Surprisingly, our data is suggestive of LL animals having even greater mechanical power than CON animals, although this difference was not statistically significant at an alpha of 0.05 ($p = 0.12$, ES = 1.18; figure 1).

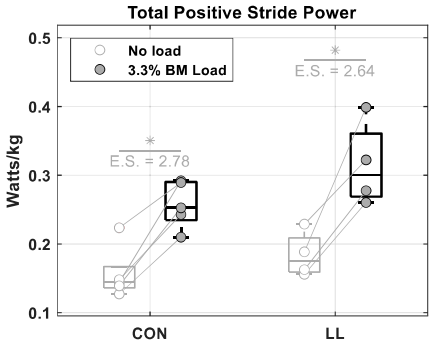

Figure 1 Total positive stride power (watts/kg) for both CON and LL animals. *significant difference due to loading ($p < 0.05$).

CONCLUSIONS

LL animals required no less limb power to carry additional mass compared to CON, despite the observed large reduction in metabolic energy consumption [5]. Increases in limb power in LL animals were isolated to the right (chronically loaded) limb, specifically driven by a larger increase in power at the ankle from unloaded to loaded walking. We propose that muscle-level adaptations may explain the improved locomotor economy in LL animals compared to CON animals. Further work is being conducted to investigate whether adaptations to muscular architecture explain how animals were able to achieve improvements in locomotor economy after growth-period loading. Preliminary findings indicate adaptations not only in muscle mass, but also in sarcomere properties after limb loading.

INTRODUCTION

In baseball pitching, friction between fingertips and ball is an important factor in pitching performance. Our previous study showed that in fastball pitching, the application of rosin powder to the fingertips increased ball spin rate and improved ball control [1]. On the other hand, under wet conditions, the ball spin rate and ball speed decreased and ball control got worse [1]. These results are thought to be caused by the change in the friction between fingertips and the ball as well as the resulting upper limb motion during pitching.

In this study, we estimated the coefficient of friction (COF) between the fingertips and the ball and investigate the effects of the difference in the COF on upper limb motion during fastball pitching.

METHODS

The subjects were six experienced male pitchers who threw overhand. The pitch was a four-seam fastball. The friction conditions between the fingertips and the ball were as follows: no application between the fingertips and the ball (unapplied condition), water applied condition, rosin powder applied condition, and pine resin applied condition.

We measured whole-body kinematics during pitching using a motion capture system. We also captured videos of the ball and fingers during the release process from the side of the subject using a high-speed camera. The translational and angular velocities of the ball were estimated from the trajectories of multiple marks drawn on the ball.

Based on the study of Fuss et al.[2], we estimated the COF between the fingertips and the ball using the translational and angular velocities of the ball. We calculated the external rotation angle of the shoulder during pitching based on the study by Miyashita et al.[3]. The centrifugal force acting on the hand was calculated using the hand velocity v_{hand}, the pitching radius R and the mass of the ball m. We used v_{hand}^2/R as the index for the centrifugal force acting on the ball during pitching.

RESULTS AND DISCUSSION

The mean COF under the water-applied condition (0.91±0.20) was 29.3% lower ($p < 0.01$) than that under the unapplied condition (1.28±0.24). On the other hand, the COF under the rosin powder applied condition (1.41±0.23) was 10.0% higher than that under the unapplied condition ($p < 0.01$). There were no significant differences in COF between unapplied and pine resin applied conditions ($p > 0.05$).

The maximum external rotational (MER) angle of the shoulder decreased by 1.4° ($p < 0.05$) in the water applied condition and increased by 0.2° ($p < 0.01$) in the rosin powder applied condition compared to the unapplied condition. The velocity of the hand at release timing decreased by 2.6% ($p < 0.01$) in the water applied condition and increased by 1.2% ($p < 0.05$) in the rosin powder applied condition compared to the unapplied condition.

The value of v_{hand}^2/R from the MER to the release time tended to be smaller in the water applied condition than in the other conditions (Fig. 1). This trend was observed in all subjects. The pitcher was not able to obtain sufficient friction force under the water applied condition and may behave to reduce the centrifugal force acting on the ball by reducing the hand velocity and increasing the radius of the circular path of the hand during pitching.

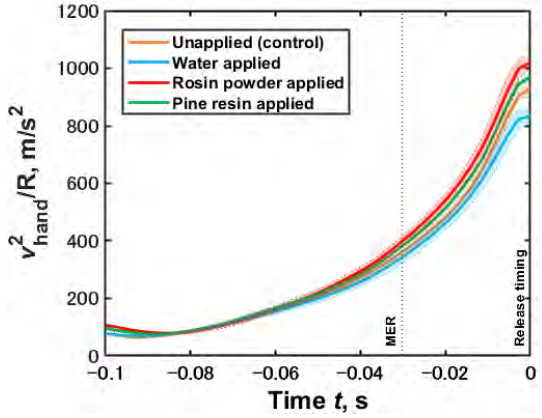

Figure 1 Representative time series of the index of centrifugal force index acting on the ball during the pitching motion.

CONCLUSIONS

The reduction of COF between fingertips and a ball resulted in decreased MER angle and decreased centrifugal force due to the decreased hand velocity and increased radius of the circular path of the hand to prevent the ball from slipping out of the hand.

BIOMECHANICS OF HANDCYCLING HIGH INTENSITY INTERVAL TRAINING

INTRODUCTION

Up to 68% of people with spinal cord injuries (PwSCI) report shoulder pain[1] which makes exercise challenging for this population. High intensity interval training (HIIT) has been recommended to improve cardiovascular health safely because it incorporates periods of active rest[2]. However, it is unclear how the increased intensity of HIIT affects shoulder loading compared to moderate intensity continuous training (MICT). Therefore, the aim of this study was to **quantify shoulder joint angles and torques during recumbent handcycling HIIT and MICT**. We used a musculoskeletal model[3] to evaluate shoulder plane, shoulder elevation, and shoulder rotation angles and torques during exercise.

METHODS

Following IRB approval, wheelchair users with SCI (n=20, 9 females) age 22(2.73) with 16.8(4.09) years of wheelchair use were recruited. Participants engaged in three recumbent handcycling protocols 2-7 days apart[4]: (1) Baseline to determine peak power output (PPO); (2) HIIT: 10x1 min 90% PPO, 1 min 10% PPO; (3) MICT: 45% PPO until equivalent workload to HIIT reached. Handle loads were collected using a handle instrumented with a six-axis load cell (ATI). Segment kinematics (23 markers) were recorded using a 10-camera system (Vicon). We used an acromion marker cluster to determine scapular motion[5]. Kinematic and hand force/moment data were collected at six workload-matched timepoints in HIIT and MICT.

Kinematic data was smoothed with a moving average filter (Matlab vR2021a). Both kinetic and motion data were filtered (2nd-order Butterworth, cutoff frequency = 10 Hz and 8Hz, respectively). The first 10 propulsion cycles were averaged at each timepoint. A musculoskeletal model of the shoulder[3] was scaled to each subject (OpenSim v3.4) and used to calculate joint angles and torques using inverse kinematics and inverse dynamics. Angle range of motion (RoM) and mean torque magnitude were averaged over all timepoints. Normally distributed datasets were compared using paired t-tests (R v4.1.2); non-normal using Wilcoxon signed ranks tests (α = 0.05). RoM and torques were compared between HIIT and MICT at each timepoint and are reported as median (median absolute deviation).

RESULTS

There were no differences in joint angle RoM between HIIT and MICT (Table 1). HIIT torques were 38.3% higher than MICT on average (Fig. 1B, $p<0.001$).

Table 1: Angle RoM and Torque (τ). Bold values indicate significant difference ($p<0.001$) between HIIT and MICT.

		Plane	Elevation	Rotation
RoM	MICT	73.9(16.7)	22.2(9.6)	78.2(20.9)
(°)	HIIT	77.9(20.2)	24.1(8.0)	74.9(20.5)
τ	MICT	10.7(3.5)	7.4(2.7)	10.4(2.8)
(Nm)	HIIT	**14.3(6.0)**	**10.2(4.4)**	**14.9(5.3)**

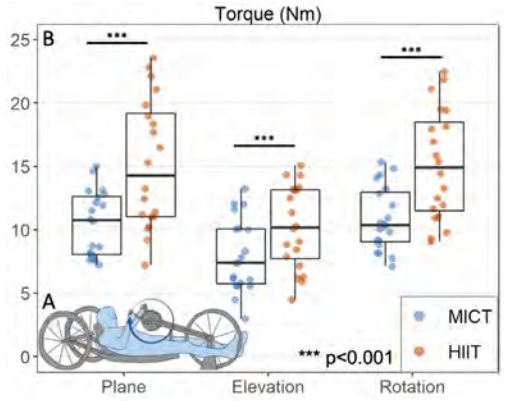

Figure 1: A) Recumbent handcycle. B) Joint torque magnitude.

CONCLUSIONS

The consistency of kinematics during HIIT and MICT is likely due to the uniform nature of handcycling. Higher torques in HIIT are therefore attributed to increased forces[4]. While increased torques are related to shoulder pain[6], it remains unclear if the torques during HIIT would contribute to shoulder tendinopathy. The cardiovascular and enjoyment benefits of HIIT[7] may warrant the increased shoulder exertion. More work is needed to determine the effect of HIIT on muscle and tendon loads to evaluate the risk of injury.

INTRODUCTION

Several studies suggest that electrical muscle stimulation (EMS) can be used as an alternative modality to voluntary exercise. EMS training improves muscle strength and prevents muscle atrophy after surgery [1]. Nevertheless, the effects of EMS training on thigh muscle mass are less understood. Therefore, this study aimed to characterize the effects of EMS training on the quadriceps and biceps femoris muscles hypertrophy.

METHODS

Thirty-five heathy male participants were divided into EMS training (n = 19) and control (n = 16) groups. In the EMS group, the participants performed EMS (Myoelectoric Medicine EMS) three times per week for 8 weeks. The EMS system was designed to simulate motor unit activities during strong voluntary muscle contraction, and stimulation frequencies gradually increased from 12 to 60 Hz. Before and after the training, maximal isometric knee extension torque was measured. The quadriceps muscle cross-sectional area (CSA) was assessed at mid-thigh (50% of the femur) and the biceps femoris muscles (long head and short head) CSA were assessed at distal (70% of the femur) regions using magnetic resonance imaging. We performed a two-way analysis of variance (ANOVA) with group (between) and time (within) as factors.

RESULTS AND DISCUSSION

We observed a significant interaction on the quadriceps femoris muscle CSA ($p = 0.016$). In the EMS group, the quadriceps femoris muscle CSA increased (Figure 1 upper, Pre: 62.0 ± 8.3 cm^2 vs. Post: 64.2 ± 8.6 cm^2, $p < 0.001$). In the Control group, the quadriceps femoris muscle CSA did not change (Pre: 63.5 ± 7.7 cm^2 vs. Post: 63.8 ± 8.9 cm^2, $p = 0.93$).

We also observed a significant interaction on the short head of the biceps femoris muscle ($p = 0.016$). The short head of the biceps femoris muscle increased in the EMS group (Figure 1 lower, Pre: 4.4 ± 1.0 cm^2 vs. Post: 4.9 ± 0.9 cm^2, $p < 0.001$), but not in the Control group (Pre: 4.2 ± 0.9 cm^2 vs. Post: 4.3 ± 1.0 cm^2, $p = 0.79$). Conversely, neither main effects nor an interaction was found on the long head of the biceps femoris muscle ($p > 0.05$) (EMS group, Pre: 7.6 ± 2.2 cm^2 vs. Post: 7.8 ± 2.0 cm^2; Control group, Pre: 6.7 ± 1.7 cm^2 vs. Post: 6.5 ± 1.6 cm^2). The present results indicate that EMS training induced muscle hypertrophy of the thigh muscle. Since the short head of the biceps femoris is a deep muscle, these results suggest that the present EMS system stimulated both superficial and deep muscles adequately.

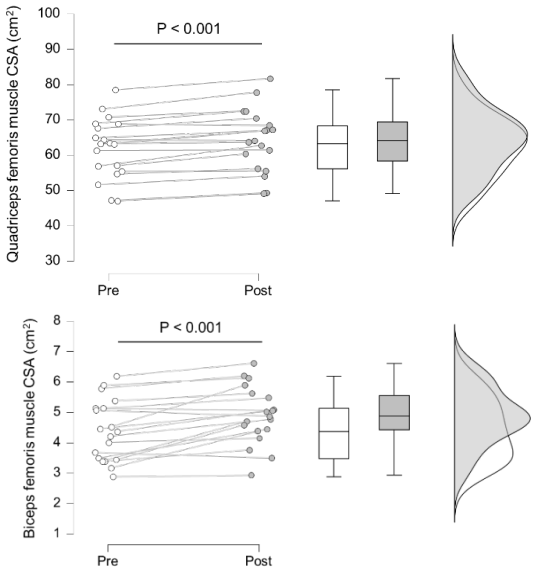

Figure 1 Changes in quadriceps femoris muscle CSA (upper) and short head of biceps femoris muscle CSA (lower) before and after EMS training. (open: Pre; filled: Post)

CONCLUSIONS

EMS training of the thigh muscles induces muscle hypertrophy of the quadriceps femoris and biceps femoris muscles, including deep muscle.

Advent of carbon thick shoe changes morphological advantages for long-distance running ability

NOBUE Ayaka[1], SANO Kanae[1] and ISHIKAWA Masaki[2]

INTRODUCTION

The technological intervention of the sport items can change the movement skill and morphological characteristics as well as enhance athletic performance. For example, the slap skate shoes and LZR Racer swimwear can enhance athletic performance but also bring important movement skills and morphological characteristics of musculotendons which have not been considered advantageous previously.

In track and field events, the advent of thick-soled carbon shoes (**Carbon Thick Shoe**) in 2017, as opposed to the traditional thin-soled light shoes (**Traditional Shoe**), has dramatically enhanced long-distance running performance. Until the advent of Carbon Thick Shoe, Achilles tendon length ($\mathbf{L_{AT}}$) was a crucial advantage for long-distance running performance [5,7]. However, it is uncertain whether the morphological advantages of $\mathbf{L_{AT}}$ for long-distance runners would be effective with the advent of Carbon Thick Shoe.

Therefore, the purpose of the present study was to examine musculoskeletal characteristics related to long-distance running performance before and after the advent of Carbon Thick Shoe. It was hypothesized that $\mathbf{L_{AT}}$ can be related to the running performance of the distance runners who wore Traditional Shoe. However, these relationships will become irrelevant with the distance runners who wore Carbon Thick Shoe. Instead, the psoas major muscle size can be crucially related to the running performance of the distance runners who wore Carbon Thick Shoe.

METHODS

Table 1 shows the physical characteristics of participating long-distance runners. The Traditional Shoe group was measured from 2014 to 2019. The Carbon Thick Shoe group who had worn them for more than 2 years was measured from 2020 to 2022.

The $\mathbf{L_{AT}}$ and the cross-sectional area (CSA) of the psoas major muscles at the Jacobi line were measured by musculoskeletal ultrasonography (Noblus, Hitachi-Aloka Inc.). The relationships between these parameters and their athletic performance (the season records of 5000 m, 10000 m and half marathon) were calculated for each group using Pearson's correlation coefficient.

Table 1. Physical characteristics of the participants

	Age (years)	Height (cm)	Body mass (kg)	Half marathon time
Traditional Shoe (n=59)	23.2±4.2	171.6±5.2	57.4±4.4	1:03:14±0:01:38
Carbon Thick Shoe (n=58)	21.5±3.6	170.8±4.8	55.8±4.6	1:03:58±0:01:51

RESULTS

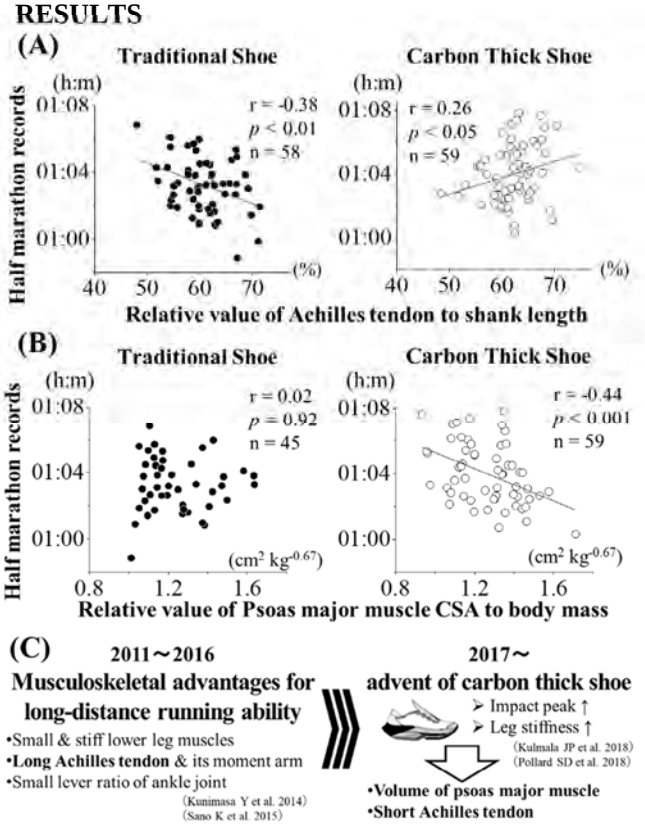

Figure 1. Relationships (A) between L_{AT} and half marathon records and (B) between psoas major muscle and half marathon records for different shoe groups and (C) schema of functional and morphological changes due to the advent of Carbon Thick Shoe.

DISCUSSION

- ✓ The increased stride due to the increased leg length of the thick soles (Stack height) can increase the hip joint [1] and psoas major muscle works.
- ✓ Carbon Thick Shoe can increase foot mechanical work and power [3], but to its detriment, may not utilize the elastic energy of AT. Consequently, the use of Carbon Thick Shoe may lead distance runners to improve postural control due to muscle-tendon modulation such as competitive trampoline athletes who have long soleus muscle length and short $\mathbf{L_{AT}}$ [2].

Different effects of a single ingestion of quercetin on motor unit recruitment in upper and lower limbs.

INTRODUCTION

Quercetin, a polyphenolic flavonoid found in onions and tea, has garnered attention as an ergogenic aid for enhancing human physical performance [1]. It exhibits high affinity for adenosine receptors and functions as an antagonist of adenosine [2], thereby promoting the release of neurotransmitters such as acetylcholine and dopamine [3]. Our previous research has demonstrated that a single ingestion of quercetin can decrease the recruitment threshold of motor units [4]. This suggests that quercetin ingestion may augment the number of motor unit activations in muscle performance (e.g. muscle endurance) and have implications for exercise and strength training. Although the previous study was investigated on the lower limb (vastus lateralis, VL), it is uncertain if similar effects would be observed in the upper limb. Caffeine, which bears structural resemblance to quercetin and functions as an antagonist of adenosine, has been reported to elicit different effects in the upper and lower limbs [5]. The present study, therefore, sought to compare the effects of quercetin ingestion on the recruitment thresholds of motor units in the biceps brachii (BB) and VL.

METHODS

In a double-blind, counterbalanced, randomized and crossover design, five adults underwent isometric elbow flexion and knee extension exercises before (PRE) and 60 minutes after (POST) ingesting quercetin glycosides 200mg (QUE) or a placebo (PLA). Each condition was separated 72hours. Four types of submaximal isometric exercises were performed using ramp contractions that incrementally applied torque from 0% to 15%, 30%, 50%, and 70% of MVC. High-density surface electromyography (HD-sEMG) was recorded from the BB and VL during ramp contractions. Individual motor units of the BB and VL were identified from HD-sEMG and changes in recruitment thresholds were examined by tracking motor units from PRE to POST.

RESULTS AND DISCUSSION

A total of 122 motor units were detected in the BB and 423 in the VL. Figure 1 indicates the different effects of quercetin and placebo ingestion on the recruitment threshold of motor units. The results show an interaction between muscle group and quercetin ingestion at 30% and 50%MVC ramp, indicating that quercetin ingestion may differently affect the recruitment thresholds of BB and VL motor units (Figure 1). The findings of this study suggest that quercetin ingestion may decrease the recruitment threshold of upper limbs motor units than lower limbs. Previous research, focused different effect of caffeine ingestion on upper and lower limbs, has been suggested that these differences may be attributed to variations in motor unit recruitment patterns and / or muscle size between the upper and lower limbs [5]. While quercetin has been shown to enhance muscle performance in both the upper and lower extremities, the extent of these effects may vary between the two muscles.

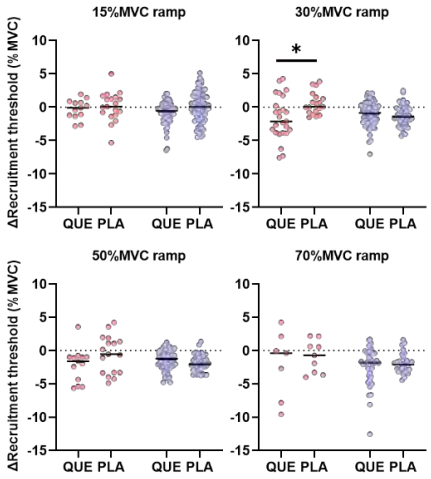

Figure 1 Difference of recruitment threshold of motor unit during ramp contractions from PRE to POST. Red and Blue dots represent difference of recruitment threshold of BB and VL motor units. * $p < 0.05$ QUE vs. PLA

CONCLUSIONS

This study assessed the effects of a single dose of quercetin on the recruitment thresholds of motor units in the BB and VL muscles using HD-sEMG. Results indicate different effects of quercetin ingestion on the recruitment threshold of upper and lower limbs motor units. Present study suggested that the ergogenic effects of quercetin may vary between upper and lower limbs.

INTRODUCTION

During the contact phase of running, the visco-elastic properties of the muscle-tendon complex (MTC) play a crucial role in functional muscle-tendon interaction and the recycling of elastic energy [1]. In sprint events of track race, the 100m and 400m athletes have different determinants of athletic performance, such as muscular endurance. Therefore, it is likely that the viscoelastic properties of the MTC also differ in these events. The aim of this study was to investigate the viscoelastic properties of the lower leg MTC in track and field athletes of100m (short sprint) and 400m (long sprint) .

METHODS

A total of 38 male subjects (n=25;100m and n=13; 400m) participated in the study. The viscoelastic properties of the MTC were measured using the vibration method under multiple load settings (similar to Fukashiro et al. [2]). The subject was placed in a seated position (ankle and knee joints 90deg), with the ball of the foot on a force plate edge. A weight was placed on the knee, and with the posture maintained by isometric contraction (the muscle force exerted was varied), the damped oscillation of the triceps surae muscle was induced. The waveforms were regressed by the least-squares method on the following equation (1) to calculate the unknowns, gamma (γ), omega(ω), a_c, a_s and M.

$$F(t)=e^{-\gamma t}(a_c cos\omega t+a_s sin\omega t)+\mathrm{Mg} \quad (1)$$

where F is force, t is time, e is Napier number, γ is damping factor, a is amplitude, ω is angular frequency, M is effective mass, and g is gravitational acceleration. Then, after consideration of the moment arm of muscle, the elastic and viscous coefficients (k and b) of MTC were calculated.

$$k = M(\omega^2+\gamma^2) \quad (2)$$
$$b=2M\gamma \quad (3)$$

From the experimental results obtained, the coefficients were calculated for every 100N up to 700N. In addition, the elasticity of MTC was separated into muscle and tendon components, based on the assumption that they are arranged in series. The calculated parameters were compared between 100m and 400m.

RESULTS AND DISCUSSION

The study found that 100m athletes had higher elastic coefficients of muscle-tendon complex (MTC) under force exertion conditions of 100-400 N. However, no difference was observed under higher force conditions or in viscous coefficients between groups. When comparing muscle and tendon separately, the elastic coefficients were significantly higher for the 100m group in muscle (**Fig 1A**) and the 400m group in tendon (**Fig 1B**). However, no significant correlation was observed between athletic performance and each coefficient in both groups. These results suggest that the 100m athletes use an increased elasticity due to increased muscle contraction, while the 400m athletes may use the higher intrinsic elasticity of tendons to achieve the overall elasticity required during sprinting, such as acceleration and maximal speed phases.

Effect of restricted thoracic expansion during shoulder external rotation on scapulothoracic and glenohumeral joint motion

Mitsuhiro Yoshimi[1], Noriaki Maeda[1], Makoto Komiya[1], Tsubasa Tashiro[1], Kazuki Kaneda[1], Satoshi Arima[1], Shogo Tsutsumi[1], Takeru Abekura[1], Yukio Urabe[1]

INTRODUCTION

Throwing injuries of the shoulder are caused by repeated throwing motions in overhead sports such as baseball. Shoulder external rotation in the throwing motion involves movement of the scapulothoracic (ST) and glenohumeral (GH) joints, thoracic spine, and thorax. Restriction of thoracic expansion may decrease ST joint motion and compensate by excessive GH joint motion. However, it is unclear how restricting the expansion of the thorax alters shoulder motion. This study aimed to elucidate changes in ST and GH joint movements caused by restricted thoracic expansion during shoulder external rotation.

METHODS

Eighteen right-handed healthy males (mean ± SD: age, 21.9 ± 1.8 years; BMI, 21.4 ± 2.0 kg/m²) participated in this study. The participants performed shoulder external rotation in two conditions: with and without restriction of the thorax. The thoracic expansion was restricted by taping, which was applied to the fifth and tenth rib positions. The participant sat and performed shoulder external rotation from 90° abduction and 75° external rotation to the maximum external rotation (MER) angle [1]. Kinematic data were measured using an electromagnetic tracking device (Liberty, Polhemus, Inc., USA). The joint kinematics data were measured based on the relative positions of the thorax, scapula, and humerus: internal rotation, upward rotation, and posterior tilt angle of the scapula relative to the thorax (ST joint), and external rotation angle of the humerus relative to the scapula (GH joint). The angles at 75° of external rotation and MER angle for each variable were measured respectively, and the difference was calculated as the angular displacement. The Wilcoxon signed-rank test was used to compare each variable in the two conditions. Additionally, the difference between with and without restricted conditions for angular displacements (displacement in the "with restriction condition" - displacement in the "without restriction condition") was calculated, and the relationship between each variable was examined using Spearman's rank correlation coefficient. The statistical significance level was set at $p<0.05$.

RESULTS AND DISCUSSION

In with restriction condition, ST posterior tilt decreased ($r=0.50$, $p<0.05$) and GH external rotation increased ($r=0.67$, $p<0.01$) in the MER angle. A decrease in displacement of ST posterior tilt ($r=0.74$, $p<0.01$) and an increase in displacement of GH external rotation ($r=0.66$, $p<0.01$) were also observed. On the other hand, no significant differences occurred in MER angle and ST internal rotation and upward rotation angles. A significant negative correlation existed between the difference in the displacement of ST posterior tilt and GH external rotation with a correlation coefficient of -0.54 ($p<0.05$, Figure 1).

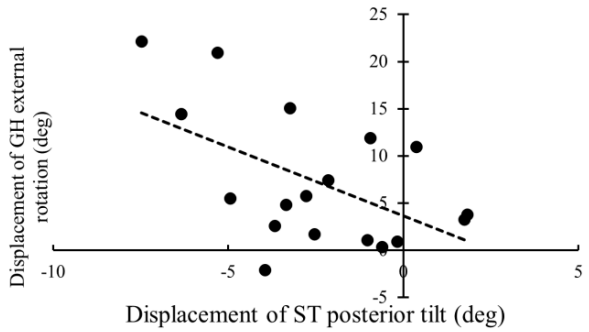

Figure 1: Correlation between displacement of ST posterior tilt and displacement of GH external rotation.

A previous study reported that a decrease in ST joint motion resulted in a decrease in MER angle [1]. However, in the present study, MER angle did not change with restriction. This was because the excessive GH external rotation compensated for the decreased motion of the ST joint. It has been reported that malfunctioning of one of the joints directly affected the other joint [2]. Restriction of thoracic expansion limited ST joint motion but may have resulted in greater GH motion to prevent a decrease in shoulder external rotation. Restriction of thoracic expansion was suggested to increase dependence on GH joint motion and possibly lead to shoulder injuries.

CONCLUSIONS

The present study indicated that restriction of thoracic expansion causes changes in ST and GH joint movements. Improvement of thoracic expansion exercises may be important in the prevention of throwing injuries of the shoulder.

INTRODUCTION

Peripheral nerves are subjected to length changes with joint movement [1, 2], possibly affecting the firing and recruitment properties of motor units. This notion stems from changes in stiffness of peripheral nerves observed in patients with neuropathologies, such as nerve compression [3] and diabites neuropathy [4]. Patients with such peripheral nerve pathologies were reported to have low motor unit firing rate [5], suggesting attenuated cortocomotor excitability. It seems therefore plausible to ask whether nerve stiffness may affect motor unit firing patterns. The purpose of this study was to investigate motor unit firing patterns during peripheral nerve stretching.

METHODS

Eighteen healthy young adults participated in this study (age: 30.3±6.0 yrs, 1.8±0.1 m, 68.8±11.3 kg, 4 females). They sat in different two hip positions. One was hip flexion position (FLEX) where sciatic nerve was stretched, whereas the other was hip extension position (EXT) where the nerve was not stretched. Peripheral nerve conduction time was measured to confirm whether the nerve was stretched. Specifically, peroneal nerve was electrically stimulated below the fibular head, and the action potential of extensor digitorum brevis was detected using electromyography (EMG). The delay between stimulation onset and the maximum of the compound muscle action potential was used to measure the conduction time. To investigate motor unit firing properties of tibialis anterior during dorsiflexion, the participants performed ramp-up isometric contractions with a 10-s ascending phase to 20% of maximum voluntary contraction (MVC) and 20-s sustain phase at 20%MVC. High density surface EMG signals was collected from tibialis anterior during the ramp-up contraction tasks during each position. Recorded monopolar surface EMG signals were analyzed and individual motor units were identified. Additionally, detected motor units were tracked between two conditions. Recruitment thresholds and firing rate at 10-20 %MVC and during 20%MVC sustain phase were calculated and compared between two conditions.

RESULTS AND DISCUSSION

The number of detected motor units was 181. Conduction time of peroneal nerve during FLEX was significantly shorter than that during EXT (FLEX: 14.9±1.4ms, H-EXT: 15.0±1.3ms, p=0.016), suggesting that peripheral nerve was stretched during hip flexion position. Motor unit recruitment thresholds was significantly higher during FLEX than during EXT ($p < 0.01$). Additionally, motor unit firing rate at 10-20%MVC during FLEX was significantly lower than during EXT ($p < 0.01$). Those results suggested a possibility that peripheral nerve stretching might affect the motor unit firing properties.

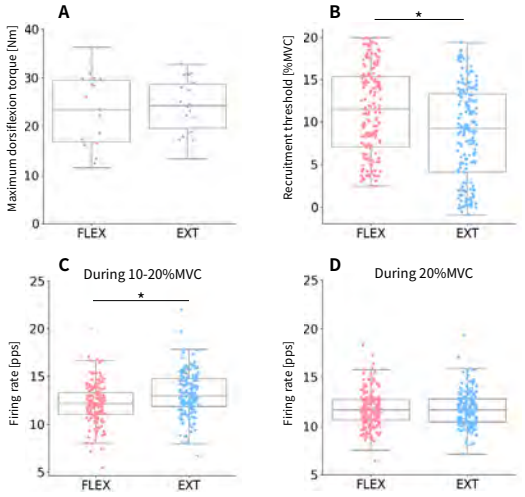

Figure 1 A. Maximum dorsiflexion torque. B. Recruitment threshold. C. Firing rate during 10-20%MVC in an ascending phase. D. Firing rate during 20%MVC in sustain phase. An asterisk represents a significant difference.

CONCLUSIONS

Peripheral nerve stretching, which was evaluated by measuring nerve conduction time by electrically stimulation, might increase motor unit recruitment thresholds and reduce the average firing rate of active motor units.

The difference in the precision of the soccer shot between dominant and non-dominant feet

Yusuke Shimotashiro[1], Masahiro Shinya[1]
[1]Graduate School of Humanities and Social Sciences, Hiroshima University, Higashi-Hiroshima, Japan.
Email: yu.shimo16@gmail.com

INTRODUCTION

In soccer, players are required to accurately shoot with both dominant and non-dominant feet. Precision or variability in kicking has been evaluated by Hunter et al. (2018) using 95% confidence ellipse [2]. However, the previous study measured shoots by the dominant foot only and did not focus on the difference between the dominant and non-dominant foot. Also, the study was limited to frontal shots and did not separately analyze straight (i.e., shooting rightward with the right foot and leftward with the left foot) and cross (i.e., shooting rightward with the left foot and leftward with the right foot) shooting direction. In light of the above, the purpose of this study was to determine the influence of the kicking foot and shooting direction on shooting precision.

METHODS

Sixteen right-footed players (male: 13, female: 3) with at least 6 years of soccer experience participated in the study. The participants were asked to make instep kicks aiming at a circular target (33 cm in diameter) as accurately as and as fast as possible as if it were a penalty kick. The target was placed at a height of 1.6 m inside the left and right goalposts. The distance from the participant to the goal was 11 m. In addition, the fastest possible shots, which did not require precision, were measured twice before the task. The number of trials was 80 in total, 20 trials for each of the four conditions of kicking foot (dominant/non-dominant foot) and shooting direction (straight/cross). A digital video camera (1920 × 1080 pixels, 120 fps) was used to measure the tangential velocity of the ball. Another camera (1920 × 1080 pixels, 60 fps) was set to measure the 2D location of the ball in the goal plane. The 20 ball locations for each condition were fitted by the bivariate normal distribution and a 95% confidence ellipse was calculated. The average velocity of the two shots taken before the task was used as the maximum shooting velocity, and the ball velocity during the task was calculated as a percentage of the maximum shooting velocity. A 2-way repeated measures ANOVA was conducted to detect the effects of kicking foot and shooting direction on the area of the 95% ellipse and the ball velocity relative to the maximum.

RESULTS AND DISCUSSION

The area of the 95% confidence ellipse with the dominant foot was 6.17 ± 1.93 m² in the straight direction and 6.62 ± 3.10 m² in the cross direction. The area of 95% confidence ellipse for the non-dominant foot was 10.22 ± 3.53 m² in the straight direction and 11.50 ± 4.81 m² in the cross direction. The 95% confidence ellipse area was significantly smaller for the dominant foot than for the non-dominant foot ($F(1,15) = 36.37$, $p < 0.001$, illustrated in Figure 1). There was no main effect of the kicking foot on the ratio of ball velocity during the task to maximum shooting velocity between the non-dominant and dominant foot.

The lack of the difference in the ball velocity relative to the maximum indicates that the observed difference in the kicking precision cannot be explained by the theory of speed-accuracy tradeoff. Antosiak-Cyrak et al. (2015) reported that the dominant foot took less time than the non-dominant foot in experienced soccer players using a task in which the foot passed through tubes of different sizes[1]. The observed difference in the kicking precision between the dominant and non-dominant foot might be interpreted as the difference in the dexterity or skill fullness.

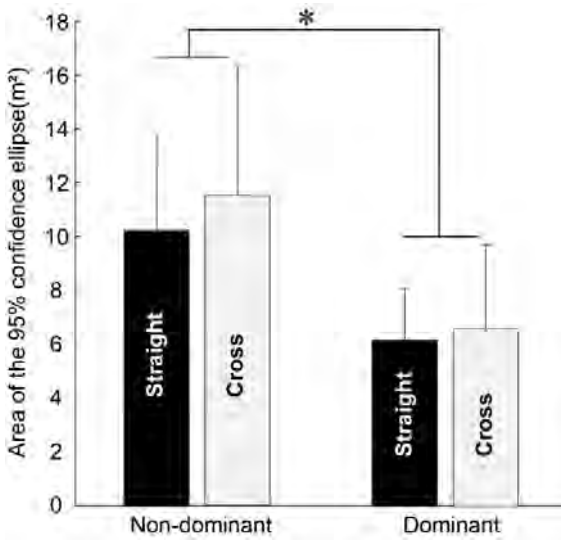

Figure 1 Comparison of 95% confidence ellipse area.
The main effect of the kicking foot was observed (* $p < 0.05$).
Error bars indicate standard deviation.

CONCLUSIONS

Shooting by the dominant foot was twice as precise as that by the non-dominant foot when the precision was quantified using the area of 95% confidence ellipse.

INTRODUCTION

In daily training, many javelin throwers work on improving their throwing technique by throwing from a slower run-up velocity than in competitions. If the acquisition of javelin velocity in throws from a slower run-up velocity differs significantly from that of a full run-up throw, then throwers and coaches need to understand these differences and adjust the run-up velocity of throws in training. the purpose of this study was to clarify the differences in the contribution of each movement to javelin velocity caused by changes in the run-up velocity of an individual. We hypothesized that as the run-up velocity of an individual changes, the acquisition of javelin velocity would also change.

METHODS

Twelve collegiate male javelin throwers were included in this study. Participants performed the following two types of throws, two times each, at maximum effort; a one-cross throw that the thrower throws from a one-step run-up (Cross), and a full run-up throw that the thrower throws in the same way as in an actual competition (Run). Of the two throws of each type, the throw with the highest resultant velocity of the grip of the javelin at the time of release was used for the analysis. The coordinates of reflective markers affixed to anatomical landmarks on the body and javelin points during the experimental trials were recorded using a motion capture system (250 Hz). The mathematically method [1] was used to calculated the javelin velocity acquired by each joint movement and the percentage (contribution) of the javelin velocity acquired by each movement to the javelin velocity at the same moment was calculated. The analysis phase was from the last fore foot touchdown (L-on) to the javelin release (Rel). Differences in parameters between Cross and Run were confirmed using a paired t-test for those that followed a normal distribution and a Wilcoxon's signed rank test for those that did not ($\alpha = 0.05$). Differences in time series data were confirmed using a paired t-test in statistical parametric mapping ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Cross had a lower forward release velocity than Run, and no significant difference was observed in the upward release velocity (Table 1). Therefore, the higher release angle observed in Cross than in Run may have been caused primarily by the decreased forward release velocity in Cross.

Despite the upward release velocity did not change significantly between the types of throwing, the contribution of trunk forward lean to upward javelin velocity was lower in Cross than in Run (Figure 1). The forward lean of the trunk in the javelin throw is caused by the converts the momentum of the whole body into trunk rotation after L-on [2]. Based on this, it is possible that less whole-body momentum was observed at L-on in Cross and that the forward lean of the trunk was subsequently less than in Run, with a concomitant decrease in their contribution to the upward javelin velocity.

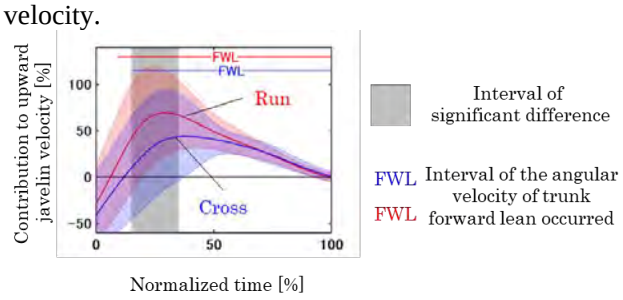

Figure 1: Contribution of the trunk forward lean to the upward javelin velocity.

CONCLUSIONS

Although no significant change in upward release velocity was observed between Cross and Run, there was a difference in the contribution of trunk forward lean. This result supports the hypothesis of the present study.

The intrinsic foot muscles contribute to controlling postural sway during single-leg stance

Momoka Nakamura[1], Moeka Samoto[1], Kei Masani[2] and Yasuhide Yoshitake[1]

INTRODUCTION

It is well-known that the center of pressure (COP) fluctuation increases during single-leg stance compared to double-leg stance [e.g., 1]. During double-leg stance, the COP fluctuates mainly in the antero-posterior (AP) direction, which represents the ankle joint plantarflexor torque and is primarily controlled by the plantarflexor muscles [2]. However, during single-leg stance, the COP fluctuation in the medio-lateral (ML) direction becomes larger and close to the one in AP direction, which probably reflects ankle inversion/eversion torque, and/or foot deformation. It is unclear which muscles contribute to this control of the COP in the ML direction. The intrinsic foot muscles are assumed to largely contribute to it, because the muscle activities in intrinsic foot muscles were reported to remarably increase during single-leg stance compared to double-leg stance [3].

Here we investigated whether the intrinsic foot muscle and the plantarflexor muscle contribute to controlling the COP fluctuation in the ML and AP directions during single-leg stance. We analyzed temporal similarity between the COP and muscle activation measured using electromyography (EMG). Also, we analyzed the temporal similarity between the COP and fasicle length meausred using ultrasound technology. Recent progress of ultrasound technology has enabled successive tracking of the fasicle length. Since the fasicle length highly relates to muscle force [4], it is very likely that the temporal changes in the fasicle length highly relates to the COP fluctuation.

METHODS

Nine healthy young adults (5 females) participated in this study. Participants quietly stood barefoot with the single leg stance (SLS; right leg) on a force plate. Five trials were conducted, with each trial lasting approximately 10 s. The COP position in the medio-lateral (COP-ML) and antero-posterior (COP-AP) directions were calculated from the vertical and horizontal forces recorded by the force plate.

Ultrasound B-mode images and surface EMG were obtained from the abductor hallucis (AH) and the medial gastrocnemius (MG) of the right leg during single-leg stance. From ultrasound images (~150 fps), fascicle length was obtained by using a validated automatic tracking algorithm [5]. Interference EMG was full-wave rectified (rEMG). After adjusting sampling frequency and applying low-pass filtering at 5 Hz with zero-phase-lag, cross-correlation function (CCF) between COP and fascicle length and between COP and rEMG were calculated for the stead-state 8 s for each COP direction and each muscle. From CCF, a distinct peak above 95% confidence limit near time 0 was identified.

RESULTS AND DISCUSSION

In CCF between COP-ML and fascicle length of AH, a distinct positive peak (0.48 ± 0.20) was found for all participants. In CCF between COP-ML and rEMG of AH, a distinct negative peak (-0.57 ± 0.19) was found for almost all participants. In contrast, a distinct peak CCF between COP-AP and fascicle length of AH was found in a very few participants while a distinct peak CCF between COP-AP and rEMG of AH showed a smaller correlation of coefficient (-0.29 ± 0.14).

In CCF between COP-ML and fascicle length/rEMG of MG, a distinct peak was obtained for some participants. In contrast, in CCF between COP-AP and fascicle length of MG, a distinct negative peak was found for all participants (-0.46 ± 0.10). In CCF between COP-AP and rEMG of MG, a distinct positive peak was found for all participants (0.47 ± 0.11). These results suggest that muscle mechanical and electrical activities of AH and MG are temporally correlated with COP-ML and COP-AP, respectively during single-leg stance.

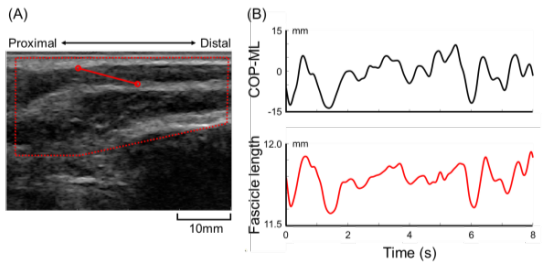

Figure 1 (A) A representative ultrasound image of AH with a fascicle (red line). (B) Example waveforms of COP-ML (upper) and fascicle length (bottom) of AH of a participant during SLS.

CONCLUSIONS

We demonstrated that AH highly contributes to controlling the COP fluctuation in the ML direction, while MG highly contributes to controlling the COP fluctuation in the AP direction during single-leg stance.

MUSCLE SYNERGY ANALYSIS OF TWO SINGLE-LEG YOGA POSTURES: COMPARISON BETWEEN PRACTITIONERS AND NON-PRACTITIONERS

Luciano Luporini Menegaldo[1]*, Dafne Pires Pinto[1], Henrique Lelis C. de Oliveira[1] and Pedro Sarmet Moreira[1]
[1] Biomedical Engineering Program, COPPE, Federal University of Rio de Janeiro, Brazil.
Email: lmeneg@peb.ufrj.br

INTRODUCTION

Several effects on human physiology have been reported in the literature regarding Yoga practice. One is the increased inhibitory gamma amino-butyric acid (GABA) neurotransmitter system activity due to vagal stimulation mediated by the breath [1], which also influences feedforward cortical control on postural control [2]. In this work, we address whether habitual Yoga practitioners modulate muscle activity, releveled by EMGs, differently from non-practitioners while performing two simple single-leg Yoga postures.

Dimensionality reduction techniques, such as the non-negative matrix factorization (NMF), have been used to decompose m muscles' EMGs into a set of $n<m$ vectors called *synergies* multiplied by n time-varying neural commands [3]. Synergy analysis might reflect biological information processing and the generation of motor commands by the central nervous system. The number of synergies a subject uses in a motor task should be proportional to the complexity or richness of that motor execution related to skill. Fewer synergies, otherwise, might reflect a poorer task execution caused by disease or lack of training. However, by performing the Yoga postures (asanas), the subject aims to keep the center of mass as stable as possible, suppressing the body movement and, perhaps, decreasing complexity. Does Yoga training increase the number of synergies due to skill? Or, otherwise, might the increased inhibitory activity reduce the number of synergies while performing a learned asana?

METHODS

Eight yoga practitioners (YG) and eight healthy non-practitioner controls (CG) participated in the study, which was approved by Institution's Ethics Committee. The YG has practiced Yoga non-interruptedly for at least six months, at least two hours a week. The volunteers performed the Vrksasana for 45 seconds twice, with a 5 minutes rest interval. In the sequence, they performed the Natarajasana twice by the same time. Only the first stable 20s were considered in the analyses after the transient phase of the postures had decayed. EMGs from 11 muscles were collected using a BTS FreeEMG 300 device: gluteus medius, gluteus maximus, biceps femoris long head, semitendinosus, vastus lateralis, rectus femoris, tensor fasciae latae, gastrocnemius medialis, erector spinae iliocostalis, obliquus externus abdominis and soleus. EMG data were sampled at 1080 Hz and processed according to [4]. We used the variability accounted for (VAF) criterion (total VAF and per muscle >90%) to select the minimal number of synergies to reconstruct the original EMGs. The synergy vectors across subjects were gathered using k-means clustering. The synergy coordination index (SCI), which evaluates the size of the resulting synergy space or the coordination among the utilized synergies, was also assessed [5]. A larger SCI expressed a smaller synergy space size and was positively correlated to balance skills in a perturbed posture test. As data was identified as nonparametric, the Mann-Whitney U-test was used to compare groups; the Wilcoxon Signed Rank test was used to compare postures.

RESULTS AND DISCUSSION

Regarding the Vrksasana, the CG presented a median (interquartile range) number of synergies of 9.5 (3.25), while the YG was 6.5 (3.25) ($p=0.0365$*, $\eta^2=0.249$). In the Natarajasana, the number of synergies was 8 (2.5) vs. 9 (1) ($p=0.1675$, $\eta^2=0.116$) for the same groups. Comparing the postures, CG $p=0.3125$ ($\eta^2=0.092$) and YG $p=0.0547$ ($\eta^2=0.240$). Natarajasana presented a tendency for a smaller SCI compared with Vrksasana (YG: 0.157 x 0.209, $p=0.0391$* $\eta^2=0.276$; CG: 0.156 x 0.226, $p=0.1049$, $\eta^2=0.044$). When both groups were merged, the median values of SCI were 0.198 for Vrksasana and 0.158 for Vrksasana ($p=0.0299$*).

CONCLUSIONS

Yoga practitioners used fewer synergies than controls for the Vrksasana, suggesting a reduction of control complexity mediated by training. This effect was not observed for the Natarajasana. Additionally, the YG used more synergies (marginal p, but large effect size) for controlling the Natarajasana posture than the Vrksasana. When both groups merged, the SCI for Natarajasana was smaller than for Vrksasana, indicating that Natarajasana requires a larger synergy space and is a more demanding and complex postural task.

BREAK DANCE MOTION ANALYSIS THROUGH MOTOR SYNERGY

Keli Shen and Jun-ichiro Hirayama

National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan.

Email: shen.keli@aist.go.jp

INTRODUCTION

Dance motion analysis is very challenging due to the complexity of movements as well as the large variety of motions across dance genres and choreographies. Motor synergy analysis is a powerful approach to understanding complex dance movements. Yet, most previous works [1, 2, 3] on dance synergies focused on simple dance motions with a limited variety in genres and choreographies. Thus, we aimed to newly analyze the motor synergies in break dance, a popular style of hip hop dance, especially their variability between choreographies.

METHODS

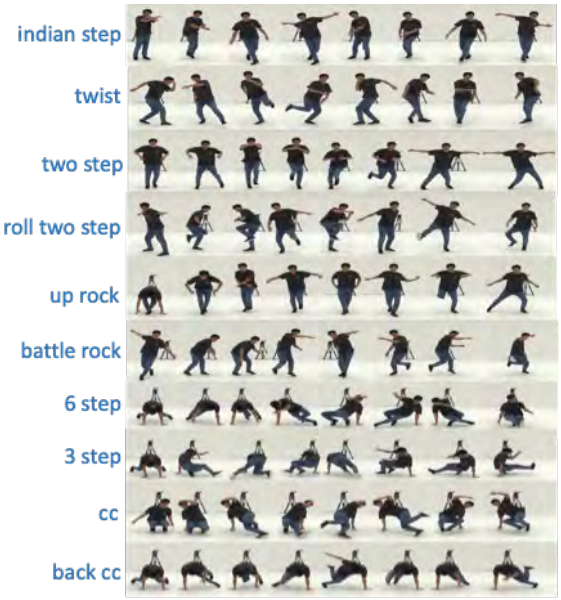

Figure 1 Key frames of ten break dance choreographies.

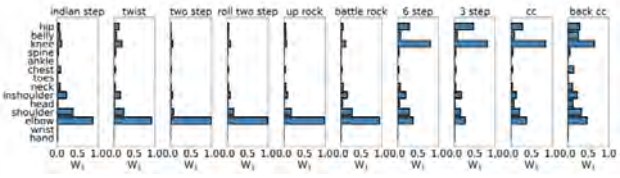

Figure 2 Motor synergy 1 of ten break dance choreographies with PCA.

Data were obtained from AIST Dance Video Database [4], and AIST++ dance datasets [5]. Three male dancers ageing in 20 − 30 years old had 6, 10, and 13 years of break dance experience. Each dancer performed four runs of ten dance choreographies shown in Figure 1. The music tempos of break dance were set to 80, 90, 100, 110, 120, and 130 beats per minute (BPM). The kinematic dance parameters were estimated [5]. First, we translated the 3D joint angles into the Euler-angle format. Then, the angle data of each choreography were segmented by the music beat timings. A root joint was discarded, and the remaining 23 joints (69 degrees of freedom) were considered in the synergy analysis. Motor synergy was computed with concatenated dance motion segments. PCA is used to minimize the following reconstruction error with respect to W and C:

$$E^2 = ||X - W \cdot C||_F^2 , \quad (1)$$

where $||\cdot||_F$ means the Frobenius norm, and X, W, and C depict the matrices of joint angles, motor synergies, and activation weights, respectively; W was taken to be orthonormal in columns.

RESULTS AND DISCUSSION

The modular motor synergy scores were summarized by taking the square root of the sum of squares of motor synergy weights in W within each body module. The 14 modules are given in Figure 2 (only the 1st PC is shown). The upper limb mainly contributes to the first six break dance choreographies, while the lower limb mainly contributes to the last four choreographies. The contribution of upper and lower limbs can be confirmed from movement key frames of dance choreographies depicted in Figure 1.

CONCLUSIONS

We recruited the modular motor synergy analysis by PCA and characterized a difference in the contributions of the upper and lower limbs. The ten choreographies were roughly divided into two groups based on the modular contributions. This synergy-based method may contribute to dance classification and motor coordination study.

INTRODUCTION

Concussions often result in short-lived to long-lasting neurological function impairment, with symptoms appearing immediately, and possibly deteriorating into permanent neural damage. Several efforts have been made to quantify the incidence concussions and to improve diagnostic methods, which are still largely inconclusive and not always accurate. An absence of specific neuromuscular markers compromises diagnostic ability and reliability. For that purpose, we chose to investigate the neural correlates of oculomotor metrics (eye tracking) and corticomuscular coherence (EEG-EMG) metrics when participants are submitted to a virtual reality-implemented optical flow paradigm.

METHODS

The study cohort was comprised of thirty-three ($N = 33$, $n = 13$ concussed) young adults ($M_{age} = 21.6 \pm 3.0$ years), with a BMI < 30, with normal or corrected-to-normal vision that had or had not had a concussion in the past 8 years ($M_{time} = 33.8 \pm 26.0$ months since last concussion). Participants completed concussion history and physical activity levels surveys. They were then prepped with the wireless EEG cap and EMG electrodes and asked to stand in a relaxed position on a force plate (960 Hz). A 5-point calibration was then performed in the virtual reality (VR) environment and a set of mock targets was used to visually verify the calibration at the beginning of each trial. They completed three trials, each with a duration of 30 seconds. Data across all devices were time locked. Cross-spectra of delta, theta, alpha, beta, low gamma, and high gamma frequency bins were calculated for each individual trial, over each contralateral brain region, in relation to each one of the four leg muscles before being averaged across the three trials for each participant.

RESULTS AND DISCUSSION

For the solei muscles, there were significant main effects of concussion history on the beta, $F(1, 120) = 4.37$, $p = .039$, $\eta_p = .035$, and low gamma, $F(1, 120) = 7.35$, $p = .008$, $\eta_p = .058$, frequency bins. Similarly, for the tibiales anterior muscles, there were significant main effects of concussion history on the beta, $F(1, 120) = 4.49$, $p = .036$, $\eta_p = .036$, and low gamma, $F(1, 120) = 6.12$, $p = .015$, $\eta_p = .049$, frequency bins. In all cases, corticomuscular coherence in the beta and low gamma frequency bins increased in concussed participants when compared to their non-concussed counterparts (Figure 1). Neural modulations and muscle activity couplings were independent of limb dominance, and that the differences observed in the cerebral cortex between groups were similar across the frontal and sensorimotor cortexes. It is well-known that EMG amplitude increases with activation intensity[1] and that increased activation amplitude during dynamic loading is a product of faster cross-bridge cycling[2]. Similarly, cortical activity shifts towards greater frequencies during dynamic force tasks, especially when rapid integration of somatosensory and visual information is present[3].

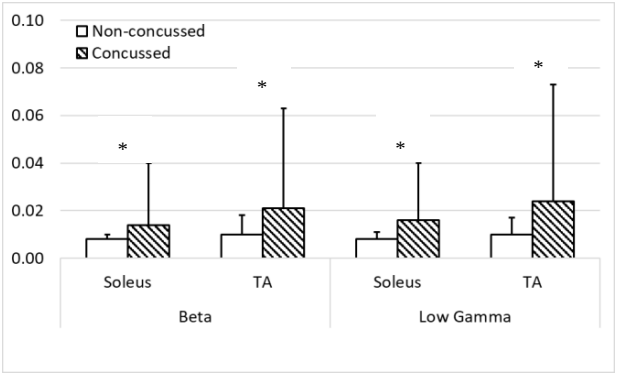

Figure 1. Means and standard deviations of corticomuscular coherence coefficient (y-axis) in β and low γ frequency bins for the solei and tibiales anterior of concussed and non-concussed groups. TA: tibialis anterior; β = 12-30 Hz; Low γ = 30-50 Hz; *: $p < .05$ between concussed and non-concussed.

CONCLUSIONS

Our results suggest that a link exists between cortical and lower extremity muscle activity dysfunction and concussion-related balance impairments persistence can be detected through a dual task visuomotor paradigm. These changes in corticomuscular coherence may predispose mTBI patients to musculoskeletal injury risk.

Awareness of Visual Offset Does Not Improve Shoulder Joint Position Sense in Virtual Reality Environment

Motoki Sakurai[1] and Andrew R. Karduna[1]
[1] Department of Human Physiology, University of Oregon, Eugene OR, USA
Email: motokis@uoregon.edu

INTRODUCTION

Humans integrate vision and proprioception to reach to a target (eg, grab a bottle), though they tend to weigh vision more heavily than proprioception [1]. Additionally, a motor learning study found that visual input could not be disregarded where participants were informed about visual offset and asked to ignore vision [2]. However, it remains unclear if humans can disregard visual input for a reaching task where motor adaption over trials is not involved. In the present study, we investigated the effect of visual offset when participants were instructed to ignore vision during a joint repositioning study. It was hypothesized that 1) induced visual offsets would result in repositioning errors consistent with the direction of the offset, and 2) the same trend in joint repositioning error would be observed even when participants were informed about offsets and asked to ignore vision.

METHODS

Sixteen healthy right-handed participants (female/male: 10/6, age: 23.3 ± 2.6 yr, height: 1.7 ± 0.1 m, weight: 68.3 ± 6.3 kg) performed a joint position sense (JPS) test in an immersive virtual reality environment (HTC VIVE, Taoyuan, Taiwan). Auditory cues guided the participants to reach to a target shoulder flexion angle (85, 90, 95, or 100º) to remember, and each target was presented three times for a total of 12 trials. Subjects were then instructed to replicate the target position as accurately as possible without auditory cues. A black marker represented a real-time hand position throughout the trial. There were total of 3 blocks of 12 trials. The first block was a familiarization block, where no visual offset was introduced for all 12 trials. Following the first block, two offset blocks (OB1 and OB2) were completed, where the task and settings were the same. The only difference between blocks was that participants were informed about the visual offset and instructed to ignore vision in OB2. In the two offset blocks, 4 out of 12 trials did not have a visual offset (0º offset) while either -8º or +8º vertical offset in the black marker position was caused for each of 4 target angles with a random order (12 trials per block – 3 offset angles x 4 target angles).

Constant error (CE) was calculated for each trial by taking a difference between a target angle and replicated angle with direction of error being taken into account. A two-way repeated measures ANOVA was performed to examine the main effect of visual offset and block as well as interactions of them on CE. Pairwise t-tests with the Bonferroni correction were performed for post-hoc testing when a significant effect or interaction was observed in the ANOVA. For all the statistical tests, an alpha level was set at 0.05. All statistical analyses were performed using R 4.2.2 (R Core Team)

RESULTS AND DISCUSSION

A significant main effect was found for visual offsets ($p < 0.001$), and a post-hoc pairwise t-test revealed that CE was larger when visual offsets were introduced ($p < 0.001$). Neither the effect of blocks nor the block-offset interaction was significant ($p > 0.05$). These results support the findings from a previous study in our lab which demonstrated that a visual offset causes an increase in reaching error [1]. It also demonstrated that awareness of visual offset did not increase an instant reaching task accuracy, similar to a motor adaptation study that involved reaching [2]. These results suggest that humans may rely on vision for reaching motions regardless of its accuracy when present.

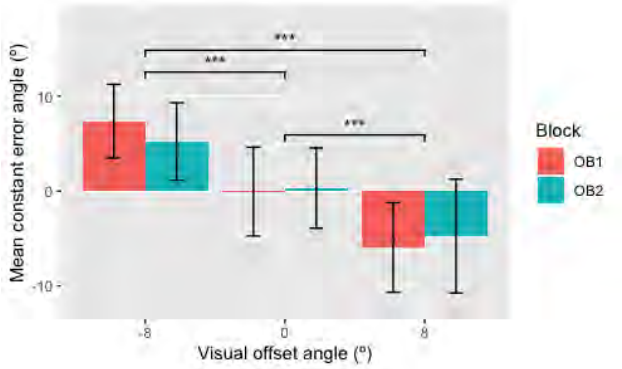

Figure 1. Mean CE with different visual offsets in OB1 and OB2 across participants. ***: $p < .001$

CONCLUSIONS

Our hypotheses were supported, with a non-significant block effect and significant visual offset effect. For shoulder flexion repositioning task, the awareness of visual offset did not help improve JPS.

EFFECTS OF DUAL-TASK CHALLENGES ON THE MULTI-OBJECTIVE OPTIMAL CONTROL STRATEGIES DURING OBSTRUCTED GAIT

INTRODUCTION

Dual-task (DT) crossing is a more challenging activity that occupies cognitive resources than single-task (ST) crossing. Studies on cognitive-motor interference employing DT conditions have demonstrated that limited attentional resources are needed for gait, postural control and balance, resulting in a greater demand for the attentional load [1]. Lu et al. developed a customized planar model of the body for simulating ST obstacle-crossing [2]. Therefore, the current study aimed to identify the control strategy of DT obstacle-crossing of different heights using a multi-objective optimal control (MOOC) technique.

METHODS

Twelve healthy adults were asked to walk at a self-selected pace on an 8-meter walkway and to cross a height-adjustable obstacle (i.e., 10%, 20% and 30% of the subject's leg length) and two task conditions (i.e., ST and DT). During DT crossing conditions, each subject not only crossed the same obstacle as in the ST condition but also concurrently counted down by 3's from a randomly generated number between 90 and 100 and speak out loud. Marker trajectories were recorded using a motion capture system (Vicon MX T-40, OMG, UK) and the ground reaction forces were measured by two forceplates (OR6-7, AMTI, USA). Obstacle-crossing was formulated as an optimal control problem with two conflicting objectives: minimization of mechanical energy expenditure (f_1) and maximization of clearances of the swing heel (f_2) and toe (f_3) above the obstacle [2]. The resulting MOOC problem was solved using the weighting method, i.e. ($W_1f_1 + W_2f_2 + W_3f_3$). The crossing speed, end-point variables, and best-compromise weighting sets were averaged across all subjects for all tasks and height conditions. These weighting sets were compared between different tasks and obstacle heights using two-way repeated ANOVA.

RESULTS AND DISCUSSION

Compared to the ST obstacle-crossing, the DT obstacle-crossing condition showed an overall decreased crossing speed but increased leading and trailing toe-obstacle clearance. There were no significant between-task differences in leading heel-obstacle distance, trailing toe-obstacle distance, and best-compromise weighting sets (Figure 1) during both ST and DT tasks.

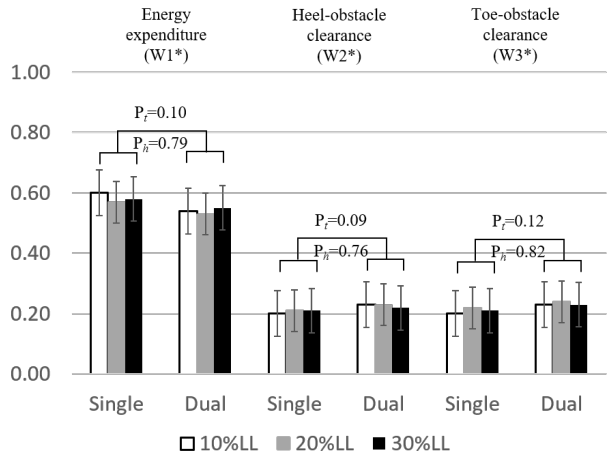

Figure 1: Means (standard deviations) of the best-compromise weighting sets (W1*, W2*, W3*), corresponding to the objective functions of mechanical energy expenditure, heel-obstacle clearance, and toe-obstacle clearance of the MOOC problem, for the single-task and dual-task crossing obstacles of three different heights: 10% (white), 20% (grey) and 30% (black) of individual subjects' leg length (LL). P-values for the main effects are also given (P_t: task effects; P_h: height effects).

CONCLUSIONS

Healthy adults were found to use similar control strategies during single-task and dual-task obstacle crossing, suggesting that the observed strategy was one at the central nervous system level. More studies shall assess the control strategy in patients with pathology.

INTRODUCTION

The previous study showed when healthy people control posture using ankle and hip strategy there is some "trading off" between ankle and hip during single leg squat. In other word, when ankle moment is high hip is low, also when hip moment is high ankle is low. the study also suggested that postural control in the frontal plane was similar to it in the sagittal plane [1]. On the other hands, Gender differences in mutual relationship of lower extremity kinetics is unclear. The mutual relationship of lower extremity movement has been reported during single leg squat by Graci V et al [2]. The study suggested females show more knee abduction and hip adduction, than males in landing and single leg squat. But not including lower extremity moment. This study aimed to investigate the difference in lower extremity moment for posture control in frontal plane between genders during single leg squat.

METHODS

Subjects were 16 healthy adults (8 males and 8 females; 21.0 ± 1.5 yrs.) without history of orthopedic disease in lower limbs. They were asked to do a single-leg squat with their right leg. We asked that they bend their knee in 2 seconds and extend in 2 seconds and repeat three times. Kinematic and force plate data were collected with an eight-camera, three-dimensional motion capture system (VICON Nexus; Vicon Motion Systems Ltd., UK) and six force plates (AMTI, USA). Thirty-five reflective markers were attached to anatomical landmarks following the Vicon Plug-in-Gait marker placement protocol. Difference in frontal plane moments of lower extremity between male and female were analyzed using independent-samples t-test (significance at $p<0.05$).

RESULTS AND DISCUSSION

As a result of comparing frontal plane moment of lower extremities between males and females, hip moment of females is higher than males one and ankle moment of females is lower than males. Differences of Knee moment between gender are no significant (Table 1). That is, compared to males, females use hip strategy more ankle strategy for posture control. Also, focusing on the hip moment of each, while all males almost had the same values, females were divided into two groups, one with the same values as males and the other with higher values (Figure 1). In other words, females use a wider variety of postural control in than males. Some females use hip strategy more ankle and others use ankle strategy hipper like male.

Table 1: Gender differences in frontal plane moment of lower extremity

Joint	Joint Moment [Nm/kg]		*p-value*
	Male	Female	
Hip	15.5 ± 2.4	21.4 ± 4.1	$p<0.05$
Knee	13.1 ± 2.8	9.34 ± 7.1	*N.S*
Ankle	3.22 ± 0.5	2.41 ± 0.7	$p<0.05$

mean ± SD independent-samples t-test (n=16)

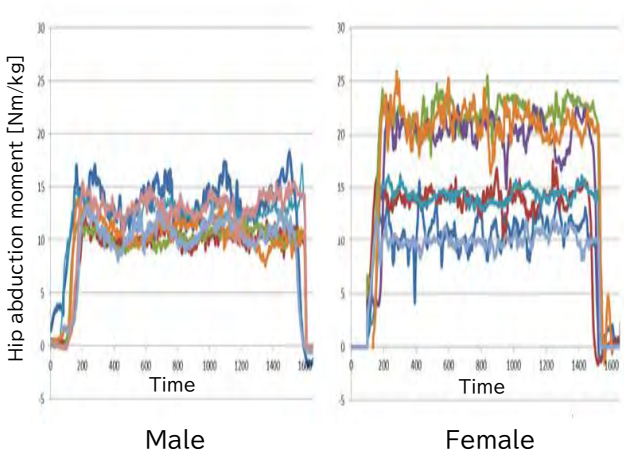

Figure 1 Gender differences in hip abduction moment during single-leg squat

CONCLUSIONS

These results demonstrate that females use a different movement strategy during single leg squat from males and that females showed more patterns of movement strategy between individual than males. We found some females employ a different movement strategy from males and such a strategy could expose females to a greater risk of hip and knee pain. For that reason, a postural control for female should be analyzed with attention to individual differences.

FORCE ENCODING IN MUSCLE SPINDLE SECONDARY ENDINGS

Jacob D. Stephens[1], Paul Nardelli[2], Lena H. Ting[1] and Timothy C. Cope[1,2]

[1] Coulter Department of Biomedical Engineering, Emory University and Georgia Institute of Technology, Atlanta, USA.[2] School of Biological Sciences, Georgia Institute of Technology, Atlanta, USA. *Email: jdstephens@gatech.edu

INTRODUCTION

Proprioception is a vital sense for the precise coordination of movement, however proprioception relies on feedback from multiple mechanosensors that are not fully-characterized. It has been postulated that length feedback from muscle spindles provide a mechanical description of the muscle tendon unit (MTU) state to the central nervous system. However, group IA afferents exhibit highly complex behavior that is not fully captured by muscle length and has been attributed to crossbridge binding properties of muscle fibers within the spindle [1]. Specifically, gr. IA firing in some passive stretch conditions can respond in part to muscle resistance to stretch, as shown by similarities to the muscle's force, as well as the yank (dF/dt), which give rise to initial bursts. On the other hand, muscle spindle gr. II afferents may be more singular in their encoding, as gr. II afferents do not terminate on the same fibers that give rise to initial bursts in IAs. We hypothesize that gr. II afferents respond to the resistive force on the muscle spindle and predict that, during imposed stretches of quiescent muscle, they can be modeled by estimates of the force on the muscle spindle.

METHODS

Preliminary data were collected from 11 afferents across 3 animals: 7 gr. IA and 4 gr. II. Length-controlled 20 mm/s ramp-hold-release stretches were applied to the triceps surae MTU in deeply anaesthetized rats. Action potentials were recorded via glass microelectrodes from the dorsal root of the spinal cord, and afferents were classified as either IA or II according to conduction velocity and responses to muscle twitch and vibration. Afferent firing profiles were fit to muscle force and yank using constrained optimization in MATLAB according to Blum et al in 2017 [1] and 2019 [2].

RESULTS AND DISCUSSION

As has been reported previously, gr. IA afferent firing rates could be reproduced with linear combinations of force and yank. Firing profiles were fit with a yank coefficient of 16 ± 14 pps/N/s (mean ± sd) and a force coefficient of 147 ± 81 pps/N, with a variance accounted for (VAF) of 0.74 ± 0.34. In comparison, gr. II afferents were best predicted with a similar force coefficient of 185 ± 56 pps/N and a smaller yank coefficient of 3 ± 2 pps/N/s, with a VAF of 0.89 ± 0.06. To ensure this small yank component was not a coincidence in the optimization, fits were run again without yank. In this iteration, the force component increased by 14 pps/N (p<1e-12, paired t-test) and the VAF decreased by 0.037 (p<1e-7, paired t-test), indicating yank did contribute to the model fit.

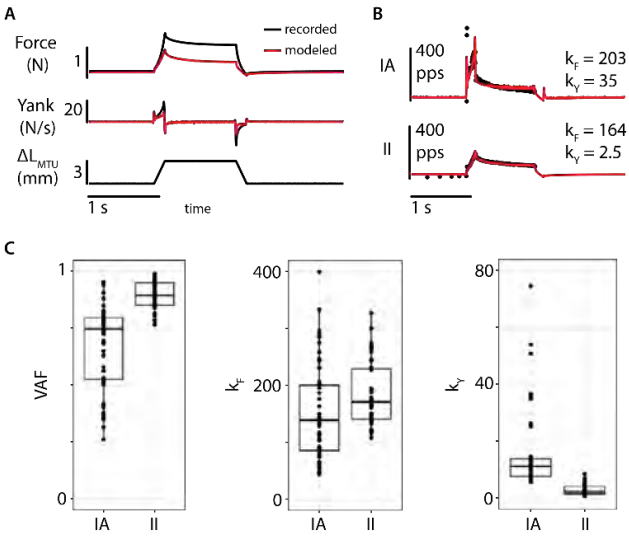

Figure 1 A) Example traces of recorded MTU length, MTU force, MTU yank, and IFR of a group IA afferent (black) and the estimated force and yank on contractile muscle tissues (red) according to the method described by Blum et al 2019 [2]. B) Example model fits using combinations of modelled force and yank in group IA, II, and IB afferents. C) Grouped data of model VAF, force component (k_F), and yank component (k_Y) of all afferent classes.

CONCLUSIONS

Although the yank sensitivity of gr. II afferents was non-zero, it was very low relative to the yank sensitivity of gr. IAs (means 3 and 16 pps/N/s, respectively). Thus, while gr. II afferents from muscle spindles do not appear to purely respond to forces on the spindle, the signal is biased towards force more so than gr. IAs. Considering gr. IAs and IIs together, it's possible that these afferents relay different components of imposed muscle stretches to the central nervous system.

INTRODUCTION

Human movement is coordinated by the central and peripheral factors. There is a sex differences in physical performance, in addition to muscle volume and muscle fiber composition as factors, sex differences in motor unit (MU) firing behabiour have recently reported [1]. Sex differences in central nervous system functions and hormonal influences have been pointed out as possible factors. Furthermore, hormones have been implicated in asymmetry of brain function, and high progesterone levels are known to weaken interhemispheric inhibition. These findings suggest that there are sex differences in asymmetries in motor nerve function, but sex differences in asymmetries of MU firing behaviour are not clear. The aim of this study was to examine the sex difference in laterality of MU firing behaviour during submaximal isometric contraction of first dorsal interosseous (FDI) musle in healthy young adults.

METHODS

Twenty-seven subjects (females, n = 14 and males, n = 13) were enrolled in this study. A grid of 64 multiple electrode was used to record the high-density surface electromyography (HD-EMG) from the FDI muscle. The participants were asked to perform maximum isometric voluntary contraction (MVC) of the bilateral pinch force. After MVC recording, all participants performed a submaximal isometric pinch force at 10%, 30%, and 60% MVC in a random order. Convolution blind source separation method was used to separate HD-SEMG recordings into individual MU discharge. To identify individual MUs, we used DEMUSE software [2]. A generalized linear mixed-effect model with random slopes, followed by Bonferroni multiple comparisons as a post hoc analysis, was applied to analyse the mean discharge rate. The explanatory variables were as follows; sex (female or male), side (dominant or nondominant), and MVC (10%, 30%, and 60%). The significance level was set at $p < 0.05$.

RESULTS AND DISCUSSION

We identified a total of 769 MUs (females: 318 MUs; Males: 451 MUs) that were considered for further analysis. The discharge rate showed a significant sex × side × MVC interaction ($F = 5.90$, $p = 0.0027$, $\eta^2 = 0.219$). The discharge rate showed significantly higher values at each torque level on females' dominant side than males' dominant side ($p < 0.0001$, respectively, Figure 1). Furthermore, at 60% MVC, male's nondominant side showed a significantly higher discharge rate than the dominant side ($p < 0.0001$, 95% CI = −5.516 to −2.295), but this pattern was not found in females.

Hormonal influences have been implicated in these sex differences is known to affect neurotransmitter function, and its has been reported that the MU discharge rate is higher after ovulation, when the progesterone level is high. On the other hand, a recent study reported that higher testosterone levels were associated with reduced MU action potential complexity. These findings indicate that sex hormones influence MU firing behaviour and may be one of the reasons for the observed sex differences in MU characteristics. It was also reported that high progesterone levels weakened interhemispheric inhibition, suggesting that such hormonal dynamics led to the asymmetry in the MU characteristics.

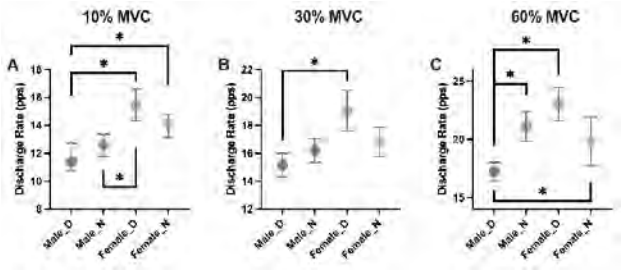

Figure 1. Comparison of discharge between dominant side and non-dominant side in females and males at 10%, 30%, and 60% MVC.

CONCLUSIONS

This study compared sex-specific MU firing behaviour and handedness in young adults using HD-SEMG. We found that males showed (1) significant asymmetry in discharge rate according to handedness at moderate and high force output and (2) a significantly lower discharge rate than females. Sex differences have been observed not only in motor function but also in disease severity, and clarification of neurophysiological sex differences will be an important finding in the rehabilitation medicine as well as in the sports science.

Kinematic analysis of controlling foot-ball acceleration at ball impact in Soccer Juggling

Kazuki Aoi[1], Takayuki Koike[1,2], and Masaaki Okauchi[1,2]
[1] Graduate school of Engineering, Oita University, Oita, Japan.
[2] Science and Technology, Oita University, Oita, Japan.

INTRODUCTION

Previous studies investigated hand juggling and paddle juggling report that the vertical acceleration of the hand and paddle at the moment of ball impact shows negative values [1]. In a study of soccer juggling, vertical acceleration of the foot also showed a negative value at the ball impact [2]. However, it is not clear how the lower limb joints control this juggling when negative acceleration occurred. The purpose of this study was to investigate how the lower limb joints move when the foot acceleration shows negative at the moment of impact by instep kicking during juggling by experienced soccer players.

METHODS

Ten male students with experience in soccer participated in this study. We asked them to perform soccer juggling by instep kicking until the ball dropped to the ground. Subjects' whole-body kinematics during juggling was captured by four high-speed cameras (For-A inc. and Ditect inc., 250 fps). The coordinates of markers attached to the body surface were transformed by the 3D DLT method, and then the joint centers were acquired. The joint angles of both left and right lower limbs were calculated by Euler angles, and then angular velocities were calculated. The acceleration of the center of gravity of the foot was calculated, and the change in acceleration before and after the ball impact was obtained. At least five consecutive cycles of kinematic variables were analyzed, with 50 frames before and after the ball impact as one cycle. In this abstract, we report the results obtained from 6 of the 10 subjects.

RESULTS AND DISCUSSION

In this study, those who showed negative foot acceleration were classified as the negative group, and those whose acceleration values were not constant were classified as the positive group. The negative group had a higher ball height than the positive group (Table 1). The angular velocity of the hip joint on the side of the juggling leg moved in the direction of extension toward impact in the negative group, while it moved in the direction of flexion in the positive group. In the knee joint angle (Figure 2), the negative group was near full extension at impact and then flexed, while the positive group was in extension at impact and then extended. In the stance leg, the hip joint was always flexed in both groups. The knee joint was slightly flexed before impact and then extended toward impact, in the negative group. The positive group showed no change in angle and angular velocity. In the ankle joint, the negative group was always in the neutral position between plantar flexion and dorsiflexion, while the positive group was always in the plantar flexed position.

The negative foot acceleration at ball impact was caused by full extension of the knee joint and plantar flexion of the ankle joint of the kicking foot at impact, which was thought to be due to the gastrocnemius muscle, a biarticular muscle that mainly acts in knee flexion and plantar flexion, being stretched by knee extension.

Table 1: Ball height during soccer ball juggling.

	Mean height (m)
Negative group	1.28 ± 0.16
Positive group	0.78 ± 0.09

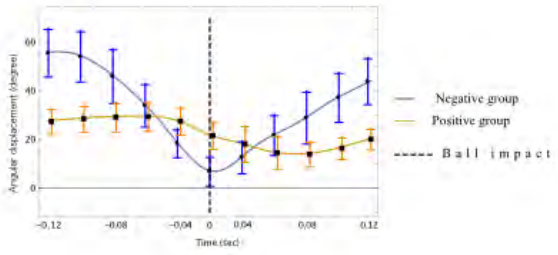

Figure 1 Angular displacement of the knee joint before and after ball impact.

CONCLUSIONS

The foot acceleration at the ball impact during soccer juggling was considered to be negative because of the coordinated movement of the joints on the leg side of the ball kicker, especially the multi-joint movement with full extension of the knee joint as the axis..

Email: inubashiri.nagisa.22n@st.kyoto-u.ac.jp

INTRODUCTION

Imitation of the instructor's posture is one of the most common training methods for whole-body motor learning, which needs goal-directed movements with multiple effectors, such as the upper and lower extremities [1]. Previous studies have separately investigated sensorimotor learning process with either upper or lower limbs [2,3]. However, it has not been elucidated how the central nervous system learns the goal-directed movements with both the upper and lower extremities in a novel sensorimotor environment. Therefore, the purpose of this study was to examine sensorimotor learning in goal-directed upper and lower extremity movements using a novel point-to-point movement task with multiple effectors.

METHODS

Nine healthy men (age: 23.2 ± 1.3 years; height: 173.6 ± 5.0 cm; body mass: 68.2 ± 10.0 kg) participated in this study conducted over two days. On both days, goal-directed point-to-point movements were performed with the endpoint of both the upper and lower extremities. Participants were asked to simultaneously move four cursors corresponding to the frontal positions of both hands and feet to four targets on the screen. The positions of the hands and feet in the frontal plane were captured by the optical motion capture system and were mapped to the cursors on the screen in real-time. On Day 1, the tasks were conducted in 300 trials where the direction of the cursor movements corresponded to the direction of the hands and feet movements (normal mapping). On Day 2, after 60 trials in normal mapping, learning trials were implemented in 300 trials where the cursor movements in mediolateral directions were reversed to the direction of the hands and feet movements (mirror-reversed mapping). Mirror-reversed mapping induced learning of goal-directed hands and feet movements in a novel visuomotor environment. After learning trials, participants performed 60 trials in normal mapping as washout trials. One of thirty targets (6 directions × 5 distances) was randomly presented around each hand and foot. We measured reaction time in each of hands and feet and the elapsed time from movement onset to the time when all cursors moved within the targets (movement time).

RESULTS AND DISCUSSION

The mean movement time for the last 10 learning trials was significantly shorter than the time at the beginning of the learning trials for all end-effectors (Figure 1; Dominant hand: DH, 1.96 ± 0.74 vs 1.02 ± 0.62 s; Non-dominant hand: NH, 1.19 ± 0.73 vs 1.03 ± 0.34 s; Dominant foot: DF, 2.33 ± 0.30 vs 1.16 ± 0.33 s, the significance level was 0.05). Decrease in the movement time indicates that goal-directed movements both with the upper and lower extremities were learned in a novel mirror-reversed visuomotor environment. In learning trials, the movement time of DH and NH was similar to each other, whereas longer movement time was observed in DF. In addition, the reaction time of DF was significantly shorter than that of DH and NH during last 10 learning trials (p = 0.002, p < 0.001, respectively). These results indicate that visuomotor learning of whole-body goal-directed movements progressed in different learning processes between the upper and lower extremities.

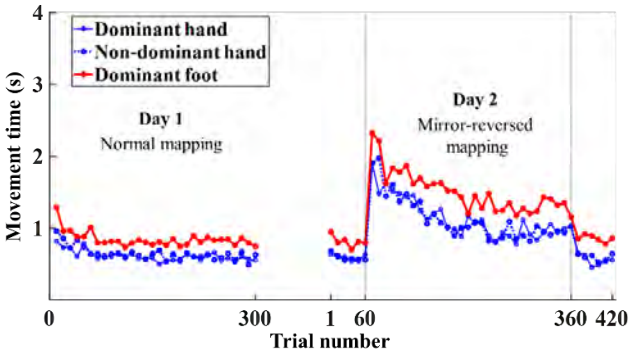

Figure 1 Movement time in each trial on Day 1 and Day 2. Movement time decreased over the course of the trials in mirror-reversed mapping. Each dot means average for all participants.

CONCLUSIONS

The goal-directed movements needed to control multiple end-effectors could be learned in a novel visuomotor environment. The process of learning would be similar in both hands but different between the upper and lower extremities.

Control of standing posture depends on adaptation of goal-directed lower extremity movements

Mai Moriyama[1], Motoki Kouzaki[1], and Shota Hagio[1]
[1] Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, Japan.
Email: moriyama.mai.45u@st.kyoto-u.ac.jp

INTRODUCTION

How do sophisticated soccer players acquire skillful manipulation of a ball with their feet depending on ever changing environments? It was revealed that goal-directed movements with lower limb can be adapted to a novel visuomotor environment using a virtual ball-kicking task [1]. Since ball-kicking movements require single-leg stance posture, the support leg would be controlled in parallel with the adaptation of the kicking-leg movements to a novel environment. Previous study examining arm-reaching during standing posture demonstrated that anticipatory postural adjustments (APAs) to maintain postural equilibrium was learned in the process of adaptation of arm movements to novel dynamic environments [2]. Therefore, we aimed to clarify the postural adjustment in the support leg depending on sensorimotor adaptation of goal-directed kicking movements.

METHODS

Nine participants performed ball-kicking movements with their right foot, while standing with their left foot on a force plate. They were instructed to look at a monitor in front of them, which displayed a cursor and a target. The cursor represented participant's right foot position on the horizontal plane, and participants shot the target virtually located at 60 cm ahead of the start position. The foot trajectories were captured in real time using motion capture system. The experimental task was constructed by the baseline, learning and washout trials (140, 210 and 130 trials, respectively). During the learning trials, the cursor trajectory was rotated to 12° clockwise relative to the actual trajectory without telling the participants. This perturbation enabled us to investigate how ball-kicking movements are adapted to the novel visuomotor environment. In each trial, kicking angle was measured as the angular difference between the target and the right-foot position when the right foot exceeded target distance. APAs were also quantified as the medio-lateral deviation of the COP position of the left foot 50 ms before onset time of right foot movement.

RESULTS AND DISCUSSION

In the learning trials, kicking angle gradually shifted leftward to compensate for the rightward error induced by the 12-degree rotational perturbation (Figure 1). After the perturbation was removed in the washout trials, it took several dozen trials for the kicking angle to return to the baseline levels, indicating that participants adapted their right foot movements to the novel visuomotor environment. APAs during the learning trials also shifted leftward as kicking angle changed leftward. Once the perturbation was removed, APAs returned to the baseline level. These results suggest that postural control was modified following the adaptation of the goal-directed movements with the kicking leg.

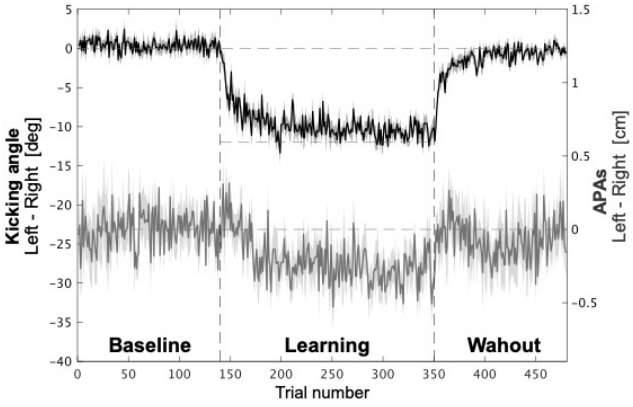

Figure 1 Time course of kicking angle and APAs.
This figure shows kicking angle (black line) and APAs (grey line) averaged across participants. A positive value of both data corresponds to the rightward deviation and vice versa. The shaded area represents the standard error of the mean. During the learning trials, the trajectories of the cursor were rotated to 12° clockwise relative to the actual trajectory. The middle horizontal line indicates the angle of 12 °, which is necessary to perfectly compensate for the perturbation.

CONCLUSIONS

We found that anticipatory postural response was modified in the process of adaptation of the focal goal-directed lower limb movements. The skilled manipulation of lower limb movements would be supported by the flexible adjustment of the postural control.

Effects of batting practice with pitch location feedback and peripheral vision on hitting variability in baseball

Masahiro Kokubu[1], Ryoichi Terahara[2], and Yudai Kawahara[2]
[1] Institute of Health and Sport Sciences, University of Tsukuba, Japan.
[2] Graduate School of Comprehensive Human Sciences, University of Tsukuba, Japan.

INTRODUCTION

In baseball batting, tracking fastballs with eyes and perceiving accurate pitch location are considered important. Visual feedback regarding bat-ball contact contributes to hitting accuracy [1]. However, the effects of concurrent feedback about the vertical and horizontal pitch locations on motor learning such as hitting velocity, accuracy, and variability have not been examined.

In addition, it is considered difficult for batters to keep their gaze on the ball until the moment of impact [2], so hitting practice using the peripheral visual field would be considered important.

Therefore, the purpose of the present study was to investigate the effects of batting practice with the feedback of pitch location and with using peripheral vision on hitting variability and velocity.

METHODS

Fifteen university baseball players (20.6±1.6 years; Mean±SD) participated in the present study. They were assigned into three groups: a practice group with pitch location feedback (FB group; n=5), a practice group with peripheral visual field (PV group; n=5), and a control group (CON group; n=5).

In the pre-test, the participants were asked to hit 15 straight pitches which were set at 120 km/h by a pitching machine. The strike zone was divided into five sections, in the high/low and inside/outside directions respectively. After each trial, they were asked to verbally answer the pitch location from the five sections for both directions. The contact position of the ball relative to the bat at impact was measured using a high-speed digital camera (480Hz), and the standard deviation of the bat-ball contact position (i.e., hitting variability) was calculated. The velocity of the ball at impact was also measured by a tracking system (Rapsodo®).

In the FB group, participants executed batting practice with straight pitches which were set at 120 km/h by the pitching machine 30 times per day. They received feedback on the pitch location in both directions immediately after each trial. Practice sessions consisted of three sessions a week for three weeks. In the PV group, participants executed front toss batting practice 40 times per day while directing their gaze at a certain point other than the ball. Practice sessions consisted of three sessions a week for two weeks. In the CON group, participants executed regular practice of the team as usual during this period. In the post-test, all participants were asked to execute the same measurement as in the pre-test.

RESULTS AND DISCUSSION

For the hitting variability, a two-way analysis of variance showed a significant interaction between group and time ($F(2,12)=4.05$, $p=.045$, $\eta_p^2=.40$). Subsequent analysis showed that the PV group showed significantly less standard deviation of the contact position in the post-test than in the pre-test ($p<.05$). There was also a tendency of less variability in the post-test compared to the pre-test in the FB group ($p<.10$). In the control group, there was no difference between the pre- and post-tests. These results suggest that practice using peripheral vision has an effect of less variability of the contact position.

In the FB group, the difference between the perceived and actual pitching position became smaller in the post-test than in the pre-test. Also, hitting velocity was larger in the post-test than in the post-test. These results suggest that there is a relationship between the ability to perceive the pitch location and the increase in batting average velocity.

CONCLUSION

Batting practice with the feedback of pitch location and with using peripheral vision would contribute to reducing hitting variability.

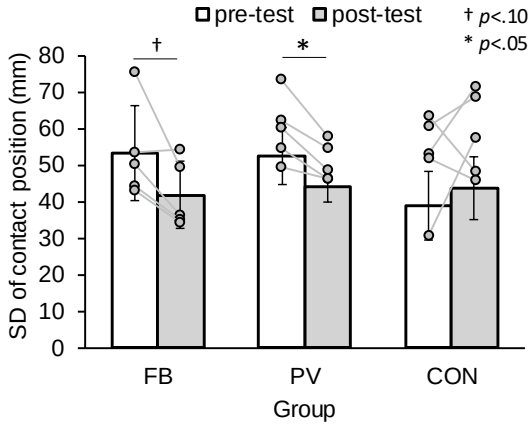

Figure 1 Hitting variability of each group in the pre- and post-test.

Direct measurements of tendon length changes during stretch-shortening cycles in rat

Atsuki Fukutani[1], Satoru Hashizume[1] and Tadao Isaka[1]
[1] Faculty of Sport and Health Science, Ritsumeikan University, Kusatsu, Japan.
Email: atsukifukutani@gmail.com

INTRODUCTION

The muscle force attained during concentric contractions is augmented by a preceding eccentric contraction. This phenomenon is called the stretch-shortening cycle (SSC). Although tendon elongation is considered the primary mechanism, we recently found that the magnitude of the SSC effect was not different even after removing the Achilles tendon [1]. To resolve these discrepant results, direct measurement of changes in Achille tendon length is required. Therefore, this study aimed to elucidate the influence of tendon elongation on the SSC effect by directly measuring the changes in Achilles tendon length.

METHODS

The rat soleus muscle (N = 9) was used in this experiment. The soleus was exposed and dissected from its surrounding connective tissues, and its blood and nerve supplies were left intact. To place the marker that can visualize the tenon length changes, a knot was placed on the aponeurosis (Figure 1, panel A). In the first experiment, isometric contraction with the maximal intensity was performed at the plateau region (optimal length), ascending limb (-2 mm from the optimal length), and descending limb (2 mm from the optimal length). During these contractions, the location of the silk knot was visualized using a stereomicroscope. In this experimental setting, the field of view was approximately 6 mm, and the number of pixels was 1,824. Thus, the pixel resolution was approximately 3.3 μm. In the second experiment, SSC and pure shortening trials were conducted. For the SSC trial, the isometric contraction was evoked at -2 mm. The muscle-tendon complex was then actively stretched to 2 mm in 1 s. Immediately after the end of the stretch, the muscle-tendon complex was actively shortened to -2 mm in 1 s. For the pure shortening trial, the isometric contraction was evoked at 2 mm, and then, a muscle-tendon complex was actively shortened to -2 mm in 1 s. During these contractions, the location of the silk knot was visualized using a video camera. In this experimental setting, the field of view was approximately 60 mm, and the number of pixels was 4,096. Thus, the pixel resolution was approximately 15 μm.

RESULTS AND DISCUSSION

For the first experiment, the magnitude of tendon elongation was 0.21 ± 0.17 mm for the optimal length, 0.14 ± 0.12 mm for the 2 mm, and 0.29 ± 0.25 mm for the -2 mm (panel B) ($p = 0.05$). Interestingly, the magnitude of tendon elongation was the largest in the smallest force condition (i.e., ascending limb condition). This result suggests that the observed tendon elongation was at least in part derived from eliminating the slack of the muscle-tendon complex. For the second experiment, the magnitude of tendon shortening attained during the shortening phase was not different significantly between SSC (0.20 ± 0.14 mm) and pure shortening trials (0.17 ± 0.09 mm) ($p = 0.322$) (Figure 1, panel C). This result indicates that the larger force attained in the SSC than in the pure shortening condition is difficult to be explained by the elastic energy stored in tendons or muscle-tendon interaction.

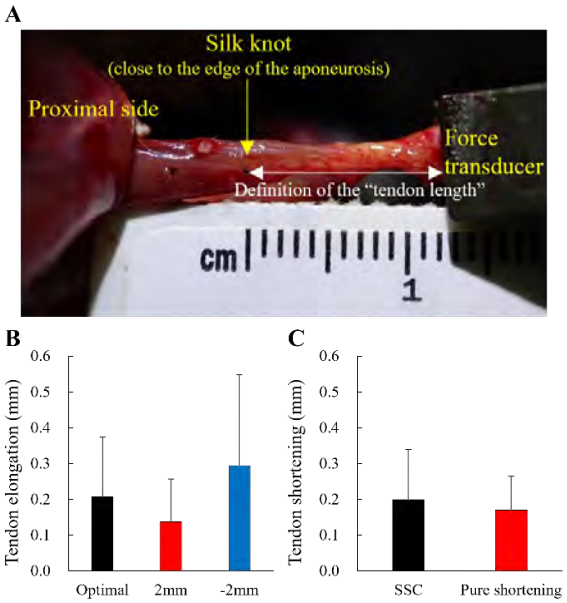

Figure 1 Experimental setting (panel A), the magnitude of tendon elongation attained during isometric contractions at different muscle lengths (panel B), and the magnitude of tendon shortening attained during the shortening phase in the SSC or pure shortening trials (panel C).

CONCLUSIONS

In conclusion, the contribution of Achilles tendon elongation to the SSC effect was negligible, at least in the case of the rat soleus and Achilles tendon. This is likely due to the small amount of tendon length changes attained during SSCs (e.g., 1.7% of the tendon length in the SSC trials). Based on our findings, tendon elongation does not necessarily explain the SSC effect, and factors other than tendon elongation can contribute to the SSC effect.

Acute effects of dynamic versus static stretching in muscle architecture in adolescents

Zhiyu Tao[1,2], Dahua Ren[2], Tianchen Huang[2] and Mianfang Ruan [2]
[1] Graduate School of Design, Kyushu University, Fukuoka, Japan.
[2] Department of Physical Education and Health, Wenzhou University, Wenzhou, China.

INTRODUCTION

Static stretching (SS) and dynamic stretching (DS) exercises are typically recommended to players of amateur and professional levels before performing any sport activities [1]. However, the number of studies on adolescents in this research field is still lacking. There is no research has used ultrasound to do the test for the lower limb stretching in adolescents now.

The purpose of this study is to summarize the acute changes in muscle structure such as the muscle fascicle length of the biceps femoris long head (BFlh) after lower limb stretching in adolescents.

METHODS

The subjects of the experiment were 10 primary school students. The sonographer used ultrasound to measure the middle region of the long head of the biceps femoris before and after DS and SS. In order to avoid interference between the two stretching methods, the subjects be separated by at least 72 hours between two tests. Since the entire muscle fascicle was not visible in the field of view of the probe, its length was estimated via the following validated equation from Blazevich et al. [2]and Kellis et al. [3]:

$FL=\sin(AA+90^{\circ})\times MT/\sin(180^{\circ}-(AA+180^{\circ}-PA))$.

AA = aponeurotic angle (the angle between the line markedas the aponeurosis and an intersecting horizontal line across the captured image); FL = muscle fascicle length; MT = muscle thickness; PA = pinnate angle (Figure 1).

RESULTS AND DISCUSSION

The changes in muscle architecture from both stretching conditions were compared (Table 1). Both FL and PA had significant interaction in the time main effect and intervention* time main effect ($p<0.01$), while MT in the above two main effects were not significantly interaction. The above results indicate that both SS and DS significantly altered PA and FL, but did not significantly altered the MT. Although there was no significant interaction between MT, PA and FL in intervention main effect ($p>0.05$), DS increased FL more significantly and reduced PA more significantly than SS.

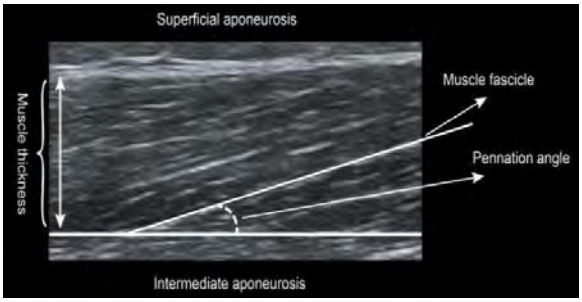

Figure 1 A two-dimensional ultrasound image of the BFlh.

CONCLUSIONS

Both dynamic stretching and static stretching can significantly change the muscle architecture of adolescents' BFlh, while static stretching has less effect on the muscle architecture than dynamic stretching.

INTRODUCTION

The quadriceps muscles lose torque generating capacity when activated simultaneously [1]. In this study, we tested if this torque loss is unique to the quadriceps muscles or if it is a common phenomenon amongst agonistic muscle groups. To achieve this, experiments were performed in New Zealand white rabbits. The torque generating capacity of the plantarflexor muscles (Plantaris (PL), medial/lateral Gastrocnemius (MG/LG), and Soleus) were measured during simultaneous and individual activation of the muscles via direct nerve stimulation of the branches of the tibial nerve. The data presented herein represents preliminary findings of an ongoing investigation.

METHODS

Plantarflexor muscles of 3 skeletally mature, New Zealand white rabbits were analysed. Maximum isometric torque was measured at 90, 100, and 110 degrees of plantarflexion. The nerve branches of LG, MG, and PL were isolated and individually activated via nerve cuffs. The soleus was activated via stimulation of the LG nerve. One maximal activation (100 Hz) was performed at each ankle angle. Peak torque was determined for each muscle individually and summed to determine the difference in torque between individual muscle activation and activation of all muscles simultaneously. Simultaneous activation of all nerve branches was performed using the same joint angles and activation levels as was done foe the individual muscle activations. Mean and standard deviation for each angle and condition were calculated, and differences between simultaneous vs. summed activations were quantified.

RESULTS AND DISCUSSION

Simultaneous activation of the plantarflexor muscles resulted in reduced torque generating capacity compared to adding the torques produced during individual activation. Across all joint angles, a mean difference of -0.31 ± 0.14 Nm (26%) was observed between the summed torque for individual muscle activation compared to the simultaneous activation of the plantarflexor muscles. The largest difference was observed at 90° (37%; -0.60 Nm). The reduced torque generating capacity observed during simultaneous activation of agonistic muscles has been attributed to lateral forces applied to the muscles by each other resulting in lateral compression of individual muscles. Previous work in isolated muscles has demonstrated that controlled lateral compression of the rabbit medial gastrocnemius, impaired the force generating capacity of the muscle in a dose-dependent manner; more lateral force resulted in increased loss of force capacity [2].

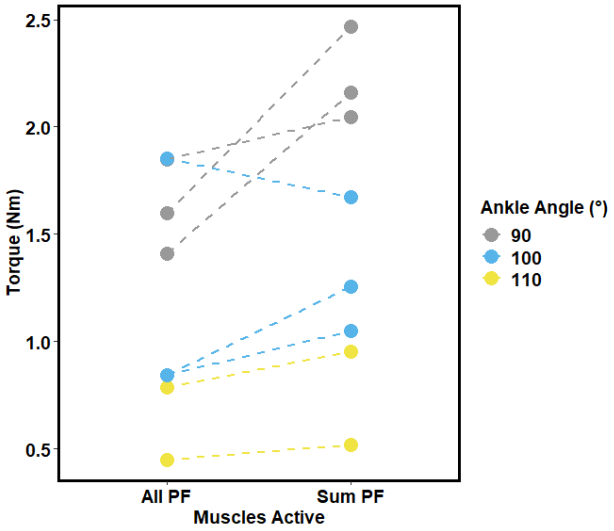

Figure 1. Plantarflexor torque produced during simultaneous activation of plantarflexor muscles (All PF) vs. summed torque of individual activation of plantarflexor muscles (Sum PF).

CONCLUSIONS

Plantarflexor torque generating capacity was impaired during simultaneous activation of the plantarflexor muscles compared to the summed torque produced during individual activation of the plantarflexor muscles. These preliminary results suggest that impaired torque generating capacity produced during simultaneous activation of agonistic muscles may be a common phenomenon of agonistic muscle groups.

INTRODUCTION

Since human soft tissues (e.g., facial skin, breasts) exhibit deformability to the force of gravity [1,2], gravity may also be a factor in deforming muscles. As muscle force-generating capacity is inherently dependent on muscle geometry, such as the force-length relationships, the orientation of gravitational force may also have an impact on muscle force. Cadaveric samples show that when laying in the prone position, removal of the skin results in a flattening of muscle and a reduction in muscle stiffness [3]. This suggests that the skin mechanical properties may play a significant role in the deformation of the muscle due to gravity and thereby in the force-generating capacity. Given that skin elasticity declines with age [4], alterations of muscle geometry caused by a decline in skin elasticity may contribute to a decrease in the force generation capacity seen with age. The current study aimed to clarify the systematic relationship between age, skin elasticity, the orientation of gravity force, muscle shape, and muscle force-generating capacity.

METHODS

Fifteen young adults (Young; 23.5 ± 1.5 yrs) and 15 old adults (Old; 64.0 ± 3.5 yrs) participated in this study. To explore the effect of muscle orientation with respect to the direction of gravity on the muscle geometry and force-generating capacity of the right medial gastrocnemius (MG) muscle, participants laid in the supine and prone positions during testing (Fig. 1). In both positions, the angle of the right ankle was fixed at 15 degrees of plantarflexion, and hip and knee joints were fully extended during measurements. The bare sole of the whole foot was attached to a flat foot pedal connected to a force transducer. Single electrical stimulation (with supramaximal intensity to the tibial nerve) was used to evoke plantar flexor torques. Then, peak torque (PT) was calculated to assess the muscle force-generating capacity. Ultrasound shear-wave elastography was used to assess skin mechanical properties (shear modulus) at the centre of MG. To measure muscle geometry, three-dimensional (3D) ultrasound recordings were utilized [5]. After reconstruction and segmentation of MG 3D geometry, MG anteroposterior (AP) length and transverse (ML) width were calculated in a 2D plane placed at 30% of the lower leg length (Fig. 1). ML/AP ratio was calculated to evaluate the representative MG 3D geometry.

RESULTS AND DISCUSSION

PT was smaller and ML/AP ratio was greater ($P < 0.05$) in the prone position compared to the supine position for both Young and Old groups. The position-related changes in PT and ML/AP ratio were greater in the Old group than the Young group ($P < 0.05$). The skin shear modulus (averaged across positions) of the Old group was smaller than that of the Young group ($P < 0.05$). There were correlations between the relative changes in ML/AP and PT (r = -0.78), between skin shear modulus and relative change in ML/AP (r = -0.69), and between skin shear modulus and relative changes in PT (r = 0.65). These results suggest that lower skin shear modulus with age promotes a flattening of the muscle shape in the prone position, which is accompanied by a greater reduction in muscle force-generating capacity.

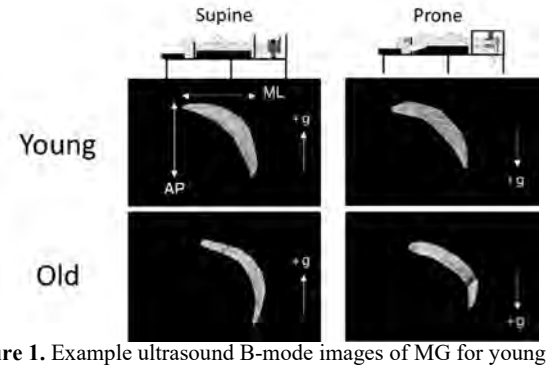

Figure 1. Example ultrasound B-mode images of MG for young (upper) and old adults (bottom) obtained by 3D ultrasound technique in the supine (left) and prone (right) positions.

CONCLUSIONS

In summary, age-related changes in skin mechanical properties affect gravity-dependent muscle shape and subsequently muscle force-generating capacity in MG.

INTRODUCTION

The tear occurring in supraspinatus tendon is more commonly than in other rotator cuff. After the tendon is torn, the altered musculotendinous architecture of supraspinatus can be found and may be associated with its dysfunctions. During the repairing surgery, tension was applied to re-attach the ends of torn tendon. Muscle fiber was then lengthened beyond the optimal length, which may compromise the contractile capacity[1]. In addition, supraspinatus stiffness which affects the extensibility of the musculotendon is one of the complications after tendon repair[2]. However, the changes in musculotendinous architecture of supraspinatus during shoulder movement are unknown in patients with supraspinatus tendon tears. Hence, this study aimed to evaluate the time-course changes and the difference between various shoulder postures in musculotendinous architecture of supraspinatus and shoulder strength in patients with full-thickness tear before and after tendon repairing.

METHODS

Six patients with unilateral full-thickness supraspinatus tendon tear were recruited for the evaluations before and three months after arthroscopic repair. The musculotendinous architecture of supraspinatus, including the fiber bundle length (FBL) and pennation angle (PA), was evaluated by sonography (ArtUs EXT-1H, Telemed, Italy) with a linear transducer (7.5- 15.0 MHz, Telemed, Italy) at the shoulder postures of resting (RS), active holding at 30° scaption (AH), and passively stretched (PS). The maximal strength of shoulder internal and external rotators, and supraspinatus muscles were evaluated by a hand-held dynamometer (MicroFET2, HOGGAN, USA). The Friedman's test with Wilcoxon signed-rank test as a post hoc test was used to compare the musculotendinous architecture between different postures, timings, and sides.

RESULTS

The FBL of supraspinatus on the affected side was shorter than that on the intact side across RS, AH, and PS postures either before or after repair. FBL in RS after repair (3.8±0.5 cm) was significantly increased with comparing to that before repair (3.7±0.6 cm). During PS, the FBL was also increased after repair (before repair: 3.8±0.5 cm, after repair: 3.9±0.5 cm). No significant difference in PA of supraspinatus was noticed between bilateral sides either before or after repair. However, PA was decreased on affected side after repair in RS (before: 12.3±1.5°, after: 11.2±1.2°) and AH (before: 13.2±1.5°, after: 12.4±1.4°). The shoulder muscle strength on the intact side was significantly larger than the affected side either before or after repair. The strength of internal rotator was increased significantly after repair (before: 5.2±2.7 kg, after: 6.7±4.1 kg), but no significant difference of strength after repair was found in external rotator and supraspinatus muscle.

CONCLUSIONS

The early or excessive mobilization after tendon repair may be helpful to avoid stiffness but may induce tendon re-tear. However, repaired tendons may receive over-stress or over-strain during shoulder movements and may thus increase the risk of re-tear. Therefore, the changes in musculotendinous architecture between contracting and stretched supraspinatus should be evaluated for the reference of the rehabilitation program and for the healing progress. Further study may be required to know the effects of rehabilitation on musculotendinous architecture of supraspinatus.

INTRODUCTION

Interaction between muscle and elastic tendon enables us to perform flexible functions during locomotion; energy conservation, power amplification, and power attenuation [1]. Especially tendon's capability of storing and reusing elastic energy provides a mechanical advantage during the stretch-shortening cycle [2,3]. Even though the 50s is the population that needs to prepare for the elderly life, few studies on tendon mechanical and functional properties have been conducted, and the information is limited. Therefore, this study investigated the elastic properties of the Achilles tendon (AT) in their 50s. In addition, the association between the elastic properties of the AT and the jumping ability was studied.

METHODS

Healthy adult males in their 50s (n = 30; height 171.5 ± 5.5 cm, weight: 73.4 ± 10.6 kg, age: 54.5 ± 2.6yrs.) and in their 20s (n = 10; height: 176.5 ± 5.7 cm, weight: 79.3 ± 9.1 kg, age: 27.2 ± 1.1 yrs.) participated in this study. While subjects performed maximum plantar flexion (PF) on a custom-built dynamometer, maximum PF torque was measured, and the elongation of AT was measured using B-mode real-time ultrasound imaging. The countermovement (CMJ) and squat jump (SJ) were performed to measure their jumping and pre-stretch augmentation ability.

RESULTS AND DISCUSSION

As shown in Figure 1, the 50s (62.9 ± 12.1 mm^2) showed a larger Achilles tendon area than the 20s (51.0 ± 8.8 mm^2) ($p < .05$). In addition, Achilles tendon maximal elongation and stiffness were smaller in the 50s (15.5 ± 4.5 mm, 32.9 ± 16.0 Nmm^{-1}) than in the 20s (21.6 ± 3.8 mm, 46.1 ± 20.3 Nmm^{-1}) ($p < .05$). Hysteresis was higher in the 50s (20.5 ± 8.8%) than in the 20s (15.2 ± 6.3%) ($p < .05$). Both CMJ and SJ height were higher in 20s (43.0 ± 9.9 cm and 34.9 ± 8.3 cm) than in 50s (26.6 ± 5.4 cm and 23.5 ± 4.7 cm) (Figure 2) ($p < .05$). Achilles tendon properties were statistically significantly associated with CMJ and SJ performance (Table 1)

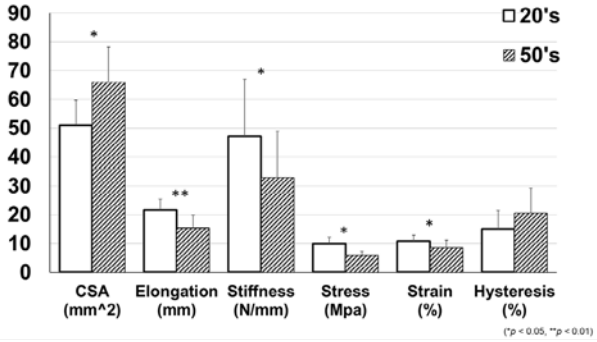

Figure 1 Comparison of the Achilles tendon properties between 50s and 20s. (*, $p < .05$; **, $p < .001$)

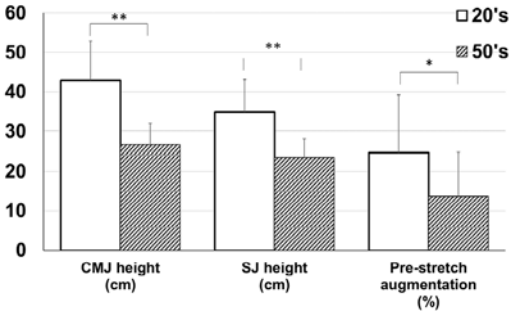

Figure 2 Jump performance and pre-stretch augmentation in the 50s and 20s. (*, $p < .05$; **, $p < .001$)

CONCLUSIONS

In conclusion, the changes in Achilles tendon elastic properties are prominent and significant from the 50s and affect jump performance. These results provide important basic information on aging, rehabilitation, and training.

INTRODUCTION

The biceps femoris long head (BFlh) has a complex fascicle architecture and is prone to strain injuries. Most of these injuries occur around the muscle-tendon junction, particularly in the proximal region. Battarmann et al. (1) associated the complexity of the proximal region of BFlh, i.e. a three-dimensional (3D) twist towards the origin, with the vulnerability to injury. However, information regarding the 3D musculo-tendinous geometry of BFlh is limited (2). Hence, the aim of this study is to identify the complexity of BFlh intramuscular aponeurosis by assessing its geometry with 3D ultrasonography.

METHODS

Series cross-sectional (CS) ultrasonograms of BFlh were taken from eleven healthy adults (mean ± SD = 22 ±2.5 years old) lying prone with the knee fully extended, while capturing the probe's 3D orientation (3). 3D volume of BFlh was reconstructed for each subject, and the intramuscular aponeurosis was identified in the CS view as a relatively flat, continuous, hyper-echogenic line. The outline of aponeurosis echo was traced along the length of BFlh to reconstruct its 3D geometry (Fig. 1). The angle of the aponeurosis relative to the global coordinate system in the CS plane was calculated using MATLAB along the aponeurosis length. The average angle (orientation) at different regions over the length i.e., 0%-20% (proximal), 40%-60% (middle) and 80%-100% (distal), were expressed relative to the angle at 50% of the aponeurosis length, with positive changes toward the lateral aspect (counter-clockwise in the proximal-distal direction) and negative toward the medial (clockwise).

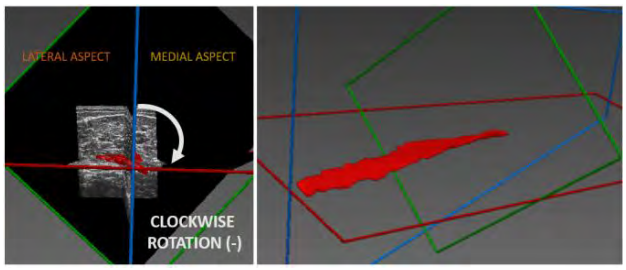

Figure 1: Aponeurosis 3D geometry reconstruction and medial and lateral twist representation.

RESULTS AND DISCUSSION

Reconstruction was successful in 7 out of 11 subjects (4 cases were discarded due to poor visualization of the aponeurosis). The average orientation of the aponeurosis differed between regions with different variations: proximal, +20º (95% CI [+5º, +36º]), middle, +1º (95% CI [-3º, +2º]), and distal, -4º (95% CI [-19º, +11º]). Considerable inter-individual differences were found (Table 1). In three subjects (no.3, no.5 no.7), the aponeurosis was systematically twisted medially (clockwise) from proximo-distally regions while in the other subjects (particularly no. 1), the aponeurosis twisted medial in the proximal-half and then from middle to distal change to lateral direction (counter-clockwise) or not at all (no.2, no. 4 and no.6).

Table 1: Average orientation of aponeurosis for three regions: proximal (0-20%) middle (40-60%), and distal (80-100%) expressed relative to the angle at 50% of the aponeurosis length.

Subject	Angle 0-20% (mean±SD) (º)	Angle 40-60% (mean±SD) (º)	Angle 80-100% (mean±SD) (º)
1	13±5	1±10	24±6
2	17±10	3±6	3±5
3	30±6	1±5	-9±4
4	-6±8	-3±4	-3±13
5	46±22	-2±3	-21±5
6	14±3	-4±5	0±5
7	27±10	-1±2	-23±3

CONCLUSIONS

The 3D orientation of BFlh intramuscular aponeurosis varies along its length to a greater extent in the proximal and distal regions. Significant inter-individual variations were observed. The twisted nature as well as inter-individual variation of the aponeurosis geometry may affect how mechanical strain and stress are distributed within and between muscle fibers, potentially affecting the susceptibility to strain injury.

INTRODUCTION

Static stretching (SS) intervention programs are generally performed in sports and rehabilitation settings. Indeed, previous studies showed that SS intervention programs could increase the range of motion (ROM) and decrease muscle stiffness [1, 2]. Interestingly, the relationship between baseline flexibility and change after a single bout of SS intervention has been examined [3]. They showed that baseline flexibility had not been related to increased ROM or decreased muscle stiffness after a single bout of stretching. Still, the relationship between change after SS intervention programs and baseline flexibility is unknown. The relationship of change in SS intervention programs with baseline flexibility is expected to clarify the future adaptation of SS intervention programs. Thus, we aimed to investigate the relationship between baseline flexibility, i.e., ROM and muscle stiffness, and changes after SS intervention program.

METHODS

In this study, we reanalyze the results of our previous studies [1, 2]. We employed data from 44 healthy young males (age: 21.1±1.1 years, body mass: 62.3±7.1 kg, height: 170.6±7.1cm). Also, we adopted the dorsiflexion (DF) ROM and muscle stiffness before (baseline) and after 4 weeks SS intervention program. In these previous studies [1, 2], we measured the DF ROM and muscle stiffness during the passive stretching test via dynamometer and ultrasonography before and after 4 weeks SS intervention program. We calculated partial correlations between DF ROM or muscle stiffness at baseline and changes or rate of change (%) after SS intervention program adjusted for total stretching duration. A p-value of <0.05 indicated statistical significance.

RESULTS AND DISCUSSION

Our results showed that there was no significant association between DF ROM at baseline and changes in DF ROM (r=0.006, p=0.971, Figure 1-A), but a significant negative association between DF ROM at baseline and rate of change (%) in DF ROM after SS intervention program (r=-0.383, p=0.011, Figure 1-B). In addition, there was a significant negative association between muscle stiffness at baseline and changes in muscle stiffness after SS intervention program (r=-0.736, p<0.001, Figure 1-C). But there was no significant association between muscle stiffness at baseline and the rate of change (%) in muscle stiffness after SS intervention program (r=-0.298, p=0.053, Figure 1-D).

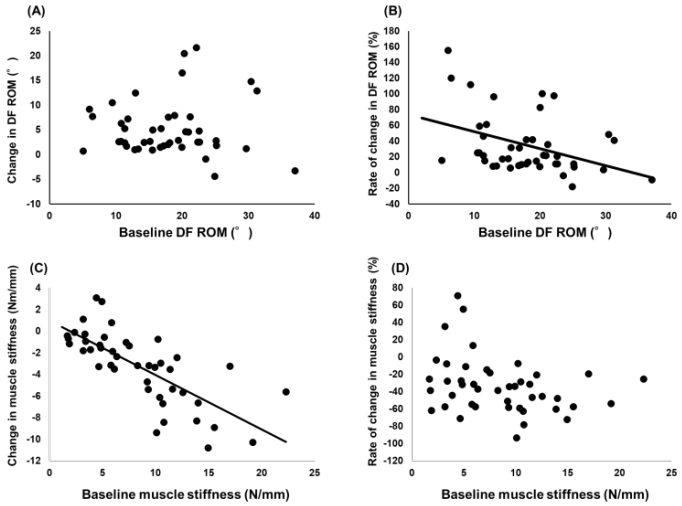

Figure 1. Association between dorsiflexion (DF) range of motion (ROM) or muscle stiffness at baseline and changes (A and C)or rate of change (%, B and D) after SS intervention program

The results of this study showed that The smaller in DF ROM before the SS intervention program, the greater increase in DF ROM after the SS intervention program. Also, the stiffer muscle stiffness before the SS intervention program, the greater decrease in muscle stiffness after the SS intervention program. Thus, our results suggested that the participants with lower flexibility (i.e., small ROM or stiff muscle stiffness) showed greater improvement in flexibility after the SS intervention program.

CONCLUSIONS

It is possible that the young male with lower flexibility before the SS intervention program had greater improvement in flexibility after the SS intervention program.

INTRODUCTION

External forces from our environment impose transverse loads on our muscles. Previous studies [e.g., 1] have demonstrated that transverse loads result in a decrease in the longitudinal muscle force. Changes in muscle architecture at rest and during contraction are suggested to contribute to the declined force. A most familiar external force for humans is gravity, which can play a role in pulling down soft tissues in humans [2]. Therefore, it is possible that the force-generating capacity of muscle is dependent on the orientation of the muscle relative to gravity, which is accompanied by the deformation of the muscle. The purpose of this study was to determine whether force-generating capacity and muscle geometry are influenced by the orientation of the muscle with respect to gravity. In this study, we especially focused on the standing posture as humans are primarily active in this posture.

METHODS

Force-generating capacity and muscle geometry were examined for the plantarflexor muscles in 16 healthy young adult males (21.5 ± 0.8 yrs, 5 female). Participants were positioned in a supine (SUPINE) and standing (STAND) posture, with the knee and hip joints fixed at ~180° and were instructed to avoid voluntary muscle activation throughout the experiment. In the standing position, special care was taken to ensure that participants did not impose their body weight onto their foot sole to prevent muscle activities in the plantarflexor muscles. The right ankle joint was set to -15° (DF15), 0° (N), and +15° (PF15) to explore the effect of length-dependent muscle stiffness.

The geometry of the right calf muscle at rest was measured using ultrasound B-mode images to determine the fascicle length of the medial gastrocnemius muscle (MG) at approximately 30% of the lower leg length. Doublet stimulus with a 20ms interstimulus interval at supramaximal intensity were delivered to the tibial nerve using a constant-current electrical stimulator to evoke maximal doublet-twitch torque from the plantarflexor muscles at each ankle position. Peak torque (PT) and rate of torque development (RTD) were subsequently determined.

The data were compared using a two-way ANOVA (2 positions × 3 ankle joint angles) with repeated measures and the rate of changes in these variables from SUPINE to STAND was also compared using a one-way ANOVA with repeated measures (3 ankle joint angles). When appreciate, a Bonferroni test was conducted for a post-hoc comparisons.

RESULTS AND DISCUSSION

PT and RTD were lower in STAND compared with SUPINE at PF15 and N ($P < 0.05$). The rate of these changes when posture was changed from SUPINE to STAND were most pronounced for PF15 (-25.9% and -23.5%) when compared to N (-16.0% and -13.3%) and DF15 (-1.3% and -0.5%). No difference in PT and RTD was observed in DF15 ($P > 0.05$).

The fascicle length was longer in SUPINE than STAND when collapsed across ankle joint angle ($P < 0.05$) with the effect of limb orientation on fascicle length being greater in PF15 (-14.8%) than DF15 (-8.2%). These results suggest that the standing posture causes a smaller peak torque, rate of torque development, and fascicle length than supine posture, especially at ankle joint angle of plantarflexed position.

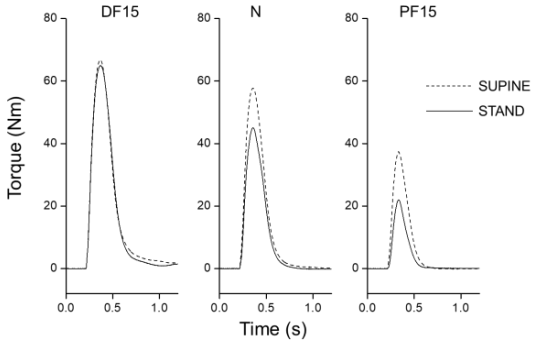

Figure 1 Representative torque signals evoked by doublet stimulation in supine (dot, SUPINE) and standing (solid, STAND) postures at DF15 (left), N (middle), and PF15 (right).

CONCLUSIONS

This study demonstrated that the orientation of muscle with respect to gravity influence both force-generating capacity and resting muscle geometry, with the largest effect seen at a plantarflexed ankle joint angle.

A BIOMECHANICAL 3D ANALYSIS OF A LAB RECORDED LATERAL ANKLE SPRAIN DURING A HANDBALL SPECIFIC FAKE-AND-CUT MANEUVER

Timo Bagehorn[1*], Kevin Bill[2], Patrick Mai[2], Tron Krosshaug[3], Uwe Kersting[2]

INTRODUCTION

Lateral ankle sprains are highly prevalent sport injuries which occur frequently in indoor and court sports (Gribble et al., 2016). Biomechanical measurements of accidental sprain injuries are rare but make important contributions to a more detailed understanding of the injury mechanism (Lysdal et al., 2022). In this case study, we present the kinematics and kinetics of a lateral ankle sprain that occurred in a force plate-equipped motion capture laboratory while studying handball-specific fake-and-cut maneuvers.

METHODS

The athlete affected was a female junior elite handball player (182 cm, 63 kg, 17 years, first Norwegian junior division). She could not continue with the measurements and could not participate in any sport for the next two days. She described a radiating calf pain and tenderness the week after the injury. She did not seek any further medical attention. The task was to perform a handball-specific fake-and-cut movement in front of a passive defender after accelerating for 6 meters and receiving a pass. Six trials performed before the injury served as reference for the analysis. The injury was recorded with a three-dimensional infrared motion capture system (82 whole-body marker set, 23 cameras, 200Hz, Qualisys AB, Sweden) and two force plates at 1000 Hz (AMTI, USA). Peak joint kinematics, kinetics, step length, and foot distance to COM were calculated.

RESULTS AND DISCUSSION

Important kinematics and kinetics are highlighted in Table 1. The injury showed excessive plantar flexion, inversion, and internal rotation of the ankle. Ankle inversion and internal rotation were higher at initial ground contact (IC), while plantarflexion was reduced. Furthermore, the injury is characterized by ankle internal rotation and inversion moments four to five times higher than the reference trials. Step length and foot distance to the COM were considerably smaller compared to the reference trials, indicating that the approach strategy was different in the preparatory phase with the foot airborne. Furthermore, a slip-catch shoe-surface interaction was observed after initial contact. This indicates an unexpected increase in shoe traction, possibly caused by the prevalent joint misalignment.

CONCLUSIONS

Preparatory maladjustment is the main contributor for injury in this particular case study.

Table 1: Peak ankle joint angles, foot kinematics, and moments.

	Injury	Time	Reference	Time
KINEMATICS	[°]	[ms]	[°]	[ms]
Plantarflexion	40.7	190	25.6 ± 1.3°	22 ± 10

INTRODUCTION

Plantar intrinsic foot muscles (PIFMs) consist of 10 muscles unilaterally and their morphological profiles differ individually [1, 2]. Theoretically, morphological profiles of a muscle determine its contractile properties: physiological cross-sectional area (PCSA) and muscle fiber length (FL) reflect maximal force production and shortening velocity, respectively. Thus, characterizing individual PIFMs from these morphological profiles may provide new insights into understanding the function of PIFMs. This study aimed to examine how individual PIFMs can be classified by the K-means cluster analysis based on the morphological parameters (PCSA and FL), which reflect the contractile properties.

METHODS

In 26 healthy young adult men, muscle volume and muscle length for each of seven PIFMs (abductor digiti minimi, ABDM; abductor hallucis, ABH; adductor hallucis oblique head, ADDH-OH; ADDH transverse head, ADDH-TH; flexor digitorum brevis, FDB; flexor hallucis brevis, FHB; quadratus plantae, QP) were measured using magnetic resonance imaging. The other three muscles (i.e., lumbricals, flexor digiti minimi, and plantar interossei) were excluded from the analysis due to their small size. PCSA and FL of each PIFM were estimated by using the measured data (muscle volume/length) and those previously reported in the cadaveric studies about pennation angle [1], FL to muscle length ratio [2], and FL [2]. After individually standardizing PCSA and FL by Z-score, K-means clustering was performed on 182 data samples (26 participants × 7 muscles) with PCSA and FL as attributes. The optimal number of clusters for K-means clustering was determined as four by the elbow method.

RESULTS AND DISCUSSION

Morphological profiles of each PIFM and the number of components classified into each cluster by the K-means clustering are summarized in Table 1. The relationship between PCSA and FL (standardized by Z-score) of individual PIFMs is shown in Figure 1. Cluster 1 consisted of all ADDH-OH and over half of FHB, indicating large PCSA and short FL (high force production at slow shortening velocity). Cluster 2 included all ABH and FDB, most of ABDM, and below half of FHB, indicating large PCSA and moderate FL (high force production at moderate shortening velocity). Cluster 3 included all QP with moderate PCSA and long FL (moderate force production at high shortening velocity). Cluster 4 consisted of all ADDH-TH and few ABDM, indicating small PCSA and moderate FL (small force production at moderate shortening velocity).

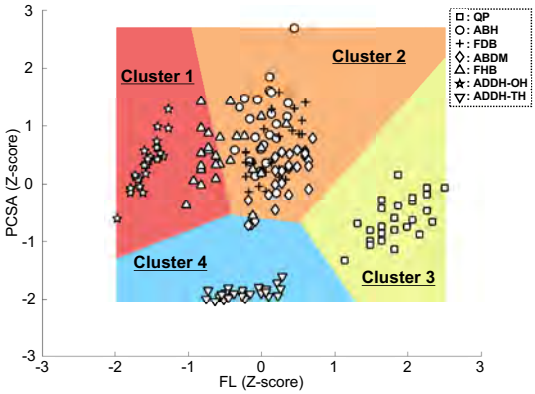

Figure 1 The relationship between PCSA and FL of individual PIFMs with the result of the K-means cluster analysis.

CONCLUSIONS

The K-means clustering based on morphological profiles (PCSA and FL) of individual PIFMs may become a novel approach for interpreting their function from viewpoint of maximal force production and shortening velocity.

INTRODUCTION

Catastrophic cervical spinal (c-spine) injury is a life-altering condition that can occur in rugby union during misdirected tackles. The complex dynamics of the c-spine during such injurious scenarios has been studied via musculoskeletal forward dynamic (FD) simulations [1]. However, this can quickly become a computationally inefficient solution due to the set of ordinary differential equations (ODEs) that needs to be solved, and the simulation results can be biased by the study design and design variables chosen by the researcher. The aim of this study was to investigate whether a Gaussian Processes (GPs) generative model, trained using musculoskeletal FD simulations, can predict the external forces and the c-spine intervertebral joint motion and internal forces during theoretical head-first impacts without solving ODEs.

METHODS

A synthetic dataset was generated via 117 forward dynamic simulations in OpenSim 4.3 using a specific model for the rugby population that was previously validated for axial head impacts [1]. The c-spine kinematic patterns that were simulated were hyperextension of all the intervertebral joints and first order buckling, which results in extension of the first 5 intervertebral joints and flexion of the lower cervical spine. The Bayesian GP Latent Variable Model (GPLVM) [2] was employed to learn similarities and differences between simulations in a lower dimensional representation of the data, known as latent space. 94 of the simulations (~ 80%) were randomly selected to train the model and the rest was using to test it. At test time, the GPLVM generated c-spine dynamics and external forces based on other variables that were given to it, such as head rotational and linear kinematics.

RESULTS AND DISCUSSION

Figure 1 shows how the model grouped the three different head impacts in the latent space, while Table 1 illustrates the average RMSE between the model prediction and simulation results. The range of RMSE for all c-spine intervertebral joint angles in the sagittal plane was 0.06° - 0.24° (i.e 0.02% - 9.36%). The predicted c-spine internal forces across all c-spine joints had a RMSE that ranged from of 4.89 N – 31.38 N for the shear component (i.e. 0.39% - 124.51%) and 14.18 N – 105.64 N for the compressive (i.e. 0.07% - 0.48%). The average RMSE for the external forces ranged from 10.40 N to 61.31 N (i.e. 0.32% to 57.34%).
The high RMSE in percentage for the shear forces does not reflect a significant difference in absolute terms, as the range in Newtons shows.

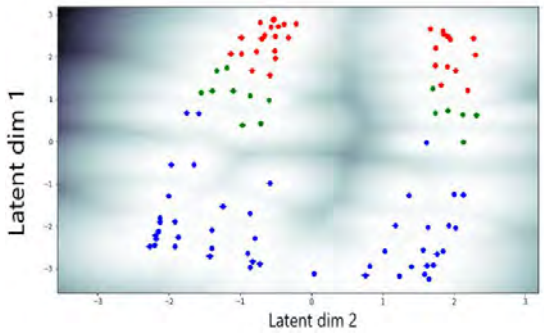

Figure 1 Representation of two dimensions of the latent space. The blue and red circles represent hyperextension and, respectively, whereas the green represent axial impacts.

CONCLUSIONS

The proposed framework is an encouraging starting point to implement probabilistic generative data-driven models as surrogate to mechanistic frameworks that rely on ODE solvers to investigate injury mechanisms. This approach will enable to run predictive simulations in future applications that are close to real-time.

INTRODUCTION

Recently, the rapidly increasing prevalence of sarcopenic obesity together with its serious consequences poses a critical health risk to the population. Muscle loss combined with the excessive amount of body fat that morbid obesity brings further enhances obesity accompanying comorbidities including reducing postural stability and thus significantly increasing the risk of fall with all the consequences [1, 2]. The best long-term results in the treatment of severe and morbid obesity are offered by bariatric surgery. Although bariatric surgeries lead to great and fast weigh loss, they are also followed by a significant loss of muscle mass which can also lead to other decline of postural stability. The aim of our study was to evaluate the influence of bariatric surgery on static postural stability.

METHODS

The research was designed as an experimental pilot study assessing postural stability before and after bariatric surgery. Eighteen subjects (13 females, 5 males) with obesity (body mass index 35–56 kg.m^{-2}), aged 27 to 67 years undergoing bariatric surgery participated in the study. The data collection was divided in two phases: pre-surgery and post-surgery. The pre-surgery measurements were performed approximately 2 weeks before the bariatric surgery and post-surgery measurements were performed 3 months after the surgery. Static and dynamic postural stability was measured and assessed using Tekscan MobileMat TM3140 pressure plate. Four postural stability parameters were evaluated: the total length of the COF sway, the length of antero-posterior and the medio-lateral COF range and the COF average speed. In four postural situations: natural stance with opened eyes, natural stance with closed eyes, maximal narrow stance with opened eyes and a maximal narrow stance with closed eyes. The measurement of each postural situation lasted 30s.

RESULTS AND DISCUSSION

The pilot study revealed statistically significant higher results (i.e. worse postural stability) after bariatric surgery for the total length of the COF sway in the natural stance with opened eyes, the total length of the COF sway in the maximal narrow stance with opened eyes and the COF average speed with opened eyes (Table 1). Our results suggest that bariatric surgery followed by fast weight loss may result into a decline in the static postural stability, mainly in more challenging situations. The natural stance may not be enough challenging to see statistically significant results. Maximal narrow stance with closed eyes might be on the other hand too challenging and therefore requiring more concentration which may lead to better results.

CONCLUSIONS

Although bariatric surgeries are considered as the most effective long-term management of morbid obesity, according to our study they may also have a negative impact on some musculoskeletal aspects such as postural stability. Further research in this topic is necessary. Our findings indicate a need for elimination of the negative effects by focusing on preservation of the muscle mass in pre-surgery and post-surgery regime.

INTRODUCTION

The countermovement jump (CMJ) is frequently used to assess physical performance. Jump height and reactive strength index (RSI) are the outcomes of CMJ performance. Jump height is associated with lower extremity work, power, and centre of mass (COM) displacement of the concentric phase. RSI is correlated with concentric COM displacement and lower extremity eccentric work calculated using ground reaction force (GRF) [1]. Age at peak height velocity (PHV) is an indicator of maturity in adolescents; at that age, height increases rapidly, and movement patterns such as jump movement are considered to change. Jump height and RSI have been reported to increase with maturity [2]. However, the relationship between jump performance and maturity, including GRF variables, has not yet been thoroughly investigated. Therefore, this study aimed to compare the characteristics of CMJ performance, including GRF variables, in adolescents of different maturity levels with those of adults.

METHODS

Ten young male soccer players (age: 22.1 ± 1.4 years; height: 171.1 ± 5.0 cm; body mass: 61.3 ± 6.0 kg) and forty-five male adolescent soccer players (age: 13.5 ± 0.9 years; height: 161.1 ± 9.0 cm; body mass: 50.3 ± 8.7 kg) participated in this study. Based on their maturity offset determined by age at PHV, adolescents were divided into the three following groups: pre-PHV (maturity offset ≤ –1.0), circa-PHV (–0.5 ≤ maturity offset ≤ 0.5) and post-PHV (1.0 ≤ maturity offset) [2]. CMJ was measured using a force plate (Ex-Jumper, DKH Co., Ltd., Japan) and divided into the following three phases. The unloading phase was defined from the start, when the vertical GRF decreased by more than 2.5% of the body weight value, to the time when the vertical GRF was at a local minimum. The eccentric phase was defined from the end of the unloading phase to the time when the COM velocity, which was calculated based on the GRF, reached 0. The concentric phase was defined from the end of the eccentric phase to takeoff time. Statistical analysis was performed using one-way analysis of variance (ANOVA), with Dunnett's t-test as a post-hoc analysis. The correlation between jump performance and the GRF variables was analysed using the Pearson product-moment correlation coefficient or Spearman's rank correlation coefficient. The significance level was set at $p < 0.05$.

RESULTS AND DISCUSSION

The adolescent group was divided into three groups with 13 adolescents pre-PHV, 24 in circa-PHV, and 8 in post-PHV group. Jump height, concentric displacement, and concentric work were significantly lower in the pre-PHV group than in young adults. However, no significant differences were found between circa- and post-PHV groups and young adults (Table 1). Jump height and concentric work were positively correlated in all the groups (r = 0.870–0.902, p = 0.002–0.001). Pre-PHV group had a lower jump performance than that of young adults. However, significant differences in jump performance were not detected in circa- and post-PHV groups and in young adults. These results suggest that adolescents in the pre-PHV phase are different from adults in jump performance. Pre-PHV group had lower concentric work than that of young adults; therefore, jump height was also lower than that in young adults.

CONCLUSIONS

In pre-PHV group, a lower jump height was found than in young adults. However, no significant differences were found between the other maturity groups and young adults. Maturity level should be considered when assessing adolescents' jump performance.

INTRODUCTION

An initial bout of eccentric exercise induces soreness and muscle force decrement (exercise-induced muscle damage; EIMD) but is then followed by a protective adaptation for subsequent bouts of the same exercise (ipsilateral repeated bout effect; IL-RBE). Interestingly, this protective effect has been shown in the contralateral limb despite not performing an initial bout of exercise (contralateral repeated bout effect; CL-RBE) and has been shown for the elbow flexors and extensors as well as the knee flexors and extensors [1] but has yet to be observed in the triceps surae. Compared to other muscle groups, the magnitude of both the initial damage and the subsequent protection in the IL-RBE has been shown to be smaller for the triceps surae, likely because of the compliant Achilles tendon preventing large scale damage to active force generating structures [2]. As the CL-RBE doesn't require physical damage to the muscle fibres of the contralateral limb, this model may be useful in identifying the mechanism(s) that better explain EIMD and the RBE for the triceps surae (e.g., neural adaptations). However, as the CL-RBE has been shown to be ~50% in magnitude of the IL-RBE, and as the presence of EIMD and IL-RBE in the triceps surae is smaller, it is unclear if a CL-RBE can be induced in the triceps surae. Therefore, the aim of this study was to quantify the CL-RBE of the triceps surae in humans.

METHODS

Young, healthy participants (mean ± SD age: 34.3 ± 2.6 years, height: 1.70 ± 0.04 m, body mass: 83.6 ± 3.5 kg) performed a bout of eccentric exercise of the triceps surae (225 heel drops; ECC) on one leg (ECC1) followed by a repeated bout on the opposite leg two days later (ECC2). ECC was performed on the edge of a force plate through a 50^0 range of motion, while wearing a weighted vest (10% body weight). Markers of EIMD were assessed before (PRE) and 2 hours (2H), 24 hours (24H), and 48 hours (48H) after each ECC bout on both limbs. Plantar flexor torque was measured during the performance of three maximal voluntary isometric plantar flexor contractions (MVCs) via an isokinetic dynamometer. Muscle soreness was rated 0-10 (visual analogue scale) during 6 tasks (3 palpation and 3 active) for a total out of 60. The size of the protective effect (index of protection) for MVC torque and soreness was calculated using the values 48H after exercise: (ECC2 - ECC1)/ECC1×100 [3].

RESULTS AND DISCUSSION

Currently, data from four participants has been analysed. Muscle soreness increased from 2H-48H after ECC1, with a similar rise but faster recovery following ECC2 (Table 1).

Table 1. Mean (±SD) muscle soreness (/60) PRE, and 2H-48H after each eccentric exercise bout of the triceps surae.

		PRE	2H	24H	48H
Soreness	ECC1	0.3 ± 0.5	3.0 ± 2.0	8.3 ± 2.5	13.5 ± 4.4
	ECC2	0.3 ± 0.5	3.0 ± 4.1	8.3 ± 6.7	9.5 ± 9.1

MVC torque dropped 19%2H after ECC1 and had not recovered at 48H post-ECC1 (32% decrement). At 2H following ECC2 with the contralateral leg, torque dropped 15% and only a decrement of 14% remained at 48H (Figure 1). The index of protection at 48H for muscle soreness and MVC torque were 29.6 ± 6.8 % and 26.7 ± 18.8 %, respectively.

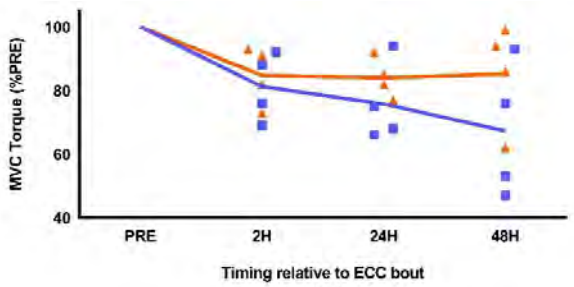

Figure 1. Mean MVC torque normalized to PRE before, and 2H–48H after the first (blue line) and second bouts (orange line) of triceps surae eccentric exercise. Participants used the opposite leg for the second bout two days after the first bout. Filled squares and triangles indicate individual data for ECC1 and ECC2, respectively.

CONCLUSIONS

Our preliminary analysis indicates that an initial bout of eccentric exercise using the triceps surae on one leg can provide protection for a subsequent bout of eccentric exercise for the contralateral limb. As such, the CL-RBE can be used for future work attempting to understand the mechanisms of EIMD/IL-RBE for this muscle group, where a large insult to the active force generating structures is absent.

INTRODUCTION

The use of biomechanical assessments in aquatic environments is essential for understanding and improving performance in sports such as swimming, diving, and surfing. However, established methods of biomechanical analysis, such as optical motion capture (OMC) systems, are not feasible for use in environments like the open sea. Inertial motion capture (IMC) systems that combine inertial measurement units with optimal control simulation of musculoskeletal models offer a potential solution, since such a system can accurately estimate kinetics and kinematics of walking and running [1]. However, natural aquatic environments are different than those in which IMC has been applied so far [2, 3]. For example, wetsuits are crucial in the ocean, and IMC sensors should be placed on the wetsuit to ensure a fixed location while practicing the sport. This could affect measurement accuracy. Therefore, we investigated the effect of wetsuits on the accuracy of IMC, by comparing the error between OMC and IMC with and without wearing a wetsuit.

METHODS

We conducted a pilot study with one participant, who walked and ran on a treadmill, while data was collected using both OMC and IMC. Each task was performed with and without a wetsuit. We then calculated joint angles and joint moments by solving optimal control problems for a sagittal plane musculoskeletal model. We created simulations by tracking the OMC and IMC data and evaluated the IMC system by comparing it to the simulation created with OMC data, both with and without the wetsuit. Joint angles from inverse kinematics, together with ground reaction forces, were tracked in the OMC simulations [4], while linear accelerations and angular velocities were tracked in the IMC simulations [1]. Here, we calculated the correlation coefficient and root mean squared error (RMSE) of the joint angles and moments of the hips, knees, and ankles, as well as of the ground reaction forces.

RESULTS AND DISCUSSION

We found that joint angles, joint moments, and ground reaction forces correlated well between the wetsuit and no-wetsuit condition, while RMSEs are similar to those in [1] (Tab. 1). The joint moment predictions with the IMC were even more similar to OMC when wearing the wetsuit than without the wetsuit (Tab. 1, Fig. 1). The correlation coefficient here was 0.95 for the recording without wetsuit and 0.98 for the recording with wetsuit.

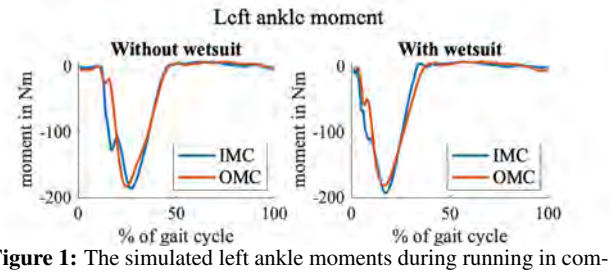

Figure 1: The simulated left ankle moments during running in comparison.

So far, we only analysed running data of one participants. We will further evaluate our methods on other participants, as well as for walking. We also plan to evaluate our algorithms by analysing motions recorded in a controlled aquatic environment.

CONCLUSIONS

In conclusion, our pilot study provides initial evidence that wearing a wetsuit does not affect the quality of motion analysis performed with IMC, meaning that there are no adverse affects when placing inertial sensors on a wetsuit instead of on the body. Future studies should assess movements recorded in an aquatic environment, to fully explore the potential of IMC in this environment.

EFFECT OF MOTOR SYNERGIES ON POSTURE AND PERFORMANCE STABILITY: A COMPARISON OF SELF- AND EXTERNAL TRIGGERED SHOOTING IN SIMULATED ARCHERY

INTRODUCTION

Successful archery performance requires stable drawing in force generation and standing in a vertical posture. Our current curiosities were about a mutual interaction of these two components, which may be affected by the trigger type of force release, e.g., release at a self-chose time or reaction to an external cue. Archery behaviors contain the actions of both upper and lower limbs, and several effectors (e.g., finger/hand forces, leg muscles) are involved in the shooting performance. Thus, the concept of synergies, which describes and quantifies the covariation patterns of multiple elements as an index of stability, would provide insight into archery performance from the perspective of biomechanics and motor control. This study employed a simulated archery shooting task in laboratory conditions and examined the effect of two release types on motor synergies and consequent archery performance consistency.

METHODS

We developed a customized bow frame that can measure the individual finger forces and frame angle. The subjects performed aim-releasing tasks on a force platform. Electrical activities of postural muscles were recorded using an electromyogram (Figure 1). In the self-triggered (ST) condition, the subjects released the target drawing force shown in the feedback screen in a self-paced manner. They released it by reacting to external signals in the external-triggered (ET) condition. We quantified postural sway indices by decomposing the center of pressure trajectories to rambling and trembling components. Uncontrolled manifold analysis was used to determine synergies (ΔV_z) in stabilizing upright posture and drawing force as stability indices. A target precision index (PRI) representing performance consistency was computed.

RESULTS AND DISCUSSION

The two synergy indices related to posture and drawing force stability were higher in the ST than in the ET condition (Table 1). We confirmed that co-contraction of the postural muscles during aim-release was relatively higher in the ET and negatively affected the postural stability. The small errors in multi-fingers force production could improve net drawing force stability in the ST condition. Further, the subjects showed relatively higher target precision under the ST condition (Table 1), which was significantly correlated with both posture and drawing force stability.

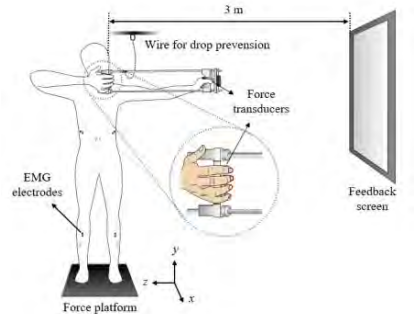

Figure 1 Experimental setup

CONCLUSIONS

The current findings suggested that the self-paced releasing with a feedforward control mechanism would be beneficial for archery performance consistency by increasing postural stability and reducing drawing force error. It can be applied in actual archery situations. Archers are generally known to use clickers and shoot in response, and a reduced reaction time to clickers was considered better archery performance [2]. Therefore, the strategy of predicting clicker drops, rather than reacting to them, could improve the consistency of archery performance.

INTRODUCTION

Surface electromyography (sEMG) helps understand the muscular origin of sprinting technique. It has been shown that maximal hip flexion and maximal hip extension angles are reached later at maximal velocity in the curve than in the straight [1]. The hip flexors and extensors activation timings were shown to influence the step frequency both at maximal velocity [2]. Since the inside leg step frequency is reduced within the curve [1], this could result from delayed inside leg activation timings. Therefore, the aim of the present experimentation was to investigate the onset of muscle activity and the sEMG amplitude of hip flexors and extensors in straight-line and curve sprinting.

METHODS

9 (6 male and 3 female) experienced-to-elite curve sprinters (mean ± SD: age = 22.8 ± 3.0 years; body mass = 70.8 ± 5.7 kg; height = 177.3 ± 6.6 cm) volunteered to participate in this study. After a 45-min self managed warm-up, the participants performed 10 and 40-m sprints within two sprinting conditions: straight-line and curve on a reconstructed lane 5 (radius = 41.58 m).
sEMG (Delsys Inc., 2148 Hz) were positioned on the *Rectus Femoris* (RF) and *Biceps Femoris long head* (BF) of both left (L) and right (R) legs (3). After full-wave rectification and band-pass filtering (20-500 Hz), the onset timings (% of stance duration) of muscle activity were identified using Teager-Kaiser energy operator and Approximated Generalized Likelihood Ratio (4). Mean sEMG amplitudes were normalised to the maximal activity of the corresponding muscle detected over the straight-line 40-m sprints. Two-way RM ANOVAs were performed.

RESULTS

There were no significant effects for condition or side neither for the onsets of muscle activity of RF ($p > 0.283$) and BF ($p > 0.412$) (figure 1); nor for the sEMG amplitude of RF ($p > 0.718$) and BF ($p > 0.111$).

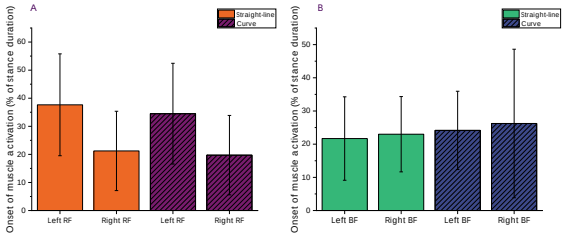

Figure 1 Mean ± *SD* onsets of muscle activity for A) *Rectus Femoris*, and B) *Biceps Femoris long head*.

CONCLUSIONS

The early acceleration phase of curve sprinting on a reconstructed lane 5 did not result in alterations of neither the onset timings nor the magnitudes of hip flexors and hip extensors muscular activity in comparison to the straight-line. Yet, this analysis only focussed on the first steps of a sprint. As already suggested by Judson et al. (5) regarding the ground reaction forces: the effect of the bend on the muscular activity during the acceleration phase could accumulate with the increasing velocity.

INTRODUCTION

In the classical ballet turn, pirouette, the dancer swings upper limbs with both legs flexed, then stands on on one toe and turns. During the pirouette, the dancer utilize the frictional forces from the floor. The dancer generates the vertical angular momentum with the frictional force during swinging upper limbs, and then turns with the reduced frictional force due to standing on tiptoe.

The frictional force can be controlled by the joint motions. The limiting frictional force is the normal force acting on the floor multiplied by the static or dynamic frictional coefficients. Whether the force from the body is greater or less than the limiting frictional force determines the foot motions [1]. As the vertical ground reaction force (GRF) varies with joint motions, dancers would adjust their performance with the slipperness. A computer simulation of a turning model would reveal techniques dealing with friction during turning. The purpose of this study is to create a whole-body model which turns and slides.

METHODS

Coordinates of markers on the whole-body and GRFs were recorded using a motion capture system during pirouettes by a female ballet dancer. The foot markers were attached at; the toe, medial and lateral sides of the metatarsophalangeal (MP) joint, and the calcaneal process. The restoring forces (F) of the viscoelastic springs assumed at the location of the foot markers were calculated using the following the equation and the sum was the simulated GRF.

$$F = -Kd - Dv|d|,$$

where K and D are the stiffness and damping coefficients, d and v are the height of a marker from its reference and the d's diffrenciation, respectively [2]. The coefficients of the viscoelastic springs will be determined by minimizing the difference between the real and simulated GRF using a genetic algorithm [3].

Dynamic and static friction forces were applied to the foot in response to foot slippage. If the magnitude of each marker velocity exceeded a reference value, the maximum dynamic friction force will be applied along the opposite direction of the marker horizontal velocity vector, otherwise the forces to move the foot will be applied. Free moments were also assumed according to the friction forces.

RESULTS AND DISCUSSION

The total viscoelastic spring forces acting on each foot could simulate the vertical GRF of the experiment, except for the forces acting during turning of the supporting foot and during landing of the free leg. The root-mean-square difference between the experimental data and the viscoelastic spring forces was less than about 55 N, which is approximately 10% of the maximum GRF. The coefficients of dynamic and static friction were 0.18 and 0.17 for the supporting foot and 0.4 for the other foot (only for the dynamic). The frictional forces calculated from the simulated vertical forces were well matched for the supporting foot during rotation but not for the other foot during contacting on the floor.

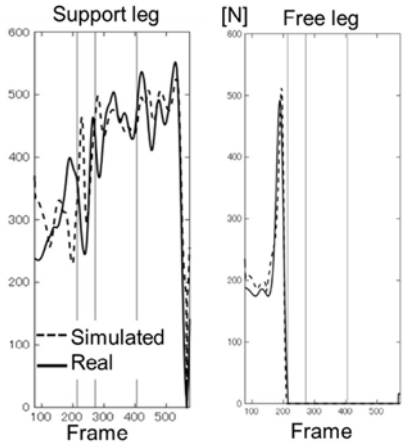

Figure 1 Simulated and real vertical GRF on feet.

CONCLUSIONS

These results suggest that to simulate the GRFs, it is necessary to assume not only viscoelastic springs assumed in the feet, but also springs in the body. With regard to the frictional forces acting on the foot while it is stationary needs appropriate estimates of the frictional coefficients.

INTRODUCTION

Countermovement (CMJ) and squat (SJ) jumps are commonly used to monitor neuromuscular performance in athletes. Traditionally, the difference between SJ and CMJ can be used as an indicator for utilization of stretch-shorten cycle (SSC) [1]. However, it is unclear how CMJ and SJ performance differs between trained and untrained individuals after matching participants' characteristics. This study examined the differences in jumping performance between athletes and healthy individuals with similar physical characteristics.

METHODS

38 collegiate male athletes (ATH; included basketball, rugby, tennis, frisbee, taekwondo etc.) and 38 healthy and active collegiate male students (CON) were recruited in this cross-sectional study (Table 1). After 2 familiarization trials (to ensure the proper execution technique for each exercise test) and a 1RM half-squat test, all participants performed the vertical jumps (SJ and CMJ) and isometric mid-thigh pull (IMTP) test on a force platform (Ballistic Measurement System, Innervations, Australia). The vertical jumps consisted of 3 maximal trials for each type of jump with 10-s rest. A 2-min passive rest was allowed between SJ and CMJ tests. Jumping height was calculated from flight time. The difference between CMJ and SJ (**Diff** = CMJ–SJ), prestretch augmentation (**PA** = [CMJ–SJ]/SJ×100%), and eccentric utilization ratio (**EUR** = CMJ/SJ) were derived from jumping height.

For the IMTP test, participants performed three 5-s long attempts, separated by a 2-min passive rest, pulling a barbell clamped to the crash bars of the power rack in a standardized body position (knee angle of 125º and hip angle of 145º). The peak force, rate of force development (RFD at 0-30, 0-60, 0-90, 0-150 and 0-200 ms), and maximal RFD (RFDmax; 30-ms sampling windows) were obtained during IMTP test.

Table 1: Characteristics of participants (n = 76)

	Athletes	Healthy Adults	Cohen's *d*
Age (yrs)	21.0 ± 2.0	21.3 ± 1.9	0.16
Height (m)	1.75 ± 0.08	1.76 ± 0.04	0.18
Body mass (kg)	73.3 ± 13.1	70.3 ± 9.5	0.27
1RM (kg)	167 ± 35*	121 ± 18	1.65
1RM/BM	2.28 ± 0.30*	1.75 ± 0.32	1.73
CMJ (cm)	44.9 ± 4.9*	39.2 ± 5.0	1.16
SJ (cm)	35.8 ± 3.7*	31.9 ± 4.0	1.02

*$p < 0.05$, compared with healthy adults.

RESULTS AND DISCUSSION

The performance of SJ, CMJ, and 1RM in ATH were significantly greater than those in CON (Table 1). The peak force (ATH vs. CON, 1188 ± 335 vs. 966 ± 227 N, $d = 0.78$, $p < 0.05$) and RFDmax (ATH vs. CON, 7305 ± 2555 vs. 6001 ± 1615 N·s^{-1}, $d = 0.62$, $p < 0.05$) during IMTP in ATH were also significantly higher than those in CON. No significant differences between groups were found in RFD at other time-intervals during IMTP. Figure 1 indicated that the Diff in ATH group was significantly greater than that in CON ($d = 0.53$, $p = 0.026$). However, no significant differences were found on PA ($p = 0.317$) and EUR ($p = 0.325$) between groups.

Previous studies reported that Diff [2], PA [3], and EUR [4] might not be sensitive indicators for monitoring or distinguishing differences in athlete performance. Although the mechanisms (e.g., utilization of SSC, storage and utilization of elastic energy, uptake of muscle slack, buildup of stimulation) explained the difference between SJ and CMJ remain unclear [5], Diff might be a sensitive indicator of differences in jumping performance between trained and untrained individuals.

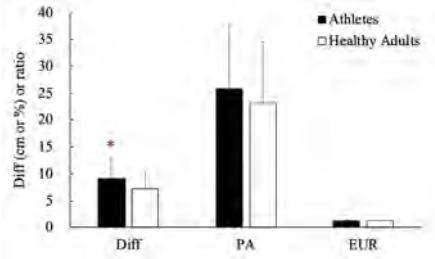

Figure 1 Differences between CMJ and SJ for the different groups. *$p < 0.05$, compared with healthy adults.

CONCLUSIONS

With matched participants' characteristics (age, height and body mass), Diff might be used as a good indicator of SSC efficiency to distinguish trained and untrained individuals. However, studies with a longitudinal design are needed to clarify the effect of chronic training on the utilization of SSC.

Get on Up; Relating Objective Hip-Hop Dance Biomechanics to Subjective Scoring

Joshua Alexander Vicente, M.S.[1], Belle Pearl Ponce de Leon, M.S.[1], Rudy Lua[1], Thomas "Rex" Ruswick[1], Makena Savola, M.S.[1], and Jacob W. Hinkel-Lipsker, Ph.D. [1]

INTRODUCTION

Hip-hop dance is a growing style of dance worldwide that typically involves an element of competition, where judges subjectively score dance performance[1]. To ensure competitive fairness, it is important to understand what judges are observing in dancers as part of the scoring process.[2] Such research would help elucidate whether judges' scores are more related to the objective biomechanics of dance moves, or other more subjective factors (e.g., attire). Therefore, the purpose of this study was to investigate the relationship between biomechanics of common dance moves among experienced dancers and how they are subjectively perceived by judges.

METHODS

Eighteen experienced adult-aged dancers were recruited for this study. Participants learned a choreographed routine, which contained two specific dance moves that were used for analysis: the arm wave, where the joints and segments of the arm move in a wave-like pattern from left to right, and inverted happy feet, where the feet move in opposition from one another alternating in transverse plane rotation. A 12-camera 3D motion capture system was used to record the coordinates of 28 retro-reflective markers at 240Hz, two force plates recorded ground reaction force data, and a separate camera provided video of each choreographed trial. These recorded video trials were be sent off sent to three professional judges for scoring.

For the arm wave, marker coordinate data were used to calculate metrics related to the displacement and velocity of arm joints and segments, as well as the shape deviation of an arm wave move from a sinusoidal wave pattern.[2] For the foot work, ground reaction force data were used to quantify the timing in forces between the two feet. Two stepwise linear regression models were then developed to test the degree to which: 1) arm wave kinematics and 2) foot work timing variables predicted judge's scores.

RESULTS AND DISCUSSION

Judges' scores for the arm wave were significantly predicted ($p < 0.001$, adjusted $R^2 = 0805$; Table 1) across all dancers by displacement of the right metacarpophalangeal (MCP) Joint (Figure 1; $p < .05$, **β** = -.331), as well as propagation velocity of the left forearm ($p < .05$, **β** = -.248) and right forearm ($p < .05$, **β** = -.891). Judges' scores for footwork were also significantly predicted by Timing Difference across all the dancers' performance ($p < .05$, **β** = -.535).

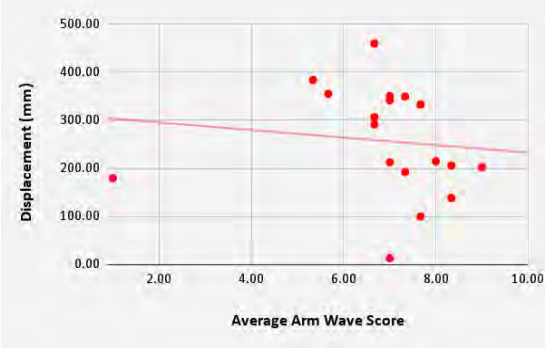

Figure 1 Right MCP Joint Displacement vs. Avg. Judges Scores.

CONCLUSIONS

Judges seemed to only focus on the beginning of the arm wave and seemed to rely on speed of both forearms to potentially show mastery & control. Using Biomechanical Analysis, this may prove fruitful to study other styles of dance or different movements common across styles to provide more predictors for performance and to catalog dance styles within academic literature.

INTRODUCTION

Recent studies of the kick start have examined the differences in backplate position and reported on the relationship between the back plate position and the horizontal velocity at the start and the subsequent transit time[1) 2)]. However, there are no studies that have reported on the details of the movement on the platform, so there is no established index to indicate the optimal back plate position for on-site instruction.

The purpose of this study was to clarify the effects in the lower hip angle in different back plate positions has on the time of the 5m and 10m distances in a swim start.

METHODS

Seven male swimmers who were members of the national swimming team and university swimming clubs. Ten motion capture systems (PrimeX13 OptiTrack, Acuity Inc., Japan) were used to acquire kinematic data from the start signal to the entry into the water. Motion data was sampled at 180 Hz, and three-dimensional coordinate data were obtained from the subject's markers.

Each swimmer participated using three back plate positions; each dive using a different back plate position and recordings of time were made from the start to 15m. The back plate position was varied in three levels: Front (the position closest to the tip of the starting platform), Back (the position farthest from the tip of the starting platform), and Prefer (the position preferably used in practice and competitions).

RESULTS AND DISCUSSION

The results of this study showed that Back had the fastest 10m elapse time and significantly smaller than Front and Prefer ($p<0.05$) (Table 1). The take-off angles were Front, Prefer and Back, with significantly smaller values for Front and Back, Prefer and Back ($p<0.05$).

Figure 1 shows that the start of extension of each joint angle of the back leg tended to be earlier in the order of Front, Prefer, and Back. The hip joint angles at the starting position (0 sec) differed, with the Back showing the largest angle. In the start of a swimming race, the swimmers respond to the starting signal, kick the starting blocks with their legs, and simultaneously raise their upper bodies to jump off of the starting blocks. This is thought to have resulted in the swimmers being able to kick out smoothly. As a result, the swimmer had enough time to raise the upper body, and the take-off angle was close to being horizontal.

Table 1: Mean and Standard deviation of the variables of each back plate positions.

Variables (n=7)	unit	Front	Prefer	Back
		Mean±SD	Mean±SD	Mean±SD
Block Time	sec	0.71 ± 0.04	0.71 ± 0.03	0.70 ± 0.06

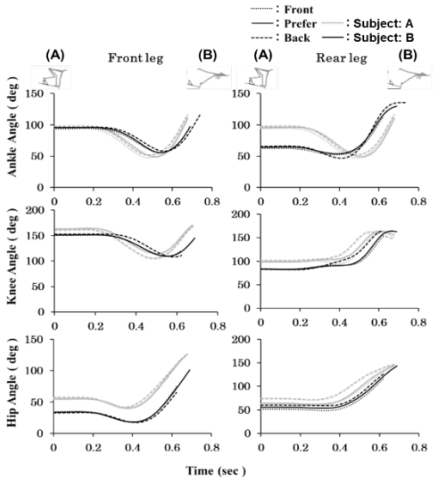

Figure 1 Joint angle at each back plate position. (A: statics posture at starting signal, B: posture at take-off)

CONCLUSIONS

The purpose of this study was to clarify the effect of the change in each joint angle of the lower limb from the start to the time of leg separation on the 5m and 10m elapse time due to the different positions of the back plate. The results showed that as the back plate position was moved backward, the take-off angle was significantly smaller and the 10m distance time was faster. The reasoning is the hip joint angle at the starting position was larger, and the timing of the start of extension of each joint angle of the back leg was earlier, which gave the swimmers enough time to raise their upper bodies.

THE INFLUENCE OF PROJECTILE MASS ON THROW DISTANCE

John H Challis
Biomechanics Laboratory, The Pennsylvania State University
Email: jhc10@psu.edu

INTRODUCTION

In 1871 Darwin commented "To throw a stone with as true an aim as a Fuegian defending himself, or in killing birds, requires the consummate perfection in the correlated action of the muscles of the hand, arm, and shoulder, and, further, a fine sense of touch."[1]. Throwing has been implicated in the the evolutionary development of brain lateralization, encephalization, language, and intelligence [2]. Previous studies have examined the accurate timing of release on throw accuracy [e.g., 3], a crucial factor which hitherto has not received much attention is the influence of projectile mass on throw performance. In hunting and self-defense the projectile mass is important as it is a factor in a projectiles kinetic energy, which in turn has implications for the result of an accurate throw on its target. Therefore, the purpose of this study was to examine the influence of ball mass on throw distance, where throw distance reflects ball kinetic energy.

METHODS

A model of the upper limb was developed which simulated a simple throwing task. The model was used to examine the influence of ball mass on throw distance. The model was based on a previously published model [4]. The muscle moment (T_M) at each joint was determined from,

$$T_M = q(t).T_{Max}.T_\phi(\phi).T_{\dot\phi}(\dot\phi)$$

Where $q(t)$ is the active state at time t, T_{Max} is the maximum isometric moment, $T_\phi(\phi)$is the normalized moments produced at joint angle ϕ, and $T_{\dot\phi}(\dot\phi)$ is the normalized moment produced at joint angular velocity $\dot\phi$. Model parameters were tuned to the physical properties of two experimental subjects [4]. The optimal control problem was to find the active state time series which produced an instant of release which maximized throw distance (and therefore effectively release velocity and kinetic energy), for ball masses ranging in mass from 5.5 to 11 kg. The different mass balls were all assumed to be spheres of the same diameter, but with different densities to allow for a range of different ball inertial properties.

RESULTS AND DISCUSSION

As would be expected throw distance decreased with increasing ball mass (Figure 1). This pattern of results can be explained using geometric scaling principles. For a throw the muscles do work to move the mass of the ball. The work (W) performed by a muscle is a function of the muscle force (F_M) and the muscle change in length (ΔL_M), therefore $W = F_M.\Delta L_M$. The force produced by a muscle is a function of its cross-sectional area (CSA) which scales as a function of body mass (m), therefore $F_M \propto CSA \propto m^{2/3}$. While the change in muscle length will scale with body length (L), and therefore is also a function of body mass ($\Delta L_M \propto L \propto m^{1/3}$). The work done in a throw scales in proportion to body mass ($W = F_M.\Delta L_M \propto m^{2/3}.m^{1/3} \propto m$). At the instant of release the projectiles kinetic energy is $KE = \frac{1}{2}m_B.v_R^2$, where m_B is the ball mass, and v_R is the ball velocity at release. The ball's velocity will be due to the work done in the throw, therefore $m \propto m_P.v_R^2$. As throw distance is a function of release velocity squared, throw distance should be inversely proportional to ball mass, a relationship which demonstrates a good fit to the simulation data (non-linear model in Figure 1).

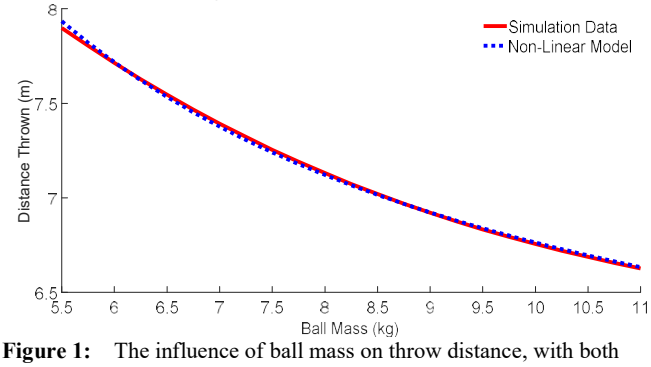

Figure 1: The influence of ball mass on throw distance, with both simulation results and geometric scaling model fit presented.

The geometric scaling non-linear model was fitted to world record shot put performances for different mass shots [5]. The error in predicting throw distance for shot put masses from 4 to 26 kg was 7%, providing further evidence in support of the veracity of the geometric scaling model of ball mass and throw distance.

CONCLUSIONS

In human throwing, throw distance is determined by the non-linear dynamics of the musculoskeletal system and ball mass, but the influence of ball mass on distance thrown can be explained by a simple relationship based on geometric scaling principles.

CHANGES IN KINEMATIC PATTERNS IN RESPONSE TO BALL VELOCITY IN TENNIS FOREHAND DRIVE

Yoon-Seok Choi[1], Ji-won Park[1], Jiho Kim[1], Dong-Gyu Baek[1], Mukyeong Shin[1] and Jaebum Park [1,2,3]

INTRODUCTION

The forehand drive is one of the most critical skills in modern tennis. Among ball-hitting behaviors in sports, tennis stroke has a unique feature such that the player monitors the velocity and trajectory of the ball for the accuracy of hitting. "*Accurate hitting a movable ball with various speeds*" in tennis competitions is essential and the most critical, which would contrast novice and skilled players. In this regard, we examined and quantified the differences in the ability to adjust the forehand drive swing in response to ball speeds. Notably, the patterns of the sequential chain of the proximal to distal segments in the transverse plane were quantified and further compared between the professional and novice group.

METHODS

Seven expert tennis players and six novice players (under three years of tennis experience for leisure purposes) participated in this study. The device, which was manufactured for launching tennis balls with prescribed velocity (i.e., angle and speed), was used. There were three conditions of the velocity, including slow (7.54 ± 0.65 m/s;) medium (10.83 ± 0.59 m/s;) and fast (14.42 ± 0.50 m/s;). The experiment was composed of 5 repetitive sets, and five trials were given in each set for each velocity condition. The order of the prescribed ball projection was randomized. An infrared camera motion capture system measured the pelvis, shoulder, upper arm, and hand kinematic variables. Further, the angular variables were quantified, including angular displacement and maximum angular velocity of segments on the transverse plane. The mean value of trials for each condition was used as the representative value of that condition. Repeated-measures two-way ANOVAs with factors, ***Group*** (expert & novice) and ***Velocity*** (three levels), were performed.

RESULTS AND DISCUSSION

Both groups showed smaller angles in takeback and angular displacement of proximal segments (pelvis, shoulder) when a ball came fast. Contrary to these results, one of the distal segments - the angular displacement of the upper-arm, increased. Maximum angular velocity of the pelvis and shoulder showed a tendency to decrease according to increasing ball velocity. These results showed that participants tried to reduce the angle in takeback and angular displacement of proximal segments to get an accurate impact. In addition, they increased the angular displacement of the upper arm to compensate for decreasing usage of proximal segments. The maximum angular velocity of the shoulder showed significant ***Group*** × ***Velocity*** interaction. From this result, it is confirmed that the expert group changed their swing strategy adeptly, especially the maximum angular velocity of shoulder compared to novice group.

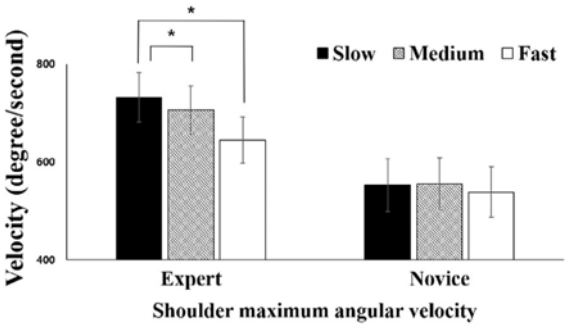

Figure 1 Averaged value of the maximum angular velocity of shoulder was shown for each group. It is also showed the statistical difference between velocity conditions. Asterisk indicates $p<0.01$.

CONCLUSIONS

Both groups changed their swing pattern according to ball velocity in a similar way reducing the usage of proximal segments and increasing that of distal segment. For the shoulder, the expert group modulated it linearly according to ball velocity, but the novice group did not. The results of this study elicited that players decrease their proximal segments. It also suggests that giving a commenting about maximum angular velocity of shoulder to the players who struggle with fast coming balls could be helpful.

CHARACTERISTICS OF THE STEPS IN EACH SECTION IN A TAILWIND SPRINT

Koichi Nakayama[1], Mizuki Makino[1], Masamichi Okudaira[2], Shota Enoki[2], Jun Koizumi[1] and Yoshiaki Manabe[2]

INTRODUCTION

One type of sprint training is called assisted training, which uses towing, downhill, and tailwind. This training is expected to improve sprinting ability by allowing the athlete to experience running faster than his or her maximum velocity by assisting during the sprint [1]. Previous studies have reported that supramaximum velocity can be experienced in towing and downhill, and that the external force of the assist causes the runner's movement to change differently from normal movement [2,3]. Studies on tailwind sprinting have reported higher sprint velocity than in no-wind conditions, based on simulation and competition data [4]. However, it is unclear what the factors increasing sprint velocity are for variables such as step frequency and step length. If we can identify the factors that cause changes in tailwind sprinting, we may gain insight to use in training. Therefore, the purpose of this study is to characterize the step that increase sprint velocity in tailwind sprint.

METHODS

Participants were 22 male students (100m PR: 10.73-12.03s) who belonged to a university track and field club. The experiment was conducted on a 120m indoor running track field lined with urethane rubber, and participants were asked to perform a 60m run. Experimental conditions were no wind and tailwind (2.0m/s) conditions. A tailwind was generated by 30 industrial fans installed on both sides at 4m intervals from the start to the finish. For data collection, a laser speed measuring machine and a high-speed camera were synchronized to capture the sprint. Laser measurement system (LDM301S; 100Hz) was placed behind the start, collected distance-time data. Velocity was calculated by differentiating the distance data. A high-speed camera (TS-5,100Hz) was installed on the side of the runway and panned to collect touchdown and take-off timing. One step was defined as the period between touchdown and take-off, and the support time, flight time, and step frequency for each step were calculated based on the time data. The average velocity from touchdown to take-off was used as the sprint velocity per step. The step length was calculated by dividing sprint velocity by step frequency. In this study, the distance from 0 m to 60 m was divided into 5 m intervals, and the average of two to three steps in that section was used as the representative value to compare no wind and tailwind. Normality of each data was checked by Shapiro-Wilk test. Since normality was not confirmed, the Wilcoxon rank-sum test was performed. The significance level was set at $p = 0.050$.

RESULTS AND DISCUSSION

In the 10-60m section, the sprint velocity was higher in tailwind than in no wind conditions (Fig.1). In the 25-30 m, 35-40 m, 45-50 m, and 50-55 m sections, the step length in the tailwind increased than no wind. In the 15-20 m and 40-45 m sections, the step frequency of the tailwind increased more than that of no wind. In the 25 m section, the tailwind flight time decreased more than no wind. In the present study, the sprint velocity increased after 10 m in the tailwind, suggesting that the sprinters were receiving tailwind-assisted changes from the acceleration phase. Although the increase in sprint velocity could be attributed to an increase in step length and step frequency, it could not be determined which variables have a dominant effect.

This may be due to a problem with the analysis method in which individual step are averaged for each section, or because the differences in step length and step frequency are small and the sprint velocity has been increased by a combination of factors. In the future, it may be necessary to examine each individual one-step change.

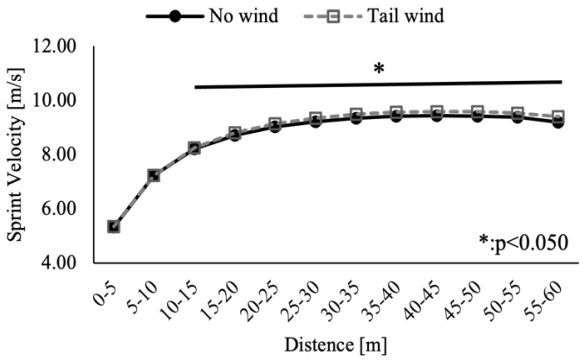

Figure 1 Change in sprint overall sprint velocity

CONCLUSIONS

In the 60m sprint with no wind and a tailwind, the sprint velocity was found to increase in the 10m to 60m section with the tailwind more than with no wind. Therefore, it was suggested that the training can be used as assisted training to experience supramaximum velocity even in an artificial tailwind.

EFFECTS OF STRENGTH TRAINING TARGETING MEDIAL QUADRICEPS/HAMSTRINGS ON KNEE JOINT BIOMECHANICS DURING SINGLE-LEG LANDING

Jiyoung Jeong[1], Dai-Hyuk Choi[2], and Choongsoo S. Shin[1]
[1] Mechanical Engineering, Sogang University, Seoul, Korea.
Email: cshin@sogang.ac.kr

INTRODUCTION

Anterior cruciate ligament (ACL) injury is one of the most frequent types of sports injuries. A previous study has demonstrated that the dynamic knee valgus and the peak valgus moment are thought to be important contributors to noncontact ACL injuries [1]. It has been documented that the lateral muscles of the lower extremity (e.g. vastus lateralis or biceps femoris) generated the knee valgus angle and moment, while the medial muscles (e.g. vastus medialis or semitendinosus/ semimembranosus) generated varus angle and moment [2,3]. Accordingly, strength training targeted at the medial quadriceps and hamstrings has been proposed previously [4], but no studies have investigated its effects on knee joint biomechanics with respect to ACL injury risk. Therefore, the purpose of this study was to examine the effect of novel strength training designed to strengthen the medial thigh muscles on knee joint kinematics and kinematics during single-leg landing.

METHODS

A total of 18 subjects without any current pain or history of lower extremity musculoskeletal injuries requiring surgery participated in the 8-week strength training targeting medial quadriceps and hamstrings (age: 22.1±1.8 yrs, height: 1.67±0.08 m, mass: 59.5±12.0 kg). This strength training program was developed based on the review of the literature and the consultation with an expert in athletic training [4].

Given that muscle thickness derived from ultrasound imaging can be an appropriate alternative to measure the individual thigh muscle strength [5], muscle thickness of individual quadriceps and hamstrings was measured using an ultrasound system. A motion capture system and a synchronized force plate were used to obtain the joint kinematics and kinetics during single-leg landing. Reflective markers were placed on the anatomical bony landmarks in the lower extremities. Kinematic and kinetic data were obtained during the stance phase from initial contact to toe-off. Joint moments were normalized to the body weight and height of each subject. Two-tailed paired *t*-tests were performed using MATLAB version R2021b. Significance levels were set at $P < 0.05$.

RESULTS AND DISCUSSION

After the strength training targeting the medial quadriceps and hamstrings, the muscle thickness of vastus medialis and semitendinosus increased by 7.9 % and 9.2 %, respectively ($P<0.001$ for both comparisons), thereby increasing M:L thigh muscle thickness ratio, as well ($P<0.001$). There were decreases in the varus-valgus excursion, the peak knee valgus, and the peak hip internal rotation moments during single-leg landing after training ($P=0.011$, $P=0.029$, and $P=0.006$, respectively, Table 1). Since previous prospective study reported that athletes who showed greater coronal plane knee angles at the time point of both initial contact and peak value sustained the ACL injury [1] and the peak knee valgus moment has been implicated to be a major mechanism of ACL injury occurring during simulated landing by inducing the high ACL strains [6], reduced knee varus-valgus excursion and peak knee valgus moment may decrease the potential risk of ACL injury.

Table 1: Kinematics/kinetics and mean EMG amplitudes both in pre- and post-training during single-leg landing (Mean ± SD).

	Pre	Post	p
Knee valgus at initial contact [deg]	1.3 ± 1.1	1.3 ± 1.2	0.991
Varus-valgus excursion [deg]	6.5 ± 1.5	5.8 ± 1.3	**0.011**
Peak hip internal rotation moment [Nm/(BW*Ht)]	0.072±0.012	0.068±0.009	**0.006**
Peak knee valgus moment [Nm/(BW*Ht)]	0.100±0.017	0.091±0.014	**0.029**

CONCLUSIONS

In conclusion, strengthened medial thigh muscles after targeted strength training altered the biomechanical risk factors of ACL injury by reducing the coronal plane knee excursion, peak knee valgus, and peak hip internal rotation moments during single-leg landing.

Effects of Wearing a Mask on Heart Rate Variability during Kendo Practice

Minato Kawaguchi and Kentaro Takahashi
[1] Department of Science and Engineering, Kanto Gakuin University, Yokohama, Japan.

Email: minato@kanto-gakuin.ac.jp

INTRODUCTION

The impact of masks on heart rate variability (HRV) has been scrutinized in various sporting events [1]. In Japan, the All Japan Kendo Federation has devised protocols to curtail the spread of the novel coronavirus during Kendo tournaments since 2020. These regulations mandate the usage of masks during Kendo matches. A previous investigation probed the influence of mask-wearing on Kendo swings and observed a significant trend in frontal swings. Nevertheless, this study only focused on a one-minute time frame and did not expound on the physiological impact of prolonged mask usage during practice. Consequently, this study aims to explicate the effect of mask-wearing on HRV while performing Kendo practice.

METHODS

Six male and one female university kendo club members participated. The subjects' ages ranged from 20 to 21 years, and their athletic experience ranged from 10 to 13 years. A three-dimensional polyurethane sports mask (Under Armour) was used. A wearable heart rate sensor, "myBeat" WHS-3 (Union Tool Co.), was used to measure body movement (acceleration) and electrocardiogram. Under the guidelines of the All-Japan Kendo Federation, a mouth shield was attached to the faceplate, and a mask was worn over the nose. Mouse shields were also worn for measurements without masks. The experiment was conducted in the following order: rest (1 minute of seated rest), *Kirikaeshi*, *Kakari-Keiko* (2 times for 20 seconds), rest, 4 minutes of *Gokaku-Keiko*, and rest. The experiments were conducted on separate days with and without wearing the mask, considering the effects of fatigue and other factors.

The data recorded by myBeat were the RR interval sequence of the electrocardiogram and the absolute acceleration. RMS values were derived for each period from the absolute acceleration time series, and if the RR interval was more significant than 1.2[s], it was excluded from the analysis as bradycardia. The RR interval mean and SD1 and SD2 of the Poincaré plot were obtained as heart rate variability indices. The frequency-domain indices, VLF, LF, and HF, were estimated based on the RR interval trend time series generated at a sampling frequency of 5 Hz. The mean values of each indicator for each phase were compared using a paired t-test. The significance level was set at 5%.

RESULTS AND DISCUSSION

There was no significant difference in RMS values between the masked and unmasked conditions during all periods. The mean RR interval was significantly smaller in the "with mask" condition in each of the later sessions of the experiment (Fig. 1). In HRV, SD1 and SD2 tended to be higher in the “without mask” condition at least after the second rest, and SD2/SD1 and LF were significantly higher in the masked condition at the last rest. These changes in HRV may be attributed to the fact that kendo is performed while observing the breathing of the opponent, resulting in a slower respiratory rhythm than in daily life and the wearing of a mask, which causes the body to take in more oxygen during inhaling.

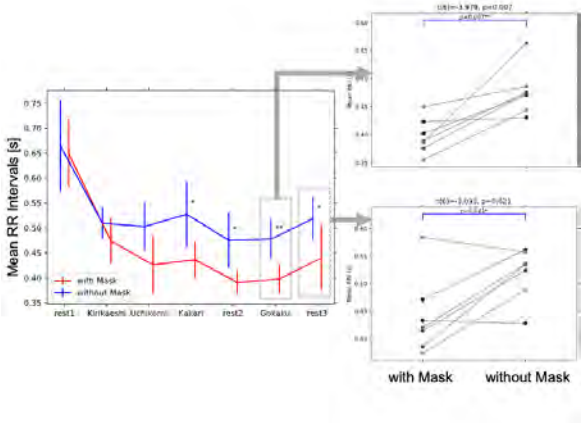

Figure 1 RR intervals [s] during Kendo practice with and without a mask. Error bar indicates the standard deviation (n=7). * = p<.05. ** = p<.01

CONCLUSIONS

During kendo practice, the presence or absence of a mask caused differences in heart rate activity, even though it did not cause differences in the magnitude of body movement. Especially in the latter half of the practice, the mask caused an increase in heart rate and a difference in heart rate variability indices (SD1, SD2, LF, and HF). One of the causes may be that the mask caused differences in breathing. In addition, since SD2/SD1 can be considered an index of sympathetic activation [2], wearing a mask may influence the autonomic nervous system.

Quantification of external work using mechanical crank power with a bicycle ergometer underestimates the net external work exerted by a human

Yuta Yamaguchi[1,2], Kosuke Taniguchi[3], Kanae Koguchi[1], Naoki Wada[2], and Tetsunari Nishiyama [1,2]

INTRODUCTION

The pedaling exercise has been widely used for the evaluation of endurance performance. Those studies utilized mechanical crank power to quantify the external work exerted by the rider. However, it is pointed out that this method fails to properly reflect the power exerted by the person, potentially leading to the misunderstanding of the data analysis and evaluation [1]. The mechanical crank power is the sum of the left and right crank powers (Figure 1). In general, the negative crank power is generated during the pulling phase [2]. Therefore, in order to maintain the mechanical crank power, surplus positive crank power is required during the pushing phase to compensate for the negative crank power [2]. The purpose of this study was to investigate the effect of the difference in methods, a conventional method of quantifying work by mechanical crank power and a method that considers surplus crank power, on endurance performance indices.

METHODS

Twenty cyclists (age: 19.7 ± 1.1 years old, height: 1.69 ± 0.04 m, body mass: 66.6 ± 7.4 kg) performed the incremental exercise test with an electromagnetically braked cycle ergometer (Excalibur Sport, Lode, Groningen, Nederland). The work rate was increased by 45W every 3 minutes. Expired gases were collected over the final 30 seconds of each stage (AE-310S, Minato medical science, Osaka, Japan). Both side crank powers were measured every 2 degrees of crank angle using a pedal force measurement system, and then the mechanical crank power ($P_{Mechanical}$) and net crank power (P_{Net}) considering surplus power were calculated (Figure 1). Relative exercise intensity, a commonly used measure of endurance performance, was quantified for mechanical crank power and net crank power, respectively. The surplus crank power ratio ($P_{Surplus}$) was calculated using the following equation.

$$P_{Surplus}\,[\%] = \frac{P_{Net}\,[W] - P_{Mechanical}\,[W]}{P_{Mechanical}\,[W]} \times 100 \qquad (1)$$

RESULTS AND DISCUSSION.

P_{Net} showed higher than $P_{Mechanical}$ for all relative exercise intensities, and $P_{Surplus}$ was shown to decrease with increasing exercise intensity (Table 1). Since the increase in $P_{Surplus}$ is related to the magnitude of negative crank power, the results of this study indicate that the rider generated less negative crank power as exercise intensity increased. This reflected the force application strategy of the rider to improve the force effectiveness by reducing the need for the propulsive leg to overcome the recovery leg (2).

On the other hand, the results of this study showed that low-intensity exercise may lead to a large underestimation (57% at $P_{50\%VO2peak}$). Negative crank power has been found to increase with decreasing exercise intensity (2, 3). Therefore, if the targeted relative exercise intensity is low, evaluation using P_{Net} is recommended.

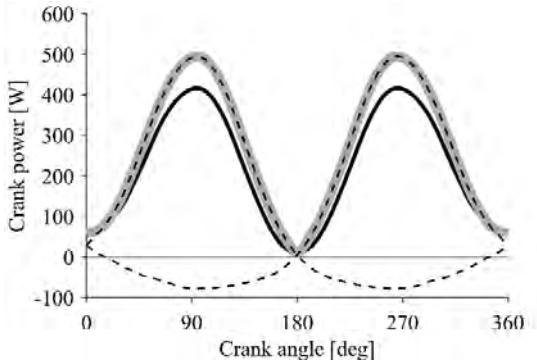

Figure 1 Typical example of the resultant force. The solid black line indicates mechanical crank power, the dashed black lines indicate crank power for each side, and the solid gray line indicates net crank power.

CONCLUSIONS

This study investigated the effect of the difference in methods that quantify the external work on endurance performance indices. The results of this study revealed that the quantification of work using $P_{Mechanical}$ underestimated net exerted work, which was more pronounced in low-intensity exercise.

Table 1 The crank power variable at each relative exercise intensity.

	$P_{Mechanical}$ [W/BW]	P_{Net} [W/BW]	$P_{Surplus}$ [%]
P_{Max}	5.0 ± 0.7	5.4 ± 0.6	9.5 ± 5.0
$P_{50\%VO2peak}$	1.9 ± 0.3	2.9 ± 0.3	57.0 ± 15.6
$P_{80\%VO2peak}$	3.7 ± 0.5	4.3 ± 0.4	20.5 ± 8.1

INTRODUCTION

Kinesiology Tape (KT) is a taping technique developed in the 1970s and has become popular and widely used by athletes and physicians of sports teams [1]. KT is constructed of breathable and stretchable material, which adheres to the skin with a medically approved adhesive. KT is designed to have the elasticity to avoid excessive restriction while providing enough pressure and support to facilitate muscle and tissue strength. However, a previous study showed that KT's application direction is not associated with improved performance and perceived the enhancement as essentially a placebo effect [2]. Furthermore, the effects on underlying force distributions of the skin attached to KT during motions are still unknown. Digital image correlation (DIC) is an optical technique based on image registration and tracking of the surface to obtain the distortion and deformation on the interested surface. It is hoped that the force distribution of the underlying skin surface aligned with taping direction can be clarified through the utilization of DIC. The purpose of the current study was to quantify the effect of KT on strain distribution under the surface skin with the DIC technique during motions using a dual-camera system.

MATERIALS AND METHODS

Fifteen healthy male individuals (age: 23.0 ± 1.5 years; height: 175.1 ± 3.4 cm; mass: 71.6 ± 8.5 kg) participated in the current study. All participants lay on the therapy bed in prone, and the examiner dotted on the surface skin of the biceps femoris muscle for image processing. Each participant was placed on an "I" strip of KT (1) with facilitation taping originating from the ischial tuberosity to the lateral femoral condyle, (2) and the inhibition taping in the opposite direction. Each participant performed isotonic knee flexion and extension under the dual-camera system (GRAS-50S5M, Point Grey, Canada). The strain distribution on the surface skin divided into fifteen regions were analyzed with principal strain using DIC analysis (Correlated Solutions, Columbia, U.S.A.). The stretch of tapes' applied strains to the underlying skin using MATLAB (Matlab R2019b) for calculating the subtraction of the corresponding regions between skin and tapes. One-way analysis of variance (ANOVA) was used to detect the differences in principal strain between two taping conditions in medial-lateral regions and proximal-distal regions. All statistical analyses were performed using SPSS 22.0 (SPSS Inc., Chicago. IL, U.S.A.) with the significance level set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

The mean strain of each 15 regions between the two taping conditions was compared to identify the differences applied to the skin surface. The results showed significantly different strain distributions of KT between two taping conditions in the proximal-distal regions across medial, middle and lateral areas (Fig. 1). It would appear that the principal compressive strain of KT increased from proximal to distal end of the hamstrings on the surface skin during all tested knee flexion and extension angles. In addition, the results showed that the principal compressive strain of KT for all regions increased as the knee flexion angles increased. From the current results, the principal strain of KT showed non-homogeneous strain from the proximal to the distal region as well as with the change of knee flexion angles.

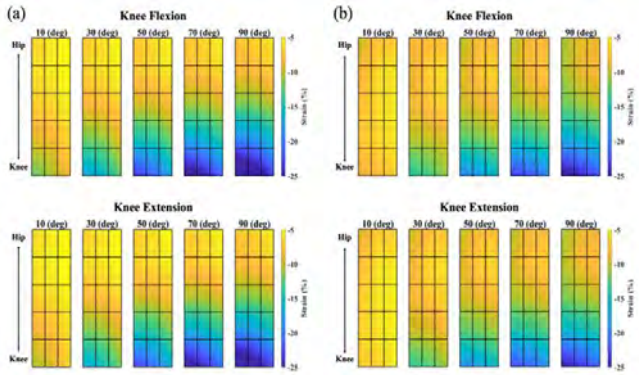

Figure 1. Average (%) principal strain distribution by using (a) facilitation (b) inhibition taping during knee flexion and extension. (The region of interest at taped muscle was divided into fifteen regions from proximal-distal regions across medial, middle and lateral areas.)

CONCLUSIONS

This is the first study to investigate the effects of KT on the principal strain of the surface skin during functional activities using a dual-camera system based on the DIC technique. The effect of KT tapping on the surface skin showed a non-homogeneous strain distribution from the proximal to the distal region at different knee flexion angles. The proposed new DIC-based method may be useful for the quantification of the effects of various KT techniques on other targeted muscles or joint movements in many patient populations and for those at different stages of rehabilitation.

Contact force during maximal snatches

Mike Webb, Mark King, Matt Pain
School of Sport, Exercise and Health Sciences, Loughborough University, Loughborough, United Kingdom
Email: m.webb@lboro.ac.uk

INTRODUCTION

A key component of the snatch is the powerful contact that the hip makes with the barbell, despite this, the magnitude of this force has not been quantified in the literature. There has been a great breadth of research into the biomechanics of the snatch; most commonly barbell kinematics of elite weightlifters are investigated [1]. The barbell kinematic research comes without the context of a measurement of force applied to the barbell by contact with the hips during the second pull [2] of the lift. A common suggestion amongst the barbell trajectory research is the minimisation of anterior-posterior movement of the barbell [3]. Investigating the size of this force is essential to understand performance and the technique employed by weightlifters in the snatch.

METHODS

Ten weightlifters (6 male, 4 female; body mass: 49-113 kg; snatch 1RM: 47-142 kg) that had competed at a minimum of national level were recruited for the study; each had given informed consent of the protocol which had been approved by Loughborough University Ethical Advisory Committee. A Tekscan F-scan force sensor (Boston, MA) was fixed to the centre of Eleiko training, providing an effective measurement area covering the full circumference of the barbell. Pressure data were collected at 250 Hz for each lift. The testing protocol consisted of a series of snatch singles, with barbell mass increasing up to 90% of maximum. Participants were instructed to warm up as would be standard for competition and to select weights as such. Sensor data of the heaviest snatch single for each individual was exported and analysed. Duration of each of the contacts was analysed, with contact defined as starting with a total force of greater than 8 N and ending when force dropped below this threshold. Both peak force and 'contact impulse' were assessed. Impulse was calculated using the trapezoidal method to integrate the force curve over time. A regression analysis was performed to establish a relationship between barbell mass and each of the variables, across the group. A regression equation and R^2 value were used to evaluate the relationships.

RESULTS AND DISCUSSION

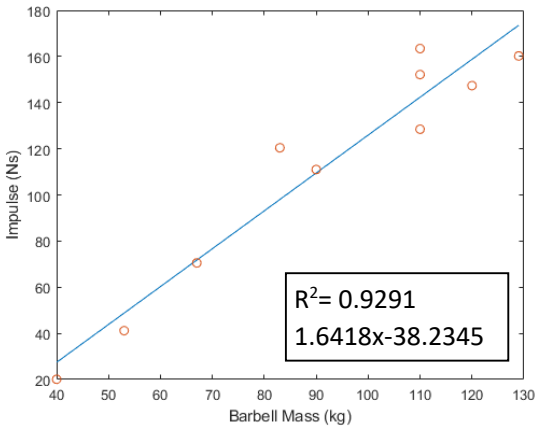

Figure 1 Contact impulse plotted against barbell mass.

The hypothesis that contact impulse increased as barbell mass increased was accepted (Figure 1). The lifters that lifted more weight generated larger impulse on the barbell, although did not necessarily apply larger impulse between their lifts as barbell mass increased. Peak force ranged from 260.1 N to 2682.5 N and contact duration ranged from 0.115 s to 0.170 s. When normalised using Sinclair total, lifters with a higher Sinclair also generated larger contact impulse with an R^2 of 0.8847.

CONCLUSIONS

The results of this study show that contact impulse on the barbell is a contributing factor in determining a lifter's ability to lift heavier loads, although varies within individuals. The Sinclair normalisation showed that even when body mass was accounted for, the 'better' lifters were able to produce larger contact impulse. Further research should look at technical aspects of the lift and the way these interact with contact force, and if possible, infer the direction of the force applied.

INTRODUCTION

In June 2021, Major League Baseball (MLB) stepped up its crackdown on foreign substances (i.e. sticky substances), except for rosin, a mixture of magnesium powder and pine resin. The reason is that the increased friction between the fingertips and the ball is expected to increase the ball spin rate. However, it is currently unknown how applied substances influence friction coefficients. In this study, we investigated the effect of rosin and sticky substances on the friction coefficient between fingertips and MLB balls. Additionally, we compared the friction coefficient between MLB and Nippon Professional Baseball Organization (NPB) balls which are often thought to be less slippery than MLB balls. Our study aimed to determine the impact of grip-enhancing agents on friction between the ball and fingertips. This study has been published elsewhere [1].

METHODS

Nine healthy adult males participated in this study. The sliding friction test between an index finger and a baseball leather sheet was performed using a capacitive six-axis force sensor as shown in Fig. 1. The leather sheet with (Fig. 1(a)) or without seams (Fig. 1(b) was extracted from the official balls of MLB and NPB balls. The leather sheet adhered to the force sensor with adhesive tape. Each participant slid their index finger in the proximal direction over the leather sheet under eight different conditions, i.e. MLB ball with and without seam under no application (Fig. 1(c)), rosin powder application (Fig. 1(b)), and sticky substance application (Fig. 1(c)) (i.e., two ball conditions with three application conditions) as well as NPB ball with and without seams under no application. The moisture level of the fingertip under no application condition was measured using a skin sensor. The friction coefficient was calculated from normal and horizontal forces measured by the force sensor during the sliding test.

RESULTS AND DISCUSSION

Under no application condition, the friction coefficient varied among participants, which is due to individual differences in the moisture levels of finger skin among participants. The rosin application increased the friction coefficient between a finger and a ball surface by more than 20%. Furthermore, the rosin application significantly reduced the variation in the friction coefficient among participants. The rosin application also reduced the variation in the friction coefficient with respect to the applied normal force. The sticky substance application increased the friction coefficient by more than 50% compared to the no-application condition. NPB balls exhibited larger friction coefficients than MLB balls at approximately 20% in no-application conditions, which indicates that MLB balls are more slippery than NPB balls. This difference was also observed after mudding or sanding.

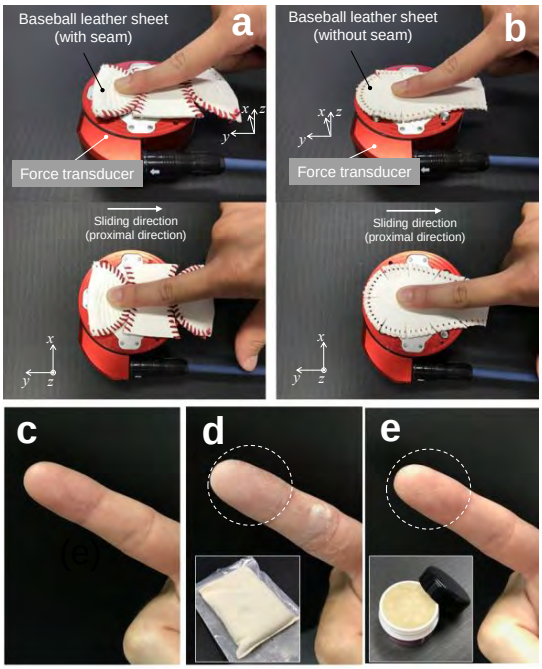

Figure 1 Experimental setup of sliding friction test for MLB ball leather sheet with seam (a) and MLB ball leather sheet without seam (b). Finger conditions: no application (c), rosin application (d), and sticky-substance application (e). [1]

CONCLUSIONS

We found that sticky substances increase friction which could positively affect the ball spin rate. The rosin application can help maintain constant friction against normal force and across pitchers, which could contribute to the fair playing field in baseball pitching in terms of friction between a finger and a ball. Our findings indicate that there is room for modification in the friction of MLB balls.

A PILOT STUDY ON THE PLANTAR PRESSURES IN FEMALES DURING SPRINTING ON NATURAL GRASS, 3G AND CORK SURFACES

Joanna Reeves, Daniel Rawson, and Sharon Dixon
Public Health and Sport Sciences, University of Exeter, Exeter, United Kingdom.
Email: j.e.reeves@exeter.ac.uk

INTRODUCTION

Artificial turf is commonly used as a playing surface due to its lower cost of maintainance compared to natural grass (grass). The third generation artificial surface (3G) has a rubber crumb infill made from recyled tyres. There are growing concerns that hazardous substances in the rubber crumb used in 3G may be harmful to the environment and/or human health and cork crumb may offer an environmentally friendly alternative [1]. However, the relative injury risk on a cork surface compared to 3G and grass has yet to be established. A stress fracture of the fifth metatarsal is a common injury in football (soccer) players, likely due to high loading of the forefoot during play [2]. The purpose of this pilot study was to compare the peak plantar pressure in the forefoot during sprinting on grass, 3G and cork in female team sport players.

METHODS

Five young female amateur team sport players (62.02 ± 8.41 kg) completed three successful 10 m sprinting trials on three surfaces (natural grass, 3G and cork) on separate days. A successful trial was considered to be within ±5% of the mean trial time. Testing on each surface was conducted on separate days with similar weather conditions and in a randomised order. All participants wore a football boot designed for female footballers (Ida Classica 22 Women's Soccer Cleat FG, Ida Sports, UK). Plantar pressure was recorded using insoles (Pedar-X®, novel GmbH, Munich, Germany). Data were processed using MATLAB (R2017b, Mathworks Inc.) with respect to the medial and lateral forefoot segments.

The peak pressure in three right foot steps per trial was averaged and the mean across trials was taken for further analysis. Effect size (Cohen's d) between conditions was calculated as the paired mean differences divided by the paired standard deviation.

RESULTS AND DISCUSSION

Data collection for participant 4 was not possible on the 3G surface due to availability. There was little to no difference in peak plantar pressure between surfaces in the medial forefoot. However, in the lateral forefoot, there was greater peak plantar pressure on the 3G surface compared to grass (d=0.5) and cork (d=0.7, Figure 1). There was no difference in peak plantar pressure between grass and cork in the lateral forefoot.

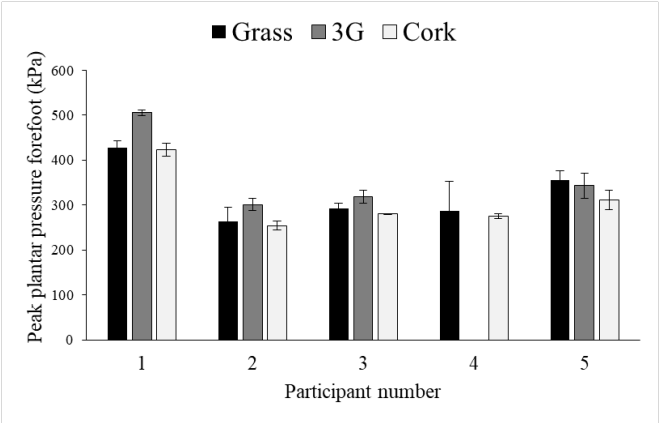

Figure 1. Mean ±SD of peak pressure in the lateral forefoot across three trials in each participant

CONCLUSIONS

Risk of lower limb injury, particularly fifth metatarsal stress fractures, may be similar on cork and grass surfaces and greater on 3G. However, future biomechanical and epidemiological studies using more participants, different populations and different movement tasks are needed to substantiate the findings of this pilot.

ACKNOWLEDGEMENTS

Relationship between Bilateral Asymmetry in Lower Limb Joint Biomechanics and Jumping Height during Single-leg Countermovement Jump

Shota Yamamoto[1], Munenori Murata[2], Rintaro Miyake[1] and Terumitsu Miyazaki[2]

[1]Graduate School of Physical Education, National Institution of Fitness and Sports in Kanoya, Kagoshima, Japan.
[2] National Institute of Fitness and Sports in Kanoya, Kagoshima, Japan.
Email: m226015@sky.nifs-k.ne.jp

INTRODUCTION

Larger bilateral asymmetry of jumping height of the single-leg countermovement jump (CMJ) was associated with smaller sprint performance [1]. Investigating the kinematics and kinetics characteristics, that cause the bilateral asymmetry of jumping height during the single-leg CMJ, might be valuable information to design training for improving sprint performance, as well as jumping performance. The previous study reported that the ankle joint kinematics were correlated with the bilateral asymmetry index of jumping height during the running single-leg jump [2], but these relationships during the single-leg CMJ remain unclear. Thus, we aimed to examine the relationships between the bilateral asymmetry in jumping height and the bilateral asymmetry in lower limb joint biomechanics during the single-leg CMJ.

METHODS

Twenty-two healthy male collegiate students (age, 20.3 ± 1.3 years; mass, 67.0 ± 9.2 kg; height, 1.71 ± 0.05 m) participated in this study. After a suitable warm-up, all participants performed five single-leg CMJs each on the right and left leg with their maximal effort in random order. Three-dimensional marker trajectories, placed on their whole body, and ground reaction force were measured using a motion capture system (250 Hz; Motion Analysis Corporation, USA) and a force plate (1000 Hz; Tech Gihan, Japan), respectively. The early and late phases of the single-leg CMJ were defined based on the vertical velocity of the center of mass (CoM): the early phase, from initiation of motion until the CoM reached zero vertical velocity, and the late phase, from the end of the early phase to take off. We calculated the bilateral asymmetry index of the lower limb joint angles and torques during the early and the late phases. We also calculated the bilateral asymmetry index of jumping height. We compared to the bilateral asymmetry index of the lower limb joint angles and torques between early and late phases using Wilcoxon's rank sum test. Additionally, Spearman's rank correlation coefficient was calculated between the bilateral asymmetry index of jumping height and the joint angles and torques. Statistical significance was defined as $p < 0.05$.

RESULTS AND DISCUSSION

The bilateral asymmetry index of jumping height was 4.02 ± 3.69 % (range, 0.08-13.98 %). The bilateral asymmetry index of lower limb joint angles and torques in the late phase was greater compared with the early phase (Figure 1). The knee extensor and ankle plantar flexor muscle groups act eccentrically during the early phase of the single-leg CMJ, while these muscle groups act concentrically during the late phase. A previous study reported that the bilateral asymmetry in muscle strength of the lower limb is greater during an eccentric contraction than during a concentric contraction [3]. However, our results (Figure 1) suggest that the findings of this previous study cannot be generalized to the single-leg CMJ. Moreover, we found that the bilateral asymmetry index of ankle joint torque during the late phase of the single-leg CMJ was significantly correlated with the bilateral asymmetry index of jumping height ($r = 0.44$, $p < 0.05$), whereas the other bilateral asymmetry index of the joint angles and torques in each phase was not significantly correlated with the bilateral asymmetry index of jumping height ($p > 0.05$). The findings imply that, during the single-leg CMJ, a reduction in bilateral symmetry of ankle plantar flexion torque, specifically during concentric contraction, might lead to a decrease in bilateral asymmetry of jumping height.

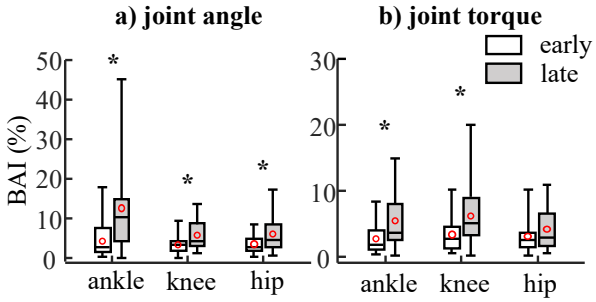

Figure 1 Bilateral asymmetry index of lower limb joint angles (a) and torques (b) during the early and late phases of the single-leg CMJ. (*: $p<0.05$)

CONCLUSIONS

We examined the relationship between the bilateral asymmetry of jumping height and the bilateral asymmetry of lower limb joint angles and torques in the early and late phases of single-leg CMJ. The results of this study showed that the bilateral asymmetry of the ankle joint torque in the late phase was positively correlated with the bilateral asymmetry of jumping height.

A Biomechanical Study of Uchimata in Judo

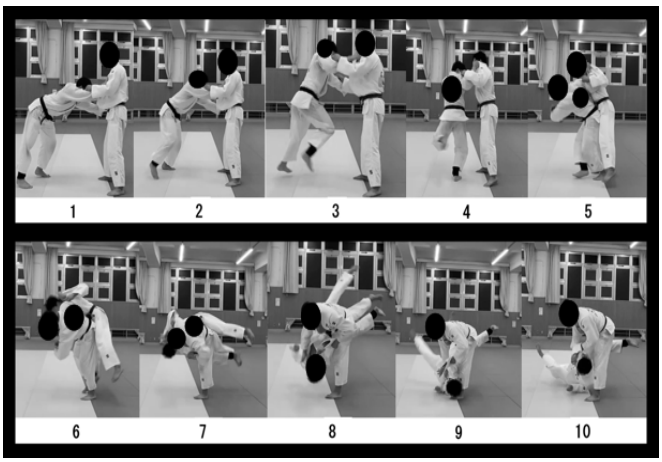
- Comparison of different skill levels-

Kazuto Hamaguchi[1] , Sora Takeuchi[1], Taisei Wada[1], Takumi Furukawa[1] and Tatsuya Deguchi [1]
[1] Graduate school of Humanities and Social Sciences, Hiroshima University /Higashi-Hiroshima, Japan.
Email: kazuto_linear@yahoo.co.jp

INTRODUCTION

Although many biomechanical studies have been conducted in judo competitions, few studies have compared the biomechanics of experienced judo players at different levels of skill, such as competition level. Therefore, the biomechanical differences in *uchimata* (inner thingh throw) of skilled judo players and unskilled players have not yet been clarified, and there is room for further investigation into how body movements are performed during a throw. The purpose of this study was to compare the biomechanics of uchimata in two groups of skilled and unskilled judo competitors at different levels of competition, and to obtain suggestions for technical instruction.

Figure 1: Sequential photographs of uchimata.



METHODS

The subjects were 20 male judo players belonging to a university judo club, 10 of whom had participated in national tournaments (hereafter referred to as "skilled players") and 10 of whom had not participated in national tournaments (hereafter referred to as "unskilled players"). Movements were recorded using an optical 3D movement analysis system, Mac3D (250 Hz). Forty-seven reflective markers were attached to the subjects with reference to Ishii et al. (2017) and Liu et al. (2022). Ground reaction forces acting on the feet during the movements were measured using a force plate (1000 Hz). After each trial, subjects introspectively rated their own performance on a 5-point scale (1=poor, 2=not so good, 3=normal, 4=good, 5=very good).

RESULTS AND DISCUSSION

In terms of movement time, athletes in the skilled group tended to have a shorter movement time than those in the unskilled group during the phase of body rotation. The maximum absolute velocity of the body center of gravity along the front-back direction was significantly greater for skilled athletes (0.87±0.23 m/s) than for the unskilled athletes (0.66±0.15 m/s) ($p=0.032$). The maximum angular velocity of the arms tended to be greater in skilled group (3.98±0.63 rad/s) than in unskilled group (3.59±0.69 rad/s), but the difference was not significant. The maximum angular velocity at the hip was significantly greater for the skilled group (1.80±0.20 rad/s) than for the unskilled group (1.39±0.19 rad/s) ($p<0.001$). The above results suggest that the speed of forward propulsion during the body rotation phase is a factor in the magnitude of the angular velocity of the hips and arms during the throwing phase.

CONCLUSIONS

In this study, skilled athletes tended to have higher angular velocity in all items compared to the unskilled athletes. The forward body center of gravity velocity of skilled athletes tended to be larger than that of unskilled athletes, and the movement time tended to be shorter.

INTRODUCTION

Hamsting injuries are among the most common injuries in athletes. Eccentric training has been shown to reduce hamstring injury rates. The Nordic Hamsting Exercise (NHE) is an eccentric exercise performed at short muscle length and has been shown to provoke changes in hamstring muscles. This study aims to assess the effects in eccentric hamstring strength, hamstring flexibility and biceps femoris long head muscle stiffness following a 6-week NHE intervention.

METHODS

Fifteen recreational male and female athletes were randomised into an NHE intervention group (n=7; 5 males and 2 females; age: 24.0±1.8y; height: 172.0±3.0cm; body mass: 85±5.1kg) and a control group (n=8; 4 males and 4 females; age: 24.3±1.3y; height: 172.0±3.0cm; body mass: 72.3±3.4kg). Isokinetic dynamometry (Cybex HUMAC2015, Massachusetts, USA) at 60º/s and 45º for eccentric and isometric peak torque respectively, myotonometry (MyotonPro, Myoton Ltd, Estonia) and manual goniometry were used to measure the outcomes. Each outcome was measured at baseline and after 6 weeks in both groups (5 days before and after the intervention programme). All data presented as means and standard error of the mean (SE). A two-way mixed ANOVA was used for all dependent variables and a level of $p < .05$ was used to accept significant differences.

RESULTS AND DISCUSSION

There was an 8% increase in eccentric peak torque and 6% increase in the isometric peak torque in the intervention group ($p < .05$), while both outcomes were reduced in the control group (time*group interactions $p<.05$). These results are in line with previously published evidence [1,2]. There was a 9% increase in hamstring flexibility in the control group while no changes observed in the intervention group (time*group interaction $p<.05$). No significant effects were observed in muscle stiffness in both groups (time*group interaction $p>.05$) (Table 1). Other studies have reported decrease in muscle stiffness after a similar intervention, however, methodological differences and limitations of the current study may be responsible for these differences [3].

CONCLUSIONS

A six-week NHE training programme may increase eccentric and isometric strength, which have both previously described as risk factors for hamstring injury. It seems that NHE has no significant effect in altering muscle flexibility and stiffness. The current evidence may inform training practice in recreational athletes as well as further research.

INTRODUCTION

The throw-in in soccer requires distance control depending on the situation. However, most previous studies have focused on obtaining the maximum distance, and it has been reported that the upper limb was the primary contributor in generating ball speed [1]. A previous study on basketball, which investigated an accurate throwing distance coordination task similar to throw-in, has reported that the upper limb movement changes with an increase in throwing distance [2]. Therefore, it is believed that the throw-in would also require similar joint coordination; however, it has not been adequately discussed. This study aimed to determine the effect of each upper limb joint on the control of ball speed in throwing distance control in a throw-in.

METHODS

Five university male soccer players (height: 172.7 ± 6.0 cm; mass: 62.8 ± 4.3 kg; age: 20.6 ± 1.4 years) participated in this study. They performed standing throw-in to the targets on the ground that were placed at every 10% relative to the throw-in distance at each participant's maximum effort. Three-dimensional coordinates data of reflective markers on a body and ball were recorded using a motion analysis system (Mac3D system, Motion Analysis, 500Hz). We calculated the kinematic parameters of the body and ball, and the generated ball speed (GS) by each joint's angular velocity was calculated as follows [3]:

$$\mathrm{GS} = \hat{\mathbf{v}}_{\mathbf{Ball}} \cdot \left(\boldsymbol{\omega}_{\boldsymbol{Joint}} \times \boldsymbol{r}_{\boldsymbol{Joint \to Ball}}\right).$$

where $\hat{\mathbf{v}}_{\mathbf{Ball}}$ is the unit vector of the ball velocity, $\boldsymbol{\omega}_{\boldsymbol{Joint}}$ is the joint angular velocity, and $\boldsymbol{r}_{\boldsymbol{Joint \to Ball}}$ is the vector from joint to the ball. Furthermore, the same calculation was performed using the unit vector of the joint angular velocity ($\boldsymbol{\omega}_{\boldsymbol{Joint}}/\omega_{Joint}$) to evaluate the effect of the positional relationship between the ball and each joint on the ball speed ($\mathrm{GS}_{\hat{\omega}}$).

RESULTS AND DISCUSSION

The angular velocity of all joints increased with an increase in throw-in distance (Figure 1B). However, only the elbow generated more ball speed as throw-in distance increased, while the other joints did not contribute to the increase in the ball speed (Figure 1A). Due to the absence of the wrist's range of motion, the wrist angle is unchanged throughout all throw-in distances. Therefore, the distance from the elbow and wrist to the ball ($r_{Joint \to Ball}$) is generally unchanged between trials, and the $\mathrm{GS}_{\hat{\omega}}$ of the elbow and wrist were constant in all throw-in distances (Figure 1C). The $\mathrm{GS}_{\hat{\omega}}$ of the shoulder decreased with the increase in throw-in distance (Figure 1C). Because the ball is positioned forward to the shoulder at the release due to the regulation [4], the shoulder rotation always generates the downward and forward ball velocity. Therefore, as the release angle increased with throw-in distance, the difference in direction between the ball velocity generated by the shoulder and the actual ball velocity increased, and the shoulder's $\mathrm{GS}_{\hat{\omega}}$ would have decreased with increasing throw-in distance. However, considering that the angular velocity of the shoulder increases with throw-in distance, the shoulder may not directly contribute to the gain of ball speed but may contribute to the increase in the angular velocity of elbow extension and the adjustment of release angle.

CONCLUSIONS

This study aimed to determine the effect of each upper limb joint on the control of ball speed in throwing distance control in a throw-in. The main finding was that the elbow was the main contributor to control of the ball's flight distance in the throw-in.

INTRODUCTION

Among the factors determining a pitcher's ability, throwing with higher ball velocity is considered to be the most important [1]. Several previous studies showed that movement of trunk during pitching was related to ball velocity [2][3]. However, these studies have primarily focused on male subjects. Although there have been several studies on female baseball players, the relationship between kinematics of the trunk and ball velocity among female players has not been reported. The purpose of this study is to investigate the relationship between ball velocity and kinematics of pelvis and upper torso in female baseball players, and obtain knowledge for teaching and coaching of pitching motion for the female players.

METHODS

Ten female collegiate baseball players (age: 20.1 ±0.8 years old, height: 1.62 ± 0.06 m, body mass: 57.0 ± 7.0 kg) participated in this study. A three-dimensional motion analysis device (VICON MX40, Vicon motion systems, UK) was used to obtain kinematic data of the segments and joints at 200 Hz. Ball velocity was measured using a speed gun (SPORTS RADAR GUN Professional Sports HP-1, Mizuno, Tokyo, Japan). After warming up, the subjects threw fastballs from a portable pitching mound toward a catcher with maximal effort. Measurement was conducted at least ten times, and the data of the fastest pitches were analyzed. Baseball pitching was divided into two phases by three critical events. Spearman's rank correlation coefficient was used to assess significant differences between ball velocity and kinematic parameters of pelvis and upper torso ($p < 0.05$). All data were processed using MATLAB (Matlab2020b, Mathworks, MA, USA).

RESULTS AND DISCUSSION

Mean ball velocity was 96.2 ±7.4 km/h. Four kinematic parameters significantly correlated with ball velocity (Table1). Forward tilt angular velocity of the upper torso at the time of stride foot contact (SFC) and its peak value during arm cooking phase was positively correlated with ball velocity. This result showed that motion of upper torso forward tilt may provide a great momentum that can be translated into increased ball velocity from stride foot contact (SFC) to before maximum shoulder external rotation (MER). The relationship between sagittal plane motion of the trunk at the time of ball release and ball velocity was shown in the previous study on male baseball players [2]. Compared to results of this study, which showed differences by event. Lateral tilt angular velocity of the upper torso at the time of maximum shoulder external rotation (MER) and its peak value during arm acceleration phase was positively correlated with ball velocity. This result suggested that a motion of upper torso lateral tilt helped to increase ball velocity from maximum shoulder external rotation (MER) to before ball release (REL). This relationship between lateral lean motion of the trunk and ball velocity was similar to the previous finding for male baseball players [3]. In this study, there was no correlation between pelvic parameters and ball velocity.

Table 1: Angular velocity data and factors associated with ball velocity

	Mean ± SD	ρ
Ball velocity (km/h)	96.2 ± 7.4	
Stride Foot Contact (SFC)		
Upper torso forward tilt (°/s)	223.9 ± 159.6	0.673*
Arm cocking phase		
Maximum upper torso forward tilt（°/s）	432.8 ± 89.0	0.685*
Maximum Shoulder External Rotation (MER)		
Upper torso lateral tilt (°/s)	298.0 ± 117.1	0.758*
Arm acceleration phase		
Maximum upper torso lateral tilt (°/s)	305.1 ± 116.7	0.758*

ρ: correlation coefficient, *$p < 0.05$

CONCLUSIONS

Forward tilt angular velocity of the upper torso at the time of SFC and during arm cooking phase and lateral tilt angular velocity of upper torso at the time of MER and during arm acceleration phase was positively correlated with ball velocity. Comparison of our results with previous studies suggested that the phase and event of movement on the sagittal plane related to ball velocity may differ between male and female baseball players.

CHARACTERISTICS OF LEG MOVEMENTS THAT INDUCE RED CARDS IN RACE WALKING

Naoki Takahashi[1], Hironari Shinkai[2]

INTRODUCTION

In race walking rules, the advancing leg must be straightened from the heel contact until the vertical upright position with the ground (i.e. not bent at the knee) [3]. The referees may issue a red card to athletes with non-legal walking techniques, and three or more red cards will result in disqualification. Therefore, the judgment of the referees is significant to an athlete's performance. Several studies have been conducted on the judgment of referees [1,2]. However, these studies do not analyze the movement at the moment the referees make their decisions, so their accuracy may be questionable. To ensure proper verification, it is necessary to analyze the movements at the moment of the referee's decision. The aim of this study was to verify the movements that result in a red card as judged by the referees.

METHODS

The subjects were the 20 male athletes and the 3 referees who participated in the 2022 competitions. Video recordings (120fps) of the movements of 10 participants who received red cards from more than one referee (RC group) and 10 participants who did not receive any red cards during the competitions (NI group) were analyzed. We measured 4 step parameters (step frequency, step length, speed, and contact time) and the knee joint angle during the contact phase. The step parameters were analyzed using an independent t-test, and the knee joint angle was analyzed using Statistical Parametric Mapping (SPM). The significance level for all tests was set at 0.05.

RESULTS AND DISCUSSION

Table 1 showed that there were no significant differences in all step parameters, indicating that the competitive level of the two groups was similar. It is possible that these step parameters do not have a significant effect on the referees' judgments. The SPM analysis revealed that there was no marked difference in the knee joint angle between the RC and NI groups at heel contact and immediately after. However, from 22 to 77% of the contact phase, the RC group showed a significantly smaller knee joint angle compared to the NI group ($p < 0.001$) (Figure 1). Furthermore, the knee of the NI group was still extended after the vertical upright position, up to 44% of the contact phase, while the knee of the RC group was either flexed or kept still. The competitive rules state that the knee extension range is from heel contact to the vertical position. However, to avoid receiving a red card from referees, it is suggested by this study that athletes need to extend their knee from the moment of heel contact to the vertical upright position or immediately thereafter. Additionally, keeping a larger knee joint angle after the vertical upright position may also help athletes avoid receiving a red card.

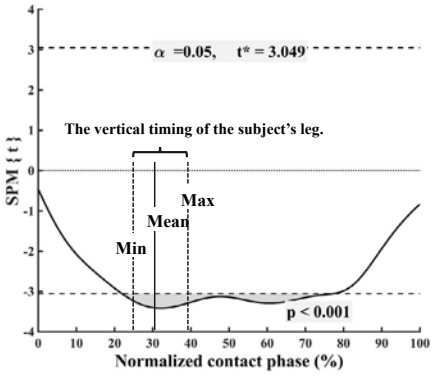

Figure 1. Results of SPM{t} for the knee joint angle. Mean, Max and Min are the instant when the subject's legs are vertical.

CONCLUSIONS

The knee joint was no marked difference at the heel contact and right after. However, our results suggests that athletes should extend their knee joint from heel contact to after the vertical upright position to avoid receiving a red card from the referees.

A Comparison of Rotation Sequences for Shoulder 3D Kinematics in the Volleyball Attack

Kiara Barrett, Hunter J. Bennett
Department of Human Movement Sciences, Old Dominion University / Norfolk, Virginia, United States.
Email: kbarr011@odu.edu

INTRODUCTION

The shoulder complex boasts a large range of motion, often causing issues with 3D kinematic calculations of joint angles. The international society of biomechanics (ISB) recommends the Euler YXY rotation sequence [1]. However, recent literature has found this rotation sequence produces complications in the tennis serve [2]. The disparity amongst the literature regarding a single "best" sequence for the shoulder supports the idea of individualizing the rotation sequence chosen for calculation based on the movement of the task. Previous investigations on rotation sequences have only included a few movements, mainly including tennis serves [2] and clinical tasks [3,4], leaving large gaps regarding movements relative to other sports. The volleyball attack, a prominent movement intrinsic to the sport, has yet to be evaluated. The purpose of this study was to determine the best rotation sequence for shoulder kinematics when performing a volleyball attack.

METHODS

Ten experienced (10 ± 3.74 yrs of experience) volleyball players were recruited to participate. After providing consent, participants completed a self-selected warmup followed by five overhead attacks aimed straight ahead. Participants were instructed to perform the attack with a follow-through where the arm crossed the body in the front, with the dominant hand ending on the contralateral side. A 12-camera motion capture system was used to record reflective markers placed on the humerus and upper trunk (thoracic and cervical). Shoulder angles were calculated in Visual3D software using six rotation sequences: ZXY, YXY, XZY, YXZ, ZYX, and XYZ (X: anteroposterior, Y: vertical, Z: mediolateral). The trial began at 'takeoff' from the ground and ended at the completion of the follow-through. Instances of gimbal lock and angle agreement with known shoulder ranges of motion (flexion/extension: 210°; abduction: 230°, and rotation: 190°) [2] were recorded.

RESULTS AND DISCUSSION

Group averages (mean(std)) for the YXY sequence were Y_1: 116.81(14.35); X_1: 110.63(11.29); Y_2: 94.75(14.63). All Tait-Bryan sequences are reported in Table 1. The YXZ and XZY sequences frequently presented with irreconcilable responses: rotations exceeded possible limits and never returned to anatomical position despite the participants doing so. Employing the ZYX and ZXY sequences resulted in unrealistic ranges of motion in three participants. The YXY and XYZ sequences produced no instances of gimbal lock or unreasonable ranges of motion in any participant. Despite instances of exceeding limits, group average range of motions were within those reported in literature.

The XZY sequence has previously shown better reliability than the YXY sequence [4] and was suggested to be better for calculating abduction and extension angles at the shoulder [3]. We found untenable angle calculations using this sequence and would not recommend it for use in examining the volleyball attack. This study provides support of both a Tait-Bryan and an Euler sequence. The XYZ may be preferred as the angles are anatomical terms that are frequently used in research/teaching. However, the YZY rotation sequence is more widely accepted, which improves cross-study comparisons.

CONCLUSIONS

We found two rotation sequences to be sufficient in calculating shoulder angles in the volleyball attack: YXY and XYZ. We recommend using the YXY rotation sequence in accordance with ISB recommendations to analyze this movement.

Associations between Unilateral Drop Landing Mechanics and Diaphragmatic Contractility in Individuals with Recurrent Lateral Ankle Sprains

Shunya Nonoyama[1], Masafumi Terada[1], and Tadao Isaka[1]
[1] Faculty of Sport and Health Science, Ritsumeikan University, Kusatsu, Japan.
Email: sh0181ek@ed.ritsumei.ac.jp

INTRODUCTION

Lateral ankle sprains represent one of the most prevalent and frequent musculoskeletal injuries with the highest recurrence rate in athletic and general populations [1]. A variety of motor-behavioral impairments is hypothesized to contribute to the high rate of recurrent ankle sprains (RAS) and to the development of long-term negative consequences of lateral ankle sprains [2]. Altered landing mechanics following an initial ankle sprain is a significant motor-behavioral impairment that is a potential target for interventions aimed at preventing RAS [3]. A prospective cohort study has reported that altered landing strategies may increase the risk of re-injury [4]. Thus, it is crucial to identify clinical factors that is associated with changes in landing biomechanics in order to provide direction for targeted interventions. A previous investigation has identified altered diaphragmatic contractility in individuals with RAS [5]. The diaphragm plays a significant role in maintaining postural stability and executing functional movement by regulating intra-abdominal pressure [6]. Therefore, the alterations in diaphragm function observed previously among patients with RAS may be linked to altered landing mechanics in individuals with RAS. However, no study has explored association of landing mechanics and diaphragmatic contractility in individuals with RAS. Therefore, the purpose of this study was to investigate the association between drop landing kinetics and diaphragmatic contractility in individuals with RAS.

METHODS

Twenty-four participants with RAS volunteered for this cross-sectional study (age: 20.8±1.4 years, height: 170.5±7.8 cm, body mass: 61.8±6.7 kg, # of LAS history: 5.3± 9.7, Min: 2, Max: 50). Participants performed six trials of unilateral drop landing tasks on the force platform in their legs involved with RAS. The following kinetic measures were quantified: a rate of force development (RFD), peak ground reaction force (GRF) in vertical, posterior, and lateral directions. All kinetics were normalized to body weight. Diaphragm contractility of the right and left hemispheres was assessed using ultrasonography in a supine position while breathing quietly. The transducer was positioned perpendicularly at the midaxillary line, over the intercostal space between the 8th and 9th ribs on both sides. Diaphragm thickness at the end of resting inspiration and expiration was measured and used to calculate the degree of diaphragm contractility. Spearman's rank correlation coefficients were used to examine the association between kinetic variables and diaphragmatic contractility. Significance was set a priori at $P < 0.05$.

RESULTS

RFD was positively and moderately correlated with the degree of the right hemidiaphragm contractility (P=0.029). Peak posterior GRF was positively and moderately correlated with the degree of the right hemidiaphragm contractility (P=0.003). Peak vertical GRF was positively and moderately correlated with the degree of the right hemidiaphragm contractility but did not reach statistical significance (P=0.050). There were no significant correlations among other variables (P>0.05, Table 1).

CONCLUSIONS

There were moderate correlations between diaphragmatic contractility and landing kinetic measures. These findings indicate that RAS participants with greater diaphragmatic contractility may have a landing strategy to manipulate higher magnitude of GRF and RFD. Future investigations are required to determine effects of therapeutic intervention aimed to improve diaphragmatic contractility on landing mechanics in patients with RAS.

INTRODUCTION

According to previous research, grading of jumping height is done by adjusting joint angles and movement time, not by adjusting muscle strength [1]. However, in many sports competitions, not only "high" and "accurate" jumps, but also "quick and accurate" jumps are required in some situations. There are few studies that have clarified the jumping height, whole-body reaction time, and joint angle changes when a certain condition of jumping height is demanded in jumping "quickly and accurately".

The purpose of this study was to clarify the changes in jumping height, whole-body reaction time, joint angle, and angular velocity of grading by jumping movements with the awareness of jumping "quickly and accurately" in addition to jumping "quickly and high".

METHODS

Fifteen male university students were used as subjects. Vertical jumps were performed. First, the subjects performed a jump with unconditioned maximal effort (F100), followed by three sets of jumps at 100%, 70%, and 50% height in grading (R100, R70, and R50, respectively). Finally, F100 was performed again. In the grading jumps, subjects were told the target percentage of each grading before the test and instructed to jump quickly in response to the light stimulus. Subjects wore a suit with reflective markers attached, and displacement of each joint and site was measured by video recording. Whole-body reaction time was measured by measuring the time it took for the foot to leave the mat after the light stimulus was visible from the measuring device. From the videos, the body center of gravity was obtained using Flame DIAS55 software, and the jumping height was calculated. The jumping height was analyzed by comparing the target and measured values in grading. From the joint angles, changes and angular velocities of the hip, knee, and ankle joints were calculated. For angular velocity, the peak angular velocity during the jumping motion and the time of its peak appearance were calculated.

RESULTS AND DISCUSSION

Significant differences were found between F100 and R70, F100 and R50, and R100 and R50 in jumping height, and jumping height decreased with decreasing target values. Subjects may have been able to distinguish leap height in terms of effort between target values even in quick conditions such as those in this study. The target (F100, T70, T50) and measured (R100, R70, R50) values for each trial by grading are shown in **Figure 1**. As the target value decreased, the measured value exceeded the target value. A previous study reported that the difficulty of grading as the subjective effort was decreased was due to subjects' underestimation in grading, and that grading became more difficult the further away from the reference value the subjects moved [2]. The present study showed similar results.

The whole-body reaction time did not differ depending on the grading conditions, suggesting that it was not affected by the movement reaction time.

The joint angle changes and angular velocities revealed that the hip and knee joint flexion angles were significantly smaller in F100 than in R100, indicating that the range of motion of the joint angles from the preparatory movement to the take-off was greater in F100. It was thought that grading was performed by the extension movements of these two joints in the vertical jump by quick movements.

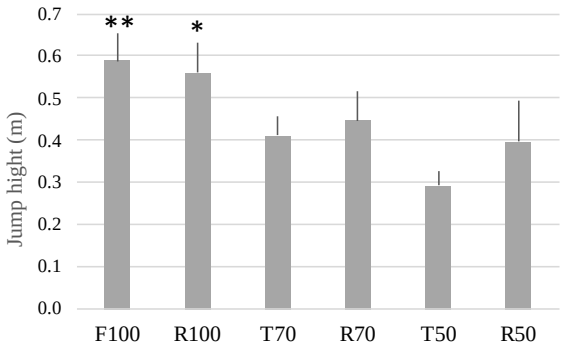

Figure 1 Target and measured values in grading (n=15). (**: R100 vs R50;P<0.05, **: F100 vs R70,R50; P<0.01)

CONCLUSIONS

It was found that in the rapid jumping motion, grading of jumping height was performed by the hip and knee joints by adjusting the amount of joint angle change.

INTRODUCTION

Sport-related injuries increase in males throughout high school, with ~68% of adolescent injuries occurring in the lower extremity [1, 6]. This is likely due to rapid, physiological changes during puberty such as bone growth and increased muscle mass, which can increase the forces experienced by the body and be a factor for higher prevalence of lower extremity injuries [2]. According to a recent study, growth-related injuries account for 30% of all severe injuries that require at least 40 days of participation time lost in soccer academies. Thus, the reduction of growth-related injuries can be important in the prevention of long-term repercussions and maximization players' potential development [5].

Investigating acceleration performance throughout puberty can provide insight into managing training load to reduce injury while also optimizing performance [3]. Therefore, the purpose of this study was to investigate the peak acceleration and acceleration integral in youth soccer players when performing various agility drills between maturation groups. It was hypothesized that peak height velocity (PHV) [4] could be estimated by peak accelerations and acceleration integrals.

METHODS

Sixty-six male youth soccer players were recruited from a local soccer club to voluntarily participate in this study (age: 12.7 ± 2.2 years). The Mirwald equation was used to determine how close the players were to their PHV. Inertial measurement units were placed on the participants bilaterally on the distal-medial tibia Participants completed a M-cone drill in which the participants ran in an M shape and made sharp cuts at each cone Data were analysed using Python v3.10.4 (Python Software Foundation, Beaverton, OR, USA). A simple linear regression was used to test if peak acceleration and an acceleration integral significantly predicted PHV (α = 0.05) using SPSS (IBM Corporation, Armonk, NY, USA).

RESULTS AND DISCUSSION

The results of the regression indicate that peak acceleration explained <0.01% of the variation in PHV [$F(1,64)=0.001$, $p=.981$]. The results of the second regression indicate that acceleration integrals explained 0.03% of the variation in PHV [$F(1,64)=0.216$, $p=.644$]. Our hypothesis that PHV could be estimated by peak accelerations and acceleration integrals was not supported. It was believed that the rapid physiological changes of increased bone and muscle mass would increase impact accelerations measured at the distal tibia. However, the results of this study emphatically refute that claim indicating the participants were able to adapt their impact attenuation along with their physiological changes.

Figure 1 Peak Height Velocity as a function of acceleration integral

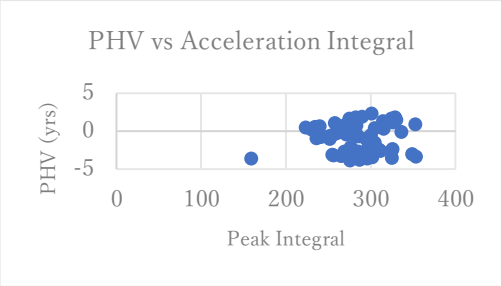

Figure 2 Peak Height Velocity as a function of peak acceleration

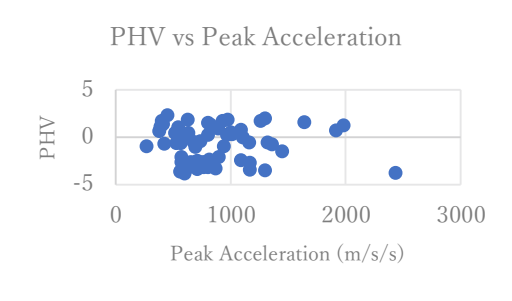

CONCLUSIONS

The results of this study provide the first evidence that acceleration performance does not increase throughout puberty. This does not align with the results of previous research [1,3,6], but our findings suggest that the changes in physiology and motor control during puberty might not be drastic enough to place players at a significantly higher risk of injury. Further research could track the acceleration performance in this age group throughout a whole practice.

INTRODUCTION

The barbell bench press is a popular exercise for enhancing the strength of the upper limbs. Maximum strength development demands a high intensity training stimulus, such as 1-4 maximum repetitions (RM) per training session [1]. However, there are limited studies observing muscle activity in the different phases of the movement during bench press at 4RM intensity.

METHODS

A cross-sectional study with repeated measurements as part of the research project was used to examine differences in the electromyographic activity during different phases of 4RM bench press. Twenty three recreationally bench press practicing participants volunteered in the study (body mass: 84.8 ± 8.9 kg, age: 23.3 ± 2.5 years, height: 181.9 ± 5.0 cm). The study included three familiarization sessions and one testing session, with at least a 72-hour interval between each session. EMG activity was recorded using Musclelab 6000 (Ergotest Technology AS, Langesund, Norway) and was collected as an average during pre-sticking (pre stick) sticking (stick) and post-sticking (post stick) phase. Electrodes were placed according to SENIAM guidelines on the: Rectus Abdominis (RA), Obliquus Abdominis (OA), Triceps Brachii, caput longum (TB), Latissimus Dorsi (LD), Anterior Deltoideus (AD), Deltoideus Posterior (DP), Pectoralis Major, pars sternalis (PM_S), Pectoralis Major, pars clavicularis (PM_C). The raw EMG signals were transformed to the square root of the mean (RMS) value by a hardware peripheral network (frequency response 20-500 kHz, averaging constant 100 ms, total error ± 0.5%). Data were sampled at 1000 Hz. The one-way ANOVA was used to evaluate differences in muscle activation between the phases during all repetitions. A repeated measures ANOVA was used to calculate the differences between repetitions, phases, and muscle activation.

RESULTS AND DISCUSSION

There were significant differences in all muscle activity between the phases: RA, $F(4,1865)=12.34$, $p < 0.001$, OA, $F(4,1865)=15.6$, $p < 0.001$, TB, $F(4,1865)=20.09$, $p < 0.001$, LD, $F(4,1865)=10.71$, $p ,< 0.001$, AD, $F(4,1865)=29.62$, $p < 0.001$, DP, $F(4,1865)=44.5$, $p < 0.001$, PM_S, $F(4,1865)=31.88$, $p < 0.001$, PM_C, $F(4,1865)=25.05$, $p > 0.001$. A Tukey post hoc revealed that activation of all muscles differed between each of the phase statistically significantly $F(4,1864)=78.36$, $p < 0.001$. However, the highest difference occurred in the pre stick phase compared to the other phases in every repetition. There was also statistically significant difference in muscle activity between repetitions $F(3,1865)=69.4$, $p < 0.001$. However, there was no significant difference between the muscle activity in each of the phases and repetitions $F(12,1849)=1.54$, $p = 0.1$.

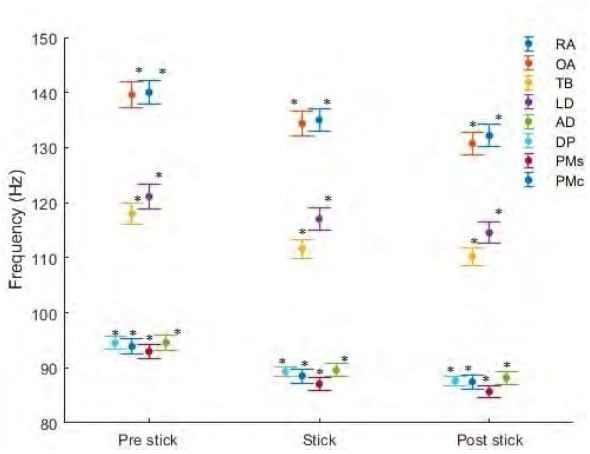

Figure 1 Frequency of discharge of individual muscles in each part of the movement phases in 4RM. *significant differences between the phases of the movement

CONCLUSIONS

Sticking phase is the most mechanically demanding point to surpass during a bench press exercise. Therefore, a decrease in muscle activity indicates exhaustion caused by overcoming this point which is observed in each of the 4RM. This exhaustion also remained in the post sticking phase.

INTRODUCTION

Our research group has found the movement characteristics of a world champion couple in competitive ballroom dancing during waltz swing [1,2]. So far, forward movement in male and backward movement in female have been focused, but the reverse movement has not yet been analyzed. The purpose of this study is to find the movement characteristics of the world champion ballroom dance couple, focusing on backward movement for male and forward movement for female.

METHODS

Thirteen national level competitive ballroom dance couples participated. The age, height, and weight were, respectively, 24.3 ± 5.6 years, 173.4 ± 6.3 cm, and 61.1 ± 4.9 kg in males, and 22.6 ± 4.7 years, 161.2 ± 6.1 cm, and 47.6 ± 5.0 kg in females. In addition, A couple that had been champions in professional competitive ballroom dancing for 10 years participated. Age, height, and weight of the champion male dancer were 40 years, 183 cm, and 76 kg; those of the champion female dancer were 40 years, 169 cm, and 52 kg.

The movements were recorded at 240 Hz using the Xsens system (MVN, Xsens, Netherlands). The trial was performed as follows. 1. Preparation (123123); 2. Natural spin turn (123123); and 3. Second half of reverse turn (123). This method is the same as our previous research [1,2]. Statistical Parametric Mapping (SPM) [2] was performed on the height of the whole body center of mass of one swing in the second half of the natural spin turn (Figure 1).

RESULTS AND DISCUSSION

As a result of SPM, there was a significant difference in the first half between the champion male dancer and the male dancers. During the descending movement in the first half, the champion male dancers descended faster and reached a lower position than the male dancers. In the rise and fall movements, the champion male dancers were superior to the male dancers in descending dance skills. On the other hand, there was a significant difference in the last part of the second half between the champion female dancer and the female dancers.

CONCLUSIONS

Even when the male dancers moved backwards and the female dancers moved forwards, the movement characteristics of the champion male and female dancers appeared.

INTRODUCTION

Many dynamic sports motions are performed by the spring-like behaviours of the whole body. This can be usually assessed by leg stiffness during the hopping jump [1], that is conventionally measured by a force plate.
Recently, wearable technology has become widely prevalent in assessing sports performance. Particularly, accelerometers and gyrosensors in smartphones are used for the assessment of sports performance [2]. However, to the best of our knowledge, smart watches that can be easily attached to the wrist are still not used for assessing kinetics during dynamic sports motions. Therefore, the purpose of this study was to test the agreement between the spring-like behaviour performances during the hopping exercise calculated using two different methods: a method measured by force plates and a method measured by a smart watch.

METHODS

Forty active sports students participated in this study (71.9 ± 10.6 kg in mass). After a self-selected warm-up and familiarisation period, each participant completed five trials of five consecutive hops with maximal effort. Maximal effort was defined as the effort to try to achieve the maximal attainable height. Participants hopped in place with their arms akimbo. Data collected during three consecutive hops between the second and fourth hop of five hops were used in the analysis. A total of 600 hops were obtained.
During the experimental trials, the ground reaction force (GRF) and acceleration data were simultaneously collected at frequencies of 1,000 Hz and 100 Hz, respectively. GRFs of feet were sampled from two force plates (0.40 m X 0.40 m; TFP-404011B, Technology Service, Nagano, Japan). Acceleration data were sampled from a smart watch (Apple watch series 7, Apple, CA, USA). Actual peak vertical GRF (peak force), peak leg compression in the middle of the ground contact phase (COM displacement), and leg stiffness were calculated using the spring–mass model for each jump in each method [3]. The peak force and leg stiffness were normalised by body mass; so, they can be calculated using a smart watch without measuring the participant's mass. The predicted peak force, COM displacement, and leg stiffness were calculated from the acceleration data of a smart watch using a custom MATLAB program. The validity of the spring-like behaviour performance predicted with the smart watch was examined by the Brand-Altman analysis.

RESULTS AND DISCUSSION

The peak force predicted by the smartwatch was strongly correlated to the actual peak force predicted by the force plate (r = 0.708; Figure 1A). Bland-Altman upper and lower limits of agreement were −17.5 N/kg and 19.4 N/kg, respectively (Figure 1B). Both the fixed bias (1.0 N/kg of Figure 1B) and proportional bias (r = 0.229 of Figure 1B) were small.

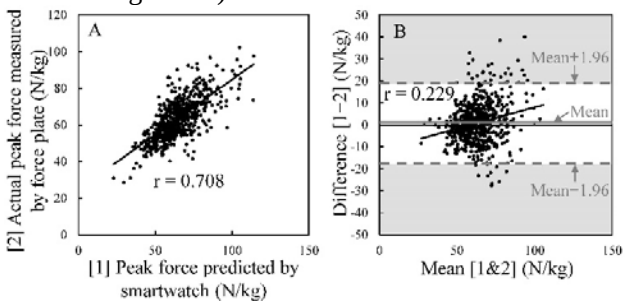

Figure 1 Panel A. Relationship between predicted peak force and actual peak force. Panel B. Bland-Altman plot for comparison of peak force between smart watch method and force plate method. The grey area indicates out of the limits of agreement.

The predicted leg stiffness by the smart watch was and moderately correlated with the actual leg stiffness by the force plate (r = 0.489). By Bland-Altman plot for comparison of leg stiffness, the random error (upper and lower limits of agreement: −0.303 N/m/kg and 0.214 N/m/kg) and proportional bias (r = −0.414) were not negligible. Therefore, during hopping, leg stiffness using the smart watch should be carefully assessed.

CONCLUSIONS

We conclude that force production, such as peak force during hopping, can be estimated by acceleration data measured by a smart watch. In contrast, the algorithm should be reconsidered and improved for the prediction of leg stiffness using a smart watch.

CROSS-SECTIONAL AREA OF HAND INTRINSIC MUSCLES AND UPPER LIMB LENGTH ASSOCIATED WITH THROWING RECORD OF FEMALE DISCUS THROWERS

Yukiho Arano[1], Shigeo Hatakeyama[2], Toshiyuki Homma[3] and Mitsuo Otsuka[1,2]

INTRODUCTION

In the discus throw discipline, several previous studies on high performance have focused on analysing throwing motion and its relationship with the throwing record of the thrower [1]. In particular, the initial velocity of the discus at release is considered an important determinant of long throwing distance [2]. Before the release motion, the discus is gripped by the distal interphalangeal (DIP) joints of the throwing hand and moves around the thrower by his/her turning motion. Therefore, a larger centrifugal force is applied for greater throws, to the hand holding the discus, immediately before release.
Conversely, the magnitude of the centrifugal force decreases when the turning radius increasesd. Hence, hand muscularity and arm length would be related to the throwing record of discus throwers because of their specific adoptation. The purpose of this study was to clarify the relationship between the morphological characteristics of the upper limbs and the throwing records of discus throwers.

METHODS

Twenty female discus throwers (age 20.6 ± 1.5 y; body height 165.90 ± 3.71 cm; mass 71.4 ± 7.2 kg; personal record of discus throw 44.70 ± 5.20 m) participated in this study.
The cross-sectional area (CSA) of the dominant hand muscles was measured in the transverse plane using a 1.5-T magnetic resonance system (ECHELON OVAL, Hitachi Medical Corporation, Tokyo, Japan). Hand images were acquired using a knee coil positioned at the centre of the magnet. The location of the distal end of the first metacarpal bone was analysed to determine the CSAs of the hand muscles. The anatomical CSAs of the dorsal interosseous, palmar interosseous, opponens digiti minimi, abductor digiti minimi, lumbrical, adductor pollicis, flexor pollicis brevis, and abductor pollicis brevis muscles perpendicular to the third finger were calculated.
The dominant upper limb length from the midpoint of both clavicles to the distal end of the third distal phalanx was measured twice using measuring tape. The average value of the two measured lengths was used for further analysis.

RESULTS AND DISCUSSION

No significant relationships of the personal record were observed between the CSAs of the dorsal interosseous, palmar interosseous, opponens digiti minimi, abductor digiti minimi, adductor pollicis, flexor pollicis brevis, or abductor pollicis brevis muscles. The lack of significant relationships may be because we focused on female throwers who handled a light 1.0 kg compared to male throwers. In contrast, a significant relationship was observed between the personal record and the CSA of the lumbrical muscles ($r = 0.581$; $P < 0.05$; Figure 1). The lumbrical muscles have a many muscle spindles and produce not only metacarpophalangeal (MP) flexor forces but also DIP extensor forces. Therefore, the hand intrinsic muscles of greater throwers might play a role in manipulating the discus by flexing the MP joints during the faster turn, monitoring the discus motion, but fixing the DIP joints against a larger centrifugal force.
A significant relationship was observed between the length of the dominant upper limb and personal record ($r = 0.475$, $P < 0.05$). Hence, the longer upper limb length of greater throwers might lead the centrifugal force to reduce. Finally, it might lead the flexor digit muscles of intrinsic hand to not develop further.

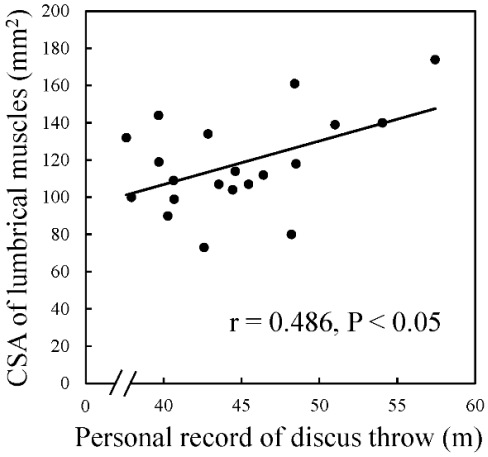

Figure 1 Correlation between the personal record of discus throw and cross-sectional area (CSA) of lumbrical muscles.

CONCLUSIONS

The dominant upper limb length was longer, and the CSA of the lumbrical muscle was larger in the greater discus throwers. Further research is required to clarify the CSA of the hand intrinsic muscles in other slice images and the relationship with the throwing record.

INTRODUCTION

The egg beater kick is used in AS (Artistic Swimming) and water polo to keep the body in the water or lift it, and is a technique that generates propulsion in the vertical upward direction (buoyancy). Furthermore, in order to obtain more points for techniques, it is important not only to keep the body on the water surface, but also to raise the height above the water, so it is important to demonstrate a higher vertical propulsion force [1][2].

Optical motion capture systems, which are mainly used in recent years, use cameras to track markers attached to the body surface must be estimated. In this study, we estimated the center of the hip joint during the eggbeater kick, and investigated the relationship between each joint angle calculated from those points and the propulsive force in the vertical direction.

METHODS

The subjects were 8 females who had participated in AS (Age: 21.6, Height: 159.1cm, Mass: 55.6kg). Trials were performed 2 times at random in 3 trials. 1: Eggbeater kick with a weight of 2.5 kg (2.5kg). 2: Eggbeater kick with a weight of 5.0 kg (5.0kg). 3: Eggbeater kick in a normal state (Normal). In all trials, the weights and hands were instructed not to touch the surface of the water in order to avoid buoyancy on the weights. In addition, 18 self-luminous LED markers on the body (iliospinale anterius, iliosinale posterius, greater trochanter, outside the patella, inside the patella, lateral malleolus, medial malleolus, 5th metatarsal bone, left and right of the 1st metatarsal bone) affixed and obtained 3D motion. In the analysis phase, the right leg was targeted, and one cycle was defined as the time when the knee joint reaches maximum extension from the maximum flexion state and returns to maximum flexion again. In addition, the angle of the hip joint was determined by estimating the hip joint center using iliospinale anterius, iliosinale posterius, and greater trochanter landmarks [3]. Abduction and internal rotation were calculated (Figure1).

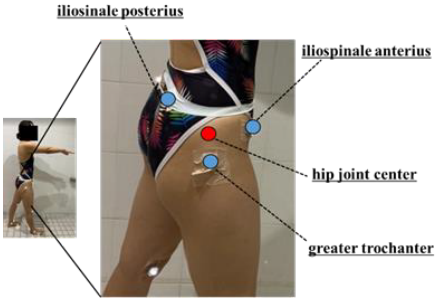

Figure 1 Estimation of Center of hip joint.

RESULTS AND DISCUSSION

During all trials, the duration of one cycle became larger and showed significantly lower values as the propulsive force increased (Normal: 0.64s, 2.5kg: 0.57s, 5.0kg: 0.54s). Table. 1 shows the average maximum and minimum values of hip flexion, abduction, internal rotation, knee flexion, and ankle plantar flexion in each trial. As a result, it was suggested that by increasing the abduction of the hip joint in the eggbeater kick, the water is captured from nearer the surface of the water and the propulsive force is increased. In addition, it is speculated that the knee joint is also flexed in the second half of one cycle, bringing the foot that catches the water closer to the water surface. However, although the hip joint abduction (HA) maximum value was significantly increased, the duration of one cycle was significantly shortened. This is thought to be due to an increase in the angular velocity of abduction. Therefore, swimmers may need to increase the contraction speed of the muscle groups around the hip joints to increase the angular velocity of abduction.

Table 1 Comparison of mean of each variable between trials.

		Normal (degree)			2.5kg (degree)			5.0kg (degree)		
		Mean	±	SD	Mean	±	SD	Mean	±	SD
Hip joint Flexion (HF)	Max	99.1	±	8.2	97.3	±	12.4	99.8	±	9.1
	Min	52.9	±	8.1	51.4	±	9.2	52.9	±	9.4
Hip joint Abduction (HA)	Max	61.7	±	6.4	66.8	±	6.4	70.1	±	9.2
	Min	51.0	±	5.8	51.3	±	6.1	53.7	±	5.9

	Min	76.3	±	20.0	67.6	±	26.4	75.9	±	17.4

* p<o.o5, ** p<0.01

CONCLUSIONS

The results of this study suggested that increasing the abduction of the hip joint may be important in obtaining higher propulsive force in the eggbeater kick.

INTRODUCTION

In paralympic cross-country sit skiing, one of the main difficulties, in the beginning, is to find the most effective sitting position on the sledge. Athletes need an adjusted sledge optimised for their particular impairment [2]. The goal of this experiment was to develop a setup to define biomechanical and neurological parameters that help to construct individually adjustable sledges. Its requirements are to enable different sitting positions to meet different anthropometric and individual characteristics of athletes [2]. Biomechanical and neurological parameters were compared in the different positions with a special focus on forward propulsion and trunk muscle control.
The purpose of this pilot study was to understand the impact of the sitting position on the forward propulsion and therefore on the feature performance of the athletes.

METHODS

In the pilot phase of this experiment five healthy able-bodied subjects, without experience in nordic skiing participated (21 ± 4 years.; F). The Experiment was performed on a treadmill with a wheel-based adjustable sledge. The three positions of the sitting platform were defined as knee-high (KH), neutral (NT) and knee-low (KL), similar to the different classes defined by the para-nordic guidelines for sit skiing. Each participant was tested in every sitting position at the same individually chosen constant speed for six minutes, performing a double poling technique. Pole forces and bipolar surface electromyography (EMG) of three trunk muscles and three muscles of the upper limbs were simultaneously recorded on the dominant side. The propulsive pole force and the EMG activity of the recorded muscles in the different sitting positions were analysed and compared off-line.

RESULTS AND DISCUSSION

Using the exerted force as a variable to compare the different sitting positions, a trend towards the highest propulsive forces in the KH position and the lowest forces in the KL position is visible. This is also reflected in the poling frequency, which is higher in the KH position than in NT and KL. KL yields the lowest value. The KH position showed the shortest cycle lengths and KL the highest. Poling time per cycle was the shortest in the KH position. These results are in agreement with results found in the literature [1]. The activation of the *m. obliquus externus abdominis* was at a similar level of activation in all positions, the activation of the *m. erector spinae* was clearly reduced in the KH position (Figure 1). Activation of *m. rectus abdominis* was slightly higher in the KL in comparison to the NT positions, while the KH position, showed a reduced activation strength, which, however, extended into the recovery phase. A pre-activation of the *m. rectus abdominis* was seen towards the end in all positions.

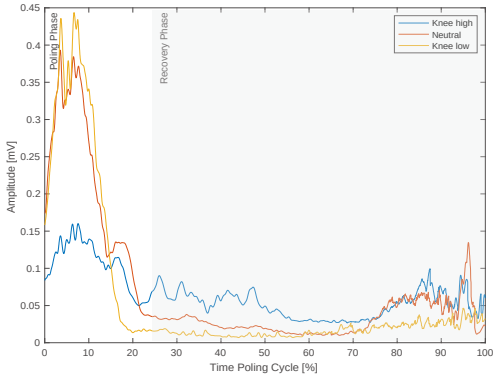

Figure 1: Mean EMG activation pattern of *m. rectus abdominis* in all sitting positions during the poling cycle

CONCLUSIONS

Visual differences between the three sitting positions were seen in the propulsive force output. Comparing the sitting positions, activation of trunk muscles responsible for flexion and extension differ in activation amplitude while the muscles that execute lateral tilt do not seem to differ. In further experiments this setup should be tested with paralympic athletes. Overall, the developed adjustable sledge and the measured biomechanical parameters offer an experimental setup that can provide insights into optimal sitting positions in paralympic cross-county sit skiing.

INTRODUCTION

In para-athletics wheelchair racing, trunk extension after pushing on the hand-rims reportedly increases wheelchair velocity. The present study was conducted to verify this phenomenon. Specifically, the centers of gravity (COGs) for the body and wheelchair were calculated and the relationship between trunk extension movements and change in each COG was investigated.

METHODS

The subject was one male wheelchair athlete in the T52 class as defined by World Para Athletics. A 12-camera Raptor-E motion capture system (MAC3Dsystem, Motion Analysis Corporation) was set up on an indoor straight course to capture propulsive movements in the final 10-m section during the 50-m sprint. Prior to the experiment, the athlete and wheelchair were affixed with 38 and 10 reflective markers, respectively. After an adequate warm-up, the athlete was instructed to run 50 m with maximum effort. The reflection markers were captured at 250 Hz during propulsive motion and the body COG was calculated from the 3D coordinates of the reflection markers. The wheelchair COG was calculated as follows. The wheelchair with reflective markers attached was suspended in two different postures and captured by camera from the side. The COG in the sagittal plane was defined as the intersection of the vectors from the suspended position to the vertical direction in the two different postures, and the COG in the frontal plane was defined as the same distance as the midpoint of the left and right rear wheel axles. The angle of trunk flexion/extension was defined as the angle between the y-axis (direction to the goal) and the vector pointing from the sacrum to C7, projected in the y–z plane of the global reference frame.

RESULTS AND DISCUSSION

The COG velocity of the wheelchair increased near the start of the push phase, and peak velocity was observed in the first half of the recovery phase. The COG velocity of the body also increased during the first half of the push phase, but showed a tendency to remain constant during the first half of the recovery phase. Peak angular velocities of trunk flexion and extension were observed in the first half of the push and recovery phases, respectively. Change in the COG velocity of the whole system (combined body and wheelchair) was similar to that of the body. The wheelchair COG velocity should have decreased during the recovery phase due to air and road resistance, but no such decrease was observed. This result suggests that extension of the trunk moved the COG of the body backwards, increasing the COG velocity of the wheelchair to maintain the COG velocity of the whole system.

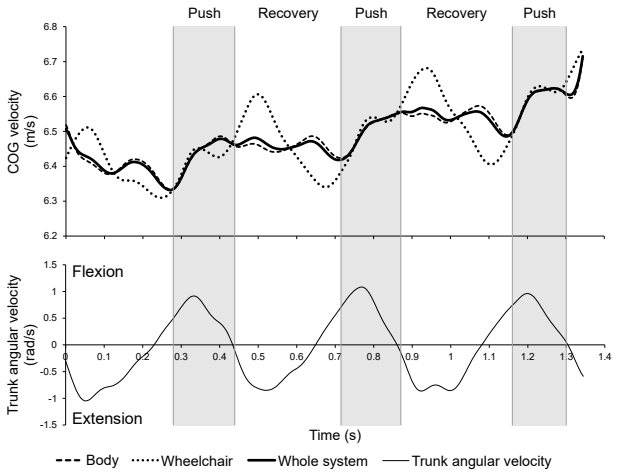

Figure 1 Velocity curves of COG and trunk angular velocity.

CONCLUSIONS

This study calculated body and wheelchair COGs and investigated the relationship between trunk extension movements and change in each COG. The results suggest that the increase in wheelchair COG velocity during the recovery phase contributes to maintaining constant COG velocity of the whole system.

INTRODUCTION

Non-specific chronic low back pain (NSCLBP), which is reported to be unable to determine a specific diagnosis, has a multidimensional cause in which various factors are interrelated [1,2]. Core stabilization exercises aim to strengthen muscles in the transversus abdominis, lumbar multifidus, erector spinae, diaphragm, and back, which are important for maintaining neuromuscular control and dynamic spinal stability [3]. Therefore, the purpose of this study was to investigate the effect of a complex exercise including core stabilization exercise on the muscle contractile properties of the erector spinae muscles in patients with NSCLBP.

METHODS

This study was conducted with 16 women (age; 59.81±8.59 years, height; 158.16±5.58 cm, weight; 59.05±9.44 kg, visual analog scale; 5.94±1.01 points) suffering from NSCLBP. The subjects performed a complex exercise of 4 weeks. Tensiomyography (TMG, TMG-100 System electrostimulator, Slovenia) was used to compare and analyze the static contractile properties of erector spinae muscles. In order to compare and analyze the contraction characteristics of the measured muscle, measure-remeasurement and intra-rater reliability index (ICC) is the highest variable, maximal radial displacement (Dm, 0.91-0.99), a variable that records the maximum contraction displacement of the muscle, and contraction up to 10 to 90% of the maximum contraction displacement. A contraction time (Tc, 0.70-0.98), which is a time-consuming variable, was used [4]. In addition, velocity of contraction (Vc), a variable that can integrate the mechanical properties provided by TMG, was calculated and analyzed by the formula [$Vc\ (mm/ms) = Dm/Tc+Td$]. SPSS 26.0 (IBM, USA) was used for all data, and paired *t*-test was used to compare measurement result variables within the group. The significance level of all statistics was set at $P<.05$.

RESULTS AND DISCUSSION

After participating in the multimodal exercise intervention program, there was a significant difference between the measurements of Dm (P=0.016) and Vc (P=0.047), excluding Tc <Figure 1>. It is judged that Dm, which has a negative correlation with muscle stiffness, is likely to have risen as stiffness has decreased due to foam rollers and exercise [5]. In addition, it is judged that the activation of the erector spinae muscle increased due to exercise, and the muscle contraction speed variable Vc increased [6,7].

CONCLUSIONS

After participating in the complex exercise intervention program, muscle stiffness of the erector spinae muscles decreased and muscle contraction speed increased in subjects with non-specific chronic low back pain.

ACKNOWLEDGEMENTS

INTRODUCTION

Highly-trained athletes of wheelchair racing show unique modalities and extraordinarily enhanced upper limb motor function that far exceed to daily use of wheelchair propulsion [1]. For the fairness of competition, wheelchair racing has a classification as their residual function. In the case of T54 class, the propulsive force is generated by the postural control and kinetic chain with the combination of upper limb and trunk functions. In contrast, racers classified as T51 have limited propulsive force due to the paralysis of their upper limb and trunk muscles but demonstrate particular compensatory upper limb movement. Such sort of residual function-depend strategy of propulsive force is worth trying to characterize biomechanical features for a better understanding of the performance of wheelchair racing. In order to deeply and precisely understand the mechanisms underlying wheelchair racing, we developed a testing simulator that enables us to measure the torque of the wheel and adjust various settings (e.g., camber angle, axle position). This study aimed to characterize the strategies of wheelchair propulsion based on the biomechanical evaluation for a wide range of residual functions and skill levels in athletes of wheelchair racing.

METHODS

Six wheelchair racers with variated ages, classifications and proficiency participated in this study. We recorded the kinematics of the upper limbs and trunk with a motion capture system (Optitrack, NaturalPoint inc., 240Hz), and the propulsive force were obtained by torque meter (UTM II, UNIPULSE corp., 1000Hz) implemented on the axle of the custom-developed simulator. The electromyography was recorded from 8 muscles on each left and right torso and upper limbs (Trigno, Delsys inc., 1000Hz). The subjects were asked to perform 20 to 30 strokes of propulsion while keeping approximately 80% of maximal effort. Ensemble averaged waveform was obtained from a chosen 10 to 15 strokes from the recorded trials.

RESULTS AND DISCUSSION

Figure 1 shows kinematic and kinetic profiles during wheelchair propulsion obtained from five athletes with spinal cord injury. The hand-rim angle at the contact and release timing gradually altered not only with the level of injury/classification but also skill level. For example, two Paralympians showed dynamic motion and higher torque exertion with relatively deep propulsion until 7 o'clock.

CONCLUSIONS

Comprehensive biomechanical analysis for wheelchair racers enables us to understand an individual's strategy for wheelchair propulsion. Our developed system has potentials to reveal mechanisms underlying wheelchair propulsion and then give athletes/coaches useful into for their training.

INTRODUCTION

Individuals with lower limb disabilities may perform cross-country skiing in a sitting posture, where ski-skiers sit on a chair to perform a double-poling technique. In comparison to traditional skiing, chair design is considered as an important element that potentially influences the performance of sit-skiing. However, the research and development of cross-country sit skiing are hindered by the limited population. Previous studies recruited able-bodied to perform sit ski and, abled body and disabled body showed discrepancy and bias from ski economy and biomechanics perspectives [1,2,3]. Particularly, able-bodied is able to generate propulsion force from lower body even though in sitting posture [4]. In order to simulate sit-ski as similar as disabled body, this study investigated the effects of seat pan angle and lower leg stabilization on lower limb muscle activation (muscle onset) of hip flexors and extensors, namely rectus femoris and biceps femoris muscles during simulated sit-ski.

METHODS

Eight abled-bodied university male students belong to sports club were recruited for this study. This study was approved by Research Ethics Committee of the Faculty of Design at Kyushu University.

A ski ergometer (Concept2, USA) and a custom-made chair with an adjustable seat pan angle (0°, 10°, and 20°) and lower leg stabilizer were used to simulate double poling during sit-skiing. Next, surface EMG was recorded from the right rectus femoris and right biceps femoris muscles using surface bipolar active EMG electrodes (BA-U410m; Nihon Santaku, Osaka, Japan), which were amplified using a bio-instrumentation amplifier (BA1104m; Nihon Santeku, Japan), band-pass filtered (15-500 Hz), and full-wave rectified. The EMG data were A/D converted using a PowerLab 16/30 device (ADInstruments, New Zealand) and transmitted to a laptop computer. The participants were instructed to perform double poling in a total of seven conditions: standing and three seat pan angles (0°, 10°, and 20°) with lower leg stabilization conditions (with, without) (Figure 1a,b). The double-poling target was 50 strokes per minute with an output of 65 watts. Subsequently, EMG analysis period was set to 20 strokes after 30 s. Threshold-based method was utilized to determined muscle onset of both rectus femoris and hamstrings.

RESULTS & CONCLUSIONS

Both rectus femoris and biceps femoris showed activation during sit-ski (Figure 1c) at all seated condition. Additional muscle onset timing showed indicate the rectus femoris and bicep femoris were activated at double poling and recovery phase, respectively. Our results suggest that seat pan angle and without lower limb stabilizer could potentially minimize the muscles onset of rectus femoris but not biceps femoris.

ACKNOWLEDGEMENTS

The authors would like to thank the participants of the study for their participation.

INTRODUCTION

The lymphatic system's capacity for clearing and recycling waste entities is essential in all aspects and stages of life. Near-infrared (NIR) imaging has been shown to accurately report lymphatic and vasculature fluid flow in an effort to better understand disease progression [1]. However, little is known about the *in vivo* drainage of tendons, especially Achilles tendons. Describing the size-dependent nature of drainage out of a region of interest is an essential first step in understanding the overall phenomenon of fluid transport, as shown previously in the rat knee joint [2]. This is exciting as previous work has demonstrated lymphangiogenesis to occur after injury to the Achilles tendon [3], meaning that a better knowledge of the mechanics at play can lead to future interventions in the healing process. We use an *in vivo* NIR imaging setup to compare the period in which the rat Achilles tendon clears out a lymphatic draining 20kDa PEG (Poly(ethylene glycol)) conjugated NIR dye, whose size prevents entry into blood vessels, to the drainage of NIR dye alone through the vasculature.

METHODS

Female Sprague-Dawley rats (Charles River Labs, 3-12 months old) received a 15µL intratendinous injection of either 20 kDa PEG conjugated with IR dye (n=5, 3 animals euthanized after 24 hours) or the IR dye alone (LI-COR, n=3) in one hind limb Achilles tendon. Subjects with missed injections were excluded. While under anesthesia, the subjects were imaged using an IVIS Spectrum (PerkinElmer) machine to measure the intensity of dye in the Achilles tendon region. At progressive timepoints after the injection (1, 3, 6, 24, 48, 72, and 96 hours), the subjects were once again anesthetized and imaged using the same settings to measure the intensity of dye remaining in the target region. The average radiance was calculated for an automatically generated freeform region of interest using the Living Image Software program (PerkinElmer) with a 4% threshold for all images. The radiance values were then normalized to the dye intensity at 1 hour. Calculations and data analysis were done in Prism (GraphPad).

RESULTS AND DISCUSSION

Normalized average radiance (the intensity of the dye remaining in the tendon space) is shown as a function of time after injection as both visualized and plotted data (Figure 1). The half-lives of the exponential fit lines to the data (2.98 hours for the conjugated dye, 2.19 hours for the dye alone) show that size-dependent clearance exists in the Achilles tendon space. Future studies involving histology of tissues and biodistribution of the dye are necessary. Experiments are also planned to observe the effects that exercise post-injection may have on the tendon space drainage kinematics in line with literature studying other regions [2]. Further, injury models may describe how lymphangiogenesis in the region might change the fluid transport properties.

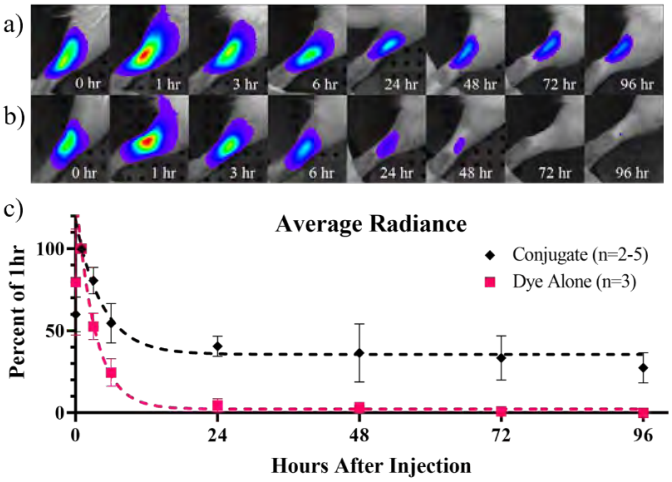

Figure 1: (a) Conjugate dye and (b) dye alone intensity decreasing over time in IVIS captures. (c) Average radiance of the two groups over time normalized to the value at 1 hour post injection.

CONCLUSIONS

In this study, we showed the rate and size dependency of biotransport of the rat Achilles tendon. Fluid transport of tendon tissue is a limited scientific space and the procedure described here helps lay the groundwork for future discoveries. Defining the kinematics of fluid transport is an essential first step to understanding the regenerative dynamics of tendons and potential interventions.

SENSITIVITY ANALYSIS OF FOUR GRAFT PARAMETERS ON KNEE KINEMATICS FOLLOWING PEDIATRIC ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION: A LINKED NEUROMUSCULOSKELETAL-FINITE ELEMENT MODELLING APPROACH

INTRODUCTION

Optimizing anterior cruciate ligament (ACL) reconstruction (ACLR) surgery is an active research focus [1]. Given variations in graft insertion, pre-tension, type, and other parameters, the ACLR presents surgeons with many options to consider. Finite element (FE) simulations can provide insight into consequences of different surgical choices on post-operative knee biomechanics [2]. We developed a linked neuromusculoskeletal (NMSK)-FE model of the paediatric knee for pre-surgery planning. Here, we assessed the sensitivity of post-operative knee kinematics to four graft parameters: type, diameter, location, and pre-tension.

METHODS

For each of the four graft parameters, three variations were used, and consequently, 81 ACLR FE knee models were created based on the lower-limb geometry of an 11-year-old female acquired from magnetic resonance imaging. Three-dimensional motion (Vicon Motion Systems Ltd, UK), ground reaction loads (AMTI, Watertown, MA, USA), and 12 lower limb muscle electromyograms were acquired during walking. The FE boundary conditions and loading were estimated using OpenSim and calibrated EMG-assisted model, respectively. Knee flexion, abduction-adduction, internal-external rotation moments, and tibiofemoral and patellofemoral joint contact forces were used to drive FE models. Secondary knee kinematics (i.e., anteroposterior, and mediolateral femoral translations, abduction-adduction, and internal-external femoral rotations) were used to assess global sensitivity analysis through Sobol' indices at five timepoints across stance phase of gait.

RESULTS AND DISCUSSION

Figure 1 shows sensitivity of secondary kinematics to surgery parameters, which varies across stance. At foot contact, first order effects of the individual graft parameters on secondary kinematics were largest. As the knee progresses through stance, second order effects (i.e., surgical parameter interactions) on secondary kinematics increased in importance. Notably, graft type (i.e., gracilis, semitendinosus, and patellar tendon) had the highest first order effect on secondary kinematics compared to the other surgical parameters at certain timepoints. Graft diameter and location had the highest second order effects on secondary kinematics. The mediolateral translation is the secondary knee kinematic most sensitive to the variation in surgical parameters.

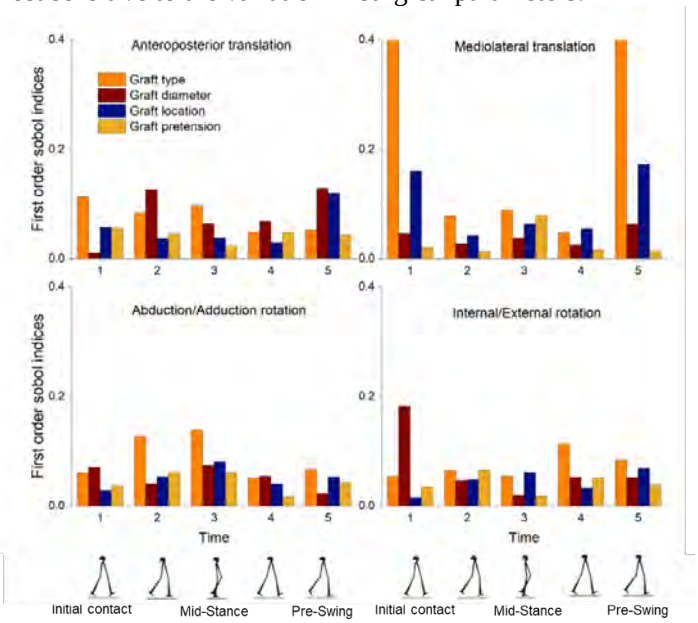

Figure 1. Global sensitivity analysis of four surgical parameters on the resulting secondary kinematics quantified by Sobol' indices for 5 timepoints of the stance phase of gait.

CONCLUSIONS

We used subject-specific FE models of the paediatric ACLR knee to assess the sensitivity of secondary knee kinematics to several surgical parameters. We found the effect of surgical parameters on secondary kinematics varies across the stance phase of gait. We will extend our analyses to encompass several additional patients with substantially different knee geometries for presentation at ISB 2023. This study will be the first comprehensive and practical sensitivity study examining the influence of paediatric ACLR surgical parameters on knee kinematics.

INTRODUCTION

Carpal tunnel syndrome (CTS) us a common disorder of the hand in clinics. For severe CTS patients, carpal tunnel release (CTR) surgery is recommended to decompress the median nerve by incising the transverse carpal ligament. Currently, the most adopted surgeries are open carpal tunnel release (OCTR) and endoscopic carpal tunnel release (ECTR). Recently, ultrasound-guided carpal tunnel release (UCTR) was developed with similar advantages of ECTR. Moreover, previous studies found the probability of Trigger Finger (TF) occurrence increased after transverse ligament release surgery.[1] However, the causes of the increased TF occurrence after different CTR techniques are seldom investigated. Thus, this study investigated the migration pattern of flexor digitorum tendon and the angle between the flexor tendon and the A1 pulley after UCTR and OCTR during different wrist angles to provide information about the risk of TF.

METHODS

Five fresh frozen cadaver hands were used in the experiments. In the experiment, the cadaver hand was secured to the customized frame in a palm-up posture and the wrist joint was mounted at the posture of neutral and flexion 30°, respectively. The index, ring, and little finger were fixed with splints in neutral position. The flexor digitorum superficialis (FDS) tendon of middle finger was applied 300 g and 500 g to simulate the finger motion at different force levels, and FDS tendons of index, ring and little fingers and flexor digitorum profrundus tendons of four fingers were applied 50 g each to maintain the tendon tension. UCTR, which can reduce the damage of anatomical structure in the carpal tunnel, was used in this study[2]. Images of tendon migration in the carpal tunnel and entrance angle at A1 pulley while applying force from 0 to 300/500 grams were recorded and measured with ultrasound transducer (TerasonTM). Friedman test were used to analyze the parameters of migrations between intact, UCTR and OCTR.

RESULTS AND DISCUSSION

Results of volar migration of FDS and changes of entrance angle at A1 pulley showed a tendency that with higher wrist flexion or increased applying force could cause higher volar migration and higher entrance angle after CTR, either OCTR or UCTR. In particular, the migration patterns of the FDS tendon of middle finger after OCTR at wrist neutral and flexion 30° and different force levels showed siginificant higher FDS volar migration comparing with intact condition. In addition, under lower applying force at wrist flexion 30°, a significant lower volar migration of FDS with UCTR was observed while comparing with those of OCTR. Therefore, UCTR might has a lower risk of inducing bowstring effect and developing trigger finger if operated under an appropriate load.

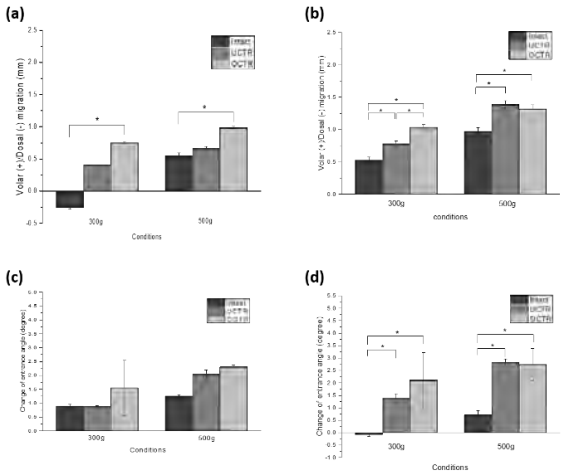

Figure 1 The volar migration at (a) wrist neutral posture and (b)wrist flexion 30˚; entrance angle of FDS at A1 pulley (c) wrist neutral posture and (d)wrist flexion 30˚ after different surgical treatments;

CONCLUSIONS

Our findings indicated that carpal tunnel release surgery strategy could influence the tendon gliding pattern in carpal tunnel and the entrance angle at A1 pulley. OCTR showed higher volar migration and change of entrance angle at each force levels and wrist postures indicated the higher risk inducing TF for CTS patients treated with OCTR than UCTR.

INTRODUCTION

Carpal tunnel release (CTR) surgery is recommended for patients with severe carpal tunnel syndrome (CTS). However, volar displacement of the flexor digitorum superficialis (FDS) tendon increases due to absence of transverse carpal ligament restraint, which increases the potential incidence of trigger finger and affects hand function [1]. Clinically, therapists are eager to find solutions to prevent subsequent complications. This study aimed to elucidate whether compressive forces can attenuate the bowstring effect after CTR.

METHODS

15 healthy adults (age: 27±3.8 years) and 13 CTS patients underwent CTR surgery (age: 52±8.5 years) participated in the institutional review board-approved study. Tendon motion was recorded at the level of the metacarpophalangeal joint using an ultrasound system (ACUSON S2000, Siemens Medical Solutions) with a linear array transducer (6–18 MHz, 18L6HD). A load cell (MLP-25, Transducer Technique, Inc.) was used to adjust the compressive force applied to the carpal tunnel and to record changes in compressive fore and a custom-designed dynamometer was used to measure finger-applied torque. The target hand is secured to the support frame with the palm facing upward. The middle finger was maintained at 60° of flexion at the proximal interphalangeal joint. Maximal voluntary isometric contraction (MVIC) was performed with the wrist joint in a neutral position and 60° of flexion. Except for just contact force, 4N, and 8N of compressive force were additionally applied in CTS patients. Entrance angles of the FDS tendon and changes of compressive force were computed for further analysis.

RESULTS AND DISCUSSION

As shown in Table 1, significant differences were observed between the healthy condition and the CTS 4N condition and the healthy condition and the CTS 8N condition for both changes in entrance angle and compressive force. Compressive force of 4N and 8N significantly inhibited the volar displacement of the FDS tendon, which was reflected in a reduction in the change in the entrance angle in CTS patients. However, increased changes in compressive force might increase pressure in the carpal tunnel, which is detrimental for the median nerve. Under MVIC, compressive forces reached approximately 1.88 N and 3.58 N in healthy adults and CTS patients, respectively, due to the fixation of the load cell above the carpal tunnel, resulting in no significant difference in changes in entrance angle or compression force.

CONCLUSIONS

Compressive force of approximately 2N is able to inhibit excessive volar migration of the FDS tendon after CTR surgery.

Assistance of the paretic knee in the sit-to-stand motion of acute stroke survivors prevents their trunk overuse

Hiroki Hanawa[1], Keisuke Hirata[2], Taku Miyazawa [1]

INTRODUCTION

Typical stroke survivors suffer from motor paralysis in their limbs. This makes it difficult for them to resist gravity and hold their posture. For example, in the sit-to-stand motion, they are unable to hold the squatting posture during the seat-off phase. Even in healthy elderly, almost maximum muscle strength is required at the knees for the seat-off. Therefore, chronic stroke patients transferred more mechanical energy from the trunk to the paretic knee [1]. This was viewed as a compensatory relationship between the less affected trunk and the paretic knee.

We hypothesized that (1) the compensatory relationship exists even in the acute phase of stroke, and (2) trunk compensations can be prevented by assisting the knee. The purpose of this study was to elucidate some of the validity of sit-to-stand exercises performed from the acute phase of stroke.

METHODS

The subjects were six acute stroke survivors. They were able to understand the study description, and signatures on a consent form were obtained. Small wireless inertial measurement units (IMU) and surface electromyography (sEMG) were used to measure their motion (both 1000Hz; Oisaka Electronics Co., Ltd.). The IMU was affixed to six locations on the body (thorax, pelvis, right and left thighs, and shanks). The electrodes of sEMG were affixed to seven muscles (right and left erector spinae, paretic gluteus maximus, long head of biceps femoris, vastus lateralis, tibialis anterior, and soleus). Subjects performed a sit-to-stand motion. The experimental conditions were two conditions: assisted and free knee joint hyperflexion prevention brace (90° restriction). We then converted the IMU data to segment angles and mechanical energy expenditure. The analyzed data were compared between the two conditions using a corresponding T-test. The significance level was set at $p = 0.05$.

RESULTS AND DISCUSSION

Mechanical energy expenditure in the thorax and pelvis up to seat-off was lower in the brace-assisted condition than in the free condition (both $p < 0.001$; Table 1). Activity in the paretic erector spinae was also smaller in the with assisted condition than in the free condition ($p < 0.001$; Figure 1). On the other hand, the posture (angle) of the six body segments was not significantly different at the start, at the end, or at seat-off.

Preventing hyperflexion of the knee resulted in decreased mechanical energy expenditure and erector spinae activity. Therefore, a compensatory relationship may have existed even in the acute phase of stroke. The fact that such assistance induces normal motor control could be a useful finding in clinical practice. On the other hand, since no kinematic changes were observed, evaluation by clinical observation is a future issue.

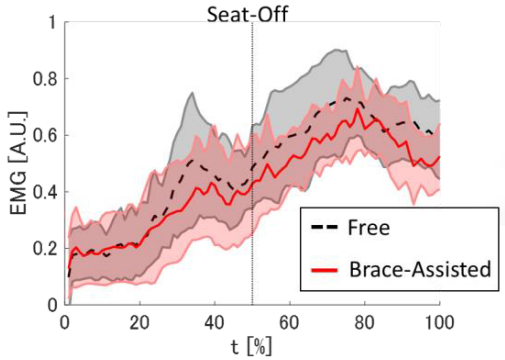

Figure 1 Muscle activity in the paretic erector spinae

CONCLUSIONS

After stroke, they adapt to motor paralysis from the acute phase and compensate with the less affected trunk. This compensatory relationship can lead to non-use of the paretic limb. The results of breaking this relationship by assisting their knee were clinically informative findings.

INTRODUCTION

Stroke is one of the leading causes of death and disability worldwide. Upper-limb motor deficit is a common consequence after stroke, which causes difficulty in performing daily activities. Mirror therapy (MT), a promising and effective intervention for improving patients' functions, becomes the focus in stroke rehabilitation recently. Traditional MT provides visual illusions of the patient's normal intact hand movements as if it were the paralyzed one and generates mirror visual feedback (MVF) by using a mirror [1]. For optimizing the delivery of MT, we have developed an innovative digital MT system [2], which can provide 3 different types of MT in different MVF conditions and training modes: unilateral MVF with unimanual training (UM-UT), unilateral MVF with bimanual training (UM-BT), or bilateral MVF with bimanual training (BM-BT). The hardware of this innovative digital MT system includes a laptop, a computer screen, an adjustable monitor stand, and a webcam. This system has been programmed with modern web programming languages, including HTML5, CSS, and JavaScript, to administer multiple previews on a single webpage, to flip the preview horizontally, and to present a preview of the webcam and to record the webcam stream from the computer. This study aimed to examine the treatment efficacies of 3 different digital MT compared with traditional MT using a mirror box (Figure 1).

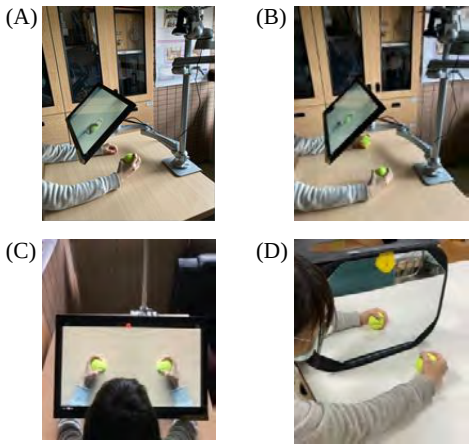

Figure 1 Conceptual illustration of 4 treatment groups: (A) uni-MVF condition and unimanual training (UM-UT); (B) uni-MVF condition and bimanual training (UM-BT); (C) bi-MVF condition and bimanual training (BM-BT); and (D) traditional MT using a mirror box.

METHODS

Twenty-two stroke patients were recruited and randomly allocated to 1 of 4 groups with a total of fifteen 1-hour therapy sessions. Outcome measures, including the Fugl-Meyer Assessment of the Upper Extremity (FMA-UE), Chedoke Arm and Hand Activity Inventory (CAHAI), and Motor Activity Log (MAL), were administrated at pre- and post-treatment. The nonparametric Kruskal–Wallis test and Wilcoxon signed-rank test were used, as appropriate.

RESULTS AND DISCUSSION

For the within-group changes, both the UM-UT and UM-BT groups had significant improvements on the FMA-UE-total and CAHAI scores. Additionally, the UM-UT and UM-BT had significant improvements respectively on the FMA-proximal and MAL scores. However, neither the BM-BT nor traditional MT groups did. For the between-group differences, no statistically significant differences but small to large effect sizes for different outcome measures were found. The preliminary results suggested that unilateral MVF with either unimanual or bimanual training delivered by the digital MT system showed significant within-group improvements in upper-limb motor and daily functions, and in the amount and quality of the affected arm and hand use in the real-world. However, more subjects need to be recruited to further validate the current results.

CONCLUSIONS

The preliminary study shows that the UM-UT and UM-BT groups of the digital MT system might be more promising as the alternative rehabilitation interventions for stroke survivors. Further large-scale study is suggested.

INTRODUCTION

The knee adduction moment (KAM) is an index of mechanical stress during walking that affects the onset and progression of knee osteoarthritis (OA) [1]. Performing a draw-in maneuver (DI) during walking is a gait modification that reduces the KAM, but does not forcibly modify trunk or lower limb movements [2]. The long-term effects of this intervention, however, are not clear. To evaluate whether knee joint function would improve with a longer DI gait intervention in patients with knee OA.

METHODS

Studies were conducted in subjects aged ≥40 years with knee OA. A daily 20-minute DI gait was performed for 6 weeks. First, 10 minutes of DI gait instruction was given, and the normal posture and thoracic kyphosis angle during DI were measured at the beginning of the intervention. At baseline and after 6 weeks, we evaluated the Knee injury and Osteoarthritis Outcome Score (KOOS), knee pain, the MOS 8 item Short-Form Health Survey (SF-8), thoracic kyphosis angle, knee joint range of motion, knee extension muscle strength, hip abduction muscle strength, and activity level.

RESULTS AND DISCUSSION

Knee pain and the thoracic kyphosis angle were reduced in the 6-week pre- and post-intervention comparison (Table 1, Figure 1). No other parameters differed significantly after the intervention compared with baseline, and the implementation rate was 86±14%, with 20 minutes or more per day being 100%. In a previous study, it was reported that proper implementation of DI decreased thoracic kyphosis angle [3], increased muscle activity of the internal abdominal oblique, external abdominal oblique, and gluteus medius muscles in the first half of the stance phase during DI gait, and smooth center of mass to the stance side, resulting in decreased KAM [2]. In the present study, thoracic kyphosis angle decreased during DI posture, suggesting that DI was performed properly. The DI gait could be learned and practiced by patients with knee OA at an average age of 70 years. 20 minutes of DI gait per day decreased KAM during gait, which was thought to decrease knee pain. In addition, DI gait was effective in improving thoracic kyphosis.

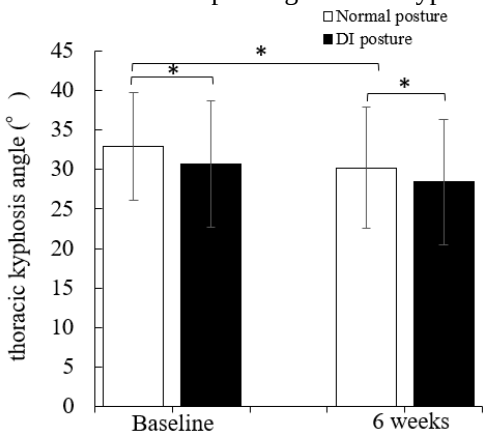

Figure 1 Effect of DI gait on the thoracic kyphosis angle.

CONCLUSIONS

After a 6-week intervention in patients with knee OA, KOOS and SF-8 scores did not improve significantly, but knee pain and thoracic kyphosis angle decreased. These results suggest that DI gait is useful as a gait modification for knee OA.

INTRODUCTION

The importance of the use of mobile applications in the health practice have grown increasingly over the years [1]. There is a need to assess if these applications can be validly and reliably used in the clinical setting as these are critical measures that evaluate the quality and effectiveness of a tool [2,3] to improve the delivery of health care in the physical therapy practice. This systematic review aimed to identify and synthesize existing studies on evidence of the concurrent validity and intra-rater, inter-rater, and test-retest reliability of mobile applications used in physical therapy.

METHODS

A literature search was conducted on nine databases: Web of Science®, PubMed®, Science Direct, Scopus®, Proquest, MEDLINE®, SPORTDiscus, and CINAHL on articles from inception to November 2021. Mendeley, Endnote and Rayyan were used for data management and screening. The methodological quality of all included studies was critically appraised using Brink and Louw Critical Appraisal Tool (CAT).

RESULTS AND DISCUSSION

Overall, 28 studies were included in the study (Figure 1). 17 articles assessed both validity and reliability, 10 assessed only reliability, and 1 assessed only validity. The apps were categorized into: apps for range of motion, balance, postural, sit-to-stand, and gait. Out of 28 studies, quality assessment scores show only 4 articles were considered poor quality, while 24 were considered good.

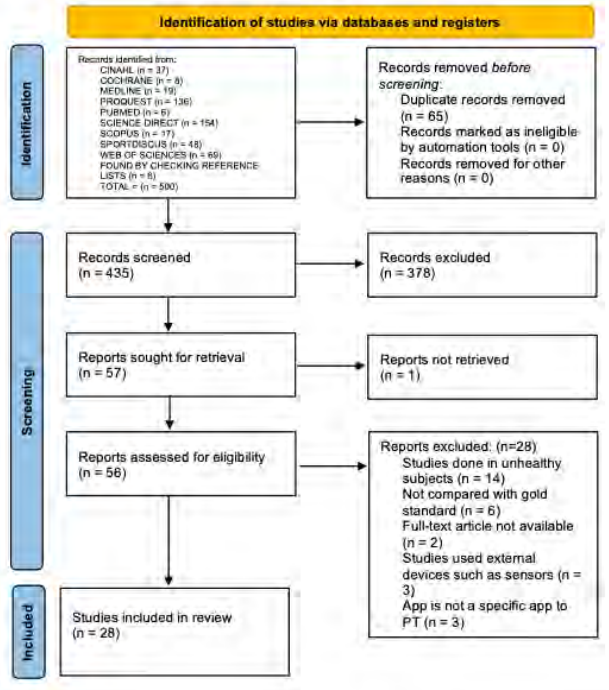

Figure 1 PRISMA Flow Diagram

CONCLUSIONS

A number of studies have demonstrated that mobile applications are valid and reliable for joint range of motion assessment, functional activity (i.e. sit to stand) and postural assessment. However, there was a wide range of results from mobile apps for measuring balance and gait; further research regarding their psychometric properties is needed.

INTRODUCTION

During walking, motor commands coordinated between the joints in each leg (intralimb coordination) generate and contorol multi joint movement of leg [1]. By applying the underlying mechanisms of intralimb coordination, previous studies using split-belt treadmills (separated double-belt treadmills) have clarified the effect of changes in joint movement during walking on able-bodied people [2], [3] and patients suffering from movement disorders [4].

Ergometer training through cyclic movements such as walking can promote walking-like muscle activity and is associated with walking function improvement [5]. The common core hypothesis claims that upper- and lower-limb movements during walking, stepping, and ergometer exercises are controlled by a common rhythm and central pattern generator [6].

Our goal was to provide stimulation equivalent to a split-belt treadmill using an ergometer. We provided the same passive ankle joint motion at a specific crank angle per cycle during cycling movement using the Ankle Assit Ergometer (AAE) we developed. The purpose of this study was to verify the motor adaptation effect from before to after the passive assitance in the ankle joint motion on healthy young subjects.

METHODS

We developed the AAE by converted the pedals of a commercial ergometer into an ankle-assisting tool driven by a motor and brake. The AAE delivered ankle dorsiflexion assistance to 5 young adult participants from 90° after the top dead center until the bottom dead center of the crank angle during cycling. Electromyography (EMG) activity of the soleus (SOL) and tibialis anterior (TA) muscles was recorded bilaterally using surface electrodes (Trigno® Wireless System; DELSYS®, Natick, MA, USA). The opposite ankle angle was recorded using a goniometer (FAC-GM150; 4Assist, Tokyo, Japan). The recorded EMG and goniometer signals were digitized simultaneously along with the ergometer crank data.

The testing parameters were the dorsiflexion angular velocity (after - bofore) at the bottom dead center with ±25° and root-mean-square EMG activity (TA/SOL) at the bottom dead center with ±25°. To compare the results of ankle dorsiflexion muscle activation before and after assistance, we used a paired t-test between before and after assistance.

RESULTS AND DISCUSSION

We confirmed a significant difference in the ankle dorsiflexion angular velocity at the bottom dead center between before and immediately after assistance (after 2.52 ± 1.58, $p < 0.05$, figure 1 left). Moreover, we confirmed a significant increase in dorsiflexion muscle activation from before to immediately after assistance (before 1.18 ± 0.64, after 9.83 ± 6.06, $p < 0.05$, figure 1 right). These effects persisted after the removal of the assistance.

We confirmed the posssibility that the AAE activates the central pattern generator and induces motor adaptation of ankle movement by limb coordination during a motion cycle.

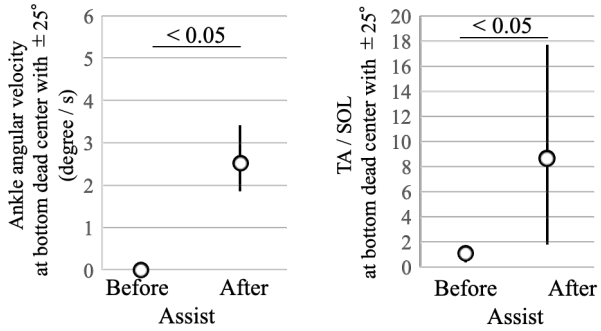

Figure 1 Ankle angular velocity and muscle activity before and after assistance

CONCLUSIONS

The developed AAE contributes to eliminating barriers to the clinical implementation of the rehabilitation tools delivering cyclic motion. As the next step, we are now going the application to stroke patients who have lost ankle joint motion.

INTRODUCTION

Lumbar spinal stenosis is a common degenerative condition and is often accompanied by pain and loss of balance. The common treatment methods for lumbar stenosis are rehabiltation exercise, and surgical intervention. In recent years, studies have shown that virtual reality (VR) training can help improve balance [1]. The aim of this study was to compare the balance ability of patients with unoperated lumbar spinal stenosis before and after VR skateboard training.

METHODS

The inclusion criteria of participants were 50-80 years old, diagnosed as patients with lumbar spinal stenosis and able to walk independently for more than 5 minutes. The measurement parameters included functional assessments and standing balance ability. The functional assessments included the Timed Up and Go test (TUG) and Five Times Sit-to-Stand test (5STS). To measure the quite standing balance ability, the center of pressure parameters such as mean distance, anteroposterior direction, and mediolateral direction on the force plate (Kistler 9286A, Kistler Instrument AG, CH) were used. The participants will receive virtual reality training for 6 weeks, 2 times a week, and 20 minutes each time (Figure 1). The content of the virtual reality training was skateboarding, and the hardware used HTC VIVE Pro (HTC Corporation, New Taipei City, Taiwan) and split belt treadmill (QQ-mill, Motekforce Link, The Netherlands).

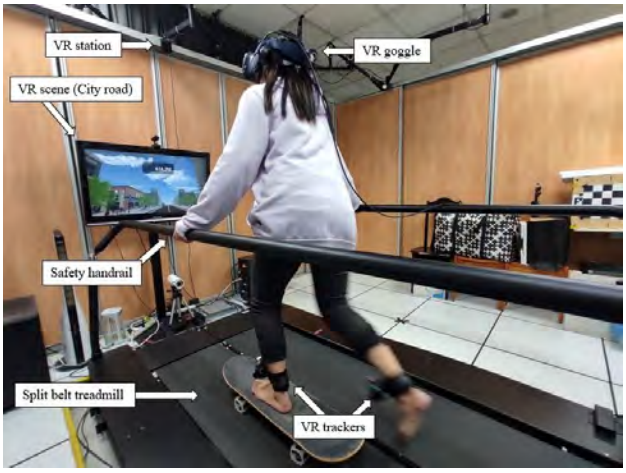

Figure 1 The VR skateboarding balance training system.

All data in this study were analyzed using IBM SPSS Statistics (19th Edition). The basic profile (age and sex) of the participants was analyzed by descriptive statistics. The Wilcoxon signed-rank test was used to compare differences within groups. Statistical significance level was set at p-value < 0.05.

RESULTS AND DISCUSSION

There are 4 participants (Age: 60.00 ± 9.40 years old), two males and two females in this pilot study. All functional assessments showed improvement, which represents an improvement in balance, but neither of them showed significant differences (Table 1). There are no significant differences in center of pressure parameters. Previous studies of virtual reality training have shown improvements in balance, and due to the small number of participants, it may be difficult to show statistical significance in this pilot study.

Table 1: The training results of No-surgery group

Measurements	Pre-training	Post-training	*p*-value
Functional assessments			
TUG (sec)	10.77 ± 3.71	9.23 ± 2.33	0.068
5STS (sec)	11.60 ± 4.79	7.10 ± 1.97	0.068
Center of pressure in quiet standing			
Total distance (cm)	0.38 ± 0.15	0.46 ± 0.22	0.465
AP distance (cm)	0.58 ± 0.29	0.56 ± 0.28	0.715
ML distance (cm)	0.23 ± 0.10	0.25 ± 0.10	0.465

AP / ML, in the anteroposterior / mediolateral direction.

CONCLUSIONS

Virtual reality skateboarding can improve balance performance in patients with lumbar spinal stenosis, and more patients will be recruited in the future to ensure the efficacy.

Effect of increasing weight-bearing during the seat-off task with sit-to-stand training augmented feedback and epidural electrical stimulation in people with incomplete spinal cord injury: A preliminary study

Tzu-Ming Chang[1] Chich-Haung Richard Yang [1,2,3] Yu-Chen Chen[4] Ming-Yung Wu[4] Sheng-Tzung Tsai[2,4]

INTRODUCTION

Functionally, increasing weight-bearing during the seat-off task is essential for patients with incomplete spinal cord injury (iSCI). It is logically associated with the assistance requiring momentum transfer during sit-to-stand (STS) and related to the ability to walk with minimal use of the upper extremities [1-2]. However, it is difficult for some severely neurological impaired patients to practice STS due to a lack of intrinsic feedback for movement control [3]. Recent literature has suggested that the mechanisms for the neuromodulation of epidural electrical stimulation (EES) combined with task-specific training may produce more substantial improvements in motor functions than functional electric stimulation [4-5]. Furthermore, some clinical studies have shown the effect of improving dynamic sitting balance and active standing with EES [5-6], but few studies investigated STS biomechanics with the EES intervention [4]. In this preliminary study, we aimed to examine the effect of increasing weight-bearing during the seat-off tasks with STS training augmented feedback and the EES in iSCI patients. We hypothesized that the patient's weight-bearing ability during the seat-off task would be enhanced after training, especially when EES turns on.

METHODS

One ASIA C subject at L2 level (age:54, BMI=27.47) undertook 16 sessions (2 days/week, total of eight weeks) of repetitive STS training & the EES. The dose of the training program is five times/ session, a total of 3 sets, with a rest period of 4-5 minutes between each set. The EES was turned on during the training. We instructed the subjects to sit on the customized body-weight support stand for safety and provided visual feedback (by two-bathroom scales) and verbal cues (by a trainer) to provide the loading feedback during training [3]. The vertical GRF and the three timing phases of STS (phase 1: the horizontal phase, phase 2: the transition phase, and phase 3: the vertical phase) were measured [7] as outcomes. We have measured both outcomes in both legs at on-off of EES condition in pre-training (0-week), 4-week, and 8-week STS training, respectively. The data showed mean ± standard deviation (SD) for the first peak force and slope and timing percentage for each STS phase.

RESULTS AND DISCUSSION

The result showed that the first peak force and slope gradually improved on the more affected leg, especially when EES was turned on; an increasing percentage was shown in phase 1, while there was no significance but variety in the percentage of phase 2 after training (Table 1). Previous studies have shown that some iSCI patients standing up with crutches [1] would reduce the trunk forward-leaning due to maintained balance and reduced weight-bearing during STS [2]. The results indicated that STS training augmented feedback contributed to the subject's weight-bearing control ability. Furthermore, the participant preferred a more 'trunk flexion impulse" strategy to stand up within the turn of EES, consistent with previous findings [5], showing that EES may enhance the reach performance in spinal cord injury.

CONCLUSIONS

STS training augmented feedback with EES could increase iSCI patients' weight-bearing ability. The effect of increasing weight-bearing by task-specific training with EES would be better than that using only EES protocol.

INTRODUCTION

Dynamic stretching (DS) is commonly performed as a warm-up before playing sports. DS consists of repetitive motions throughout the joint range. Active stiffness is an outcome of exercise performance; however, no studies have shown active muscle stiffness with DS. Tensiomyography (TMG) is a non-invasive measurement device that assesses the contractile properties of skeletal muscles in response to electrical stimulation and can assess active stiffness. The purpose of this study was to investigate the effects of DS on the contractile properties of the ankle plantar flexors and dorsiflexors.

METHODS

Seventeen healthy males (22.0 ± 1.2 years) participated in the study. DS of the ankle plantar and dorsi-flexor muscles of the dominant leg was performed. The DS protocol consisted of four sets of 30 s, and 30-s rest was given in the standing position at a pace of 60 beats per min. The control condition was standing at rest for 210 s. Muscle contractile properties of the gastrocnemius medialis were measured using TMG (TMG-S1, TMG-BMC), a displacement sensor, and 5-cm diameter circular electrodes. Electrical stimulation was performed using a rectangular monophasic wave with a pulse duration of 1 ms. The stimulation intensity was gradually increased from 20 mA until the muscle radial displacement reached a plateau on the twitch response curve. From the maximal twitch response, the TMG parameters, which were maximal radial displacement amplitude (Dm), delayed time as the time from an electrical impulse to 10% of Dm (Td), contraction time as the time from 10 to 90% of Dm (Tc), and the index representing the velocity of contraction (Vc) as Dm divided by the sum of Td and Tc (Figure 1).

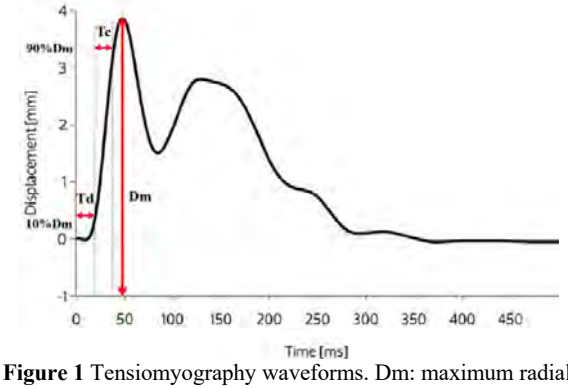

Figure 1 Tensiomyography waveforms. Dm: maximum radial displacement; Td: delayed time; Tc: contraction time.

RESULTS AND DISCUSSION

There were no significant main effects of condition, time, or interaction with Dm. There was a significant interaction for Td ($p < 0.01$). Post-hoc tests revealed that Td after DS was significantly lower than that before DS ($p < 0.01$). For Tc, a significant interaction was observed ($p < 0.05$). The post-hoc test revealed a significant decrease after DS compared with that before DS ($p < 0.01$). A significant interaction was observed for Vc ($p < 0.01$). The post-hoc test revealed a significant increase after DS compared with that before DS ($p < 0.01$). There was a significant decrease in delayed time (Td) and contraction time (Tc). A significant increase was observed in contraction velocity (Vc) after DS. A reduction in Td is indicated by an increase in muscle fibre conduction velocity. Hence, a decrease in Tc indicates an acceleration in the speed of force generation and an increase in Vc signifies an improvement in muscle performance [1, 2]. Increased muscle activity and jump performance after DS suggest an improvement in neuromuscular properties [3]. Muscle fibre conduction velocity is associated with muscle temperature [4]. It is inferred that neuromuscular properties were improved by an increase in muscle temperature after DS. Therefore, DS is effective in enhancing performance with changes in neuromuscular properties.

CONCLUSIONS

A significant reduction in delay and contraction time and a significant increase in contraction velocity were observed. These findings suggest that DS enhances neuromuscular properties without altering the mechanical muscle properties during contraction.

INTRODUCTION

Horseback riding therapy is one of the rehabilitation methods for spinal injury or brain damage. Our project team is studying to estimate for the benefits of horseback riding therapy in children with cerebral palsy (CP). The previous study showed the horseback riding therapy improved the gross motor function in the children with CP [1,2]. However little is known about the characteristic of activity of trunk muscles as the strategy of controlling the trunk posture during horseback riding. The purpose of this study was to estimate the characteristics of muscle activity pattern during the horseback riding from the view point of frequency domain of SEMG signals.

METHODS

The participants of this study were two low-birthweight children with CP (a 11-year old and a 3-month old girl, a 11-year old and a 3-month old boy, respectively) and two healthy children (a 10-year old and a 3-month old girl, an 9-year old and a 10-month old boy, respectively) as a control. Two subjects with CP had been receiving horseback riding therapy for over 9 years. The horseback riding therapy was approximately 30 minutes in duration and was performed once weekly in Iwate prefecture. SEMG signals were recorded simultaneously from eight trunk muscles during the horseback riding on the riding ground. A row SEMG signal was decomposed into five frequency bands (j = 1: 450-250 Hz, j =2: 250-125 Hz, j = 3: 125-62.5 Hz, j = 4: 62.5-31.25, and j = 5: 31.25-20 Hz, respectively) by the discrete wavelet transform [3]. Its wavelet transform coefficients were estimated by using the Daubechies-4 wavelet algorism and SEMG data of 512 points related to horseback riding. The activities of SEMG within the trunk muscle were compared by the values of the proportion of mean wavelet transform coefficient (%P_j).

RESULTS AND DISCUSSION

Figure 1 showed that the value of %P_j for the CP group at the low−frequency band (62.5-20 Hz) was smaller than that for the healthy group within the muscles of the lumbar region. The chi-square test for independence showed statistical differences of 1% for the muscles of the lumbar region. On the other hand, there was no statistical difference for the muscles of the cervical region. The activities of SEMG during horseback riding were different between the muscles of the lumbar region and the muscles of the cervical region. It was assumed that the spectral property of the surface EMG was altered by the volume conductor effects of the muscle fibers and the number of activated motor units (MUs). Recruitment strategies of lumbar region in children with CP might be higher MUs activities than the normal children during the horseback riding.

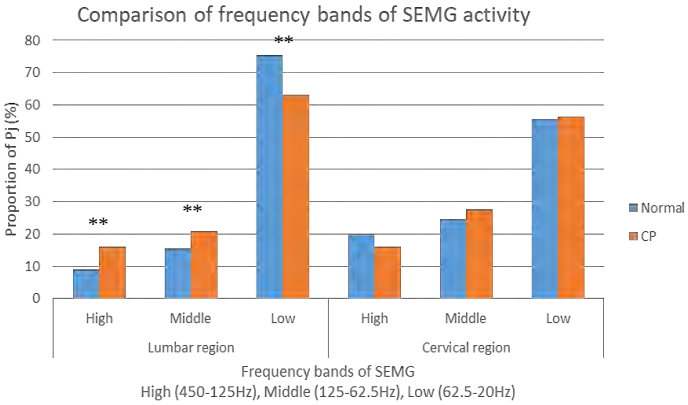

Figure 1 Comparison of frequency bands of SEMG activities. The mark ** indicates a significantly different level of 1 % of the chi-square test.

CONCLUSIONS

These results suggested that the characteristics of trunk muscle activities and the strategy of controlling the trunk posture during the horseback riding were difference between the children with CP and the healthy children. The activity of lower frequency of SEMG within the lumbar region might be suitable physiological index as an evaluation for the effect of horseback riding therapy.

INTRODUCTION

Two-point discrimination (TPD) is the ability to consciously detect the minimum distance between two points on the skin, with the smaller distance indicating better acuity. This test has been administered in various ways, at multiple different body locations across a wide range of health conditions [1,2]. However, the test is time-consuming and lacked a reference standard for subject-specific TPD information for clinical examiners. By using the statistical shape model (SSM) method, the reconstruction of the subject-specific sole of foot shape and the TPD landmarks positions might be automated whilst improved in accuracy. The study aimed to propose an approach by SSM to predict personalized TPD landmarks based on the individual sole foot shape and provide a better understanding of the two-point discrimination sensation on sole of foot in healthy individuals.

METHODS

The training shape model was reconstructed from six out of twelve healthy subjects (age: 25.5±4.5 years, height: 1.7±0.1 m, mass: 63.5±12.0 kg, BMI: 21.9±2.2, foot length: 26.5 ± 1.1 cm) without any neuromusculoskeletal diseases in the lower limbs who participated in the current study. Twenty-one markers were equally distributed and attached to bony landmarks of the sole of the feet (i.e., head of first phalanx, navicular tuberosities, 5th metatarsal bases and heels). During the experimental procedure, each subject was asked to stand on the platform at the isocentre of a smartphone (iPhone 12 Pro, APPLE) camera's field of view. Subsequently, the subject-specific sole shape model and the TPD distribution landmarks were segmented from the mobile phone photograph after the camera calibration (Figure 1). All the training models were used to establish the correspondence trainset via Iterative Closest Point (ICP) registration and Coherent Point Drift (CPD) registration for reconstructing SSM-based sole shape models with TPD landmarks. These best-aligned models were used to analyze the shape differences with Principal Component Analysis (PCA) to obtain the shape coefficients and corresponding eigenvectors (i.e., top 7 in this study). The performance of the proposed SSM approach was evaluated using the leave-one-out cross-validation scheme. The reconstruction error of the two-dimensional model used the point-to-point mean error, and root mean square error (RMSE).

Table 1: Mean error and root mean square error of the leave-one-out cross-validation of the SSM-reconstructed model (unit: mm).

Mean Error	RMSE
2.44(0.77)	2.74(0.19)

RESULTS AND DISCUSSION

Mean errors and RMSE in shape accuracy of the leave-one-out-cross-validation of the subject-specific SSM-reconstructed models were 2.44±0.77 mm and 2.74±0.19 mm, respectively (Table 1). Submillimeter accuracies were found for all reconstructed subject-specific sole of foot shape models and the TPD landmarks by using the SSM approach. From the results, the accuracies of the two-dimensional (2D) shapes and TPD landmark positions showed high accuracies.

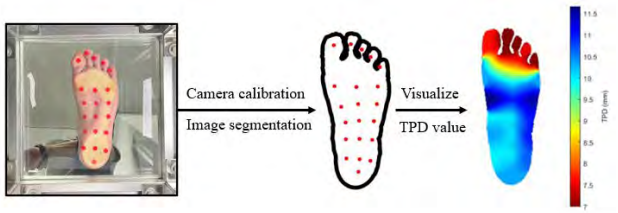

Figure 1 Experiment flowchart

CONCLUSIONS

The current study proposed a new approach that is able to reconstruct the 2D sole of the foot shape based on TPD landmarks. This approach may further set up a clear reference standard to assist clinical examiners in performing the clinical neurological assessments.

INTRODUCTION

Parkinson's disease is a common and complex neurological disease, which is also considered as a chronic, progressive neurodegenerative disease. The main clinical feature of Parkinson's disease is its characteristic motor symptoms. Major symptoms include rest tremor, bradykinesia, rigidity, and postural instability. In addition to Parkinson's disease, some other neurodegenerative diseases may also cause dopamine deficiency, leading to clinical manifestations similar to Parkinson's disease, so it is called Parkinsonism. Overall, motor symptoms in patients with Parkinson's disease tend to worsen as the disease progresses. Most previous studies have focused on examining lower extremity motor performance in patients with Parkinson's disease. However, it is inevitable that the movement disorders caused by Parkinson's disease are systemic, and the patient's hand function is also affected, which will become obvious in the later stage. Hand stiffness and tremor affect hand coordination, movement timing, fluidity of movement, and force control [1]. For patients with Parkinson's disease, dyskinesia is the symptom that most affects the functioning of daily life, but the number of previous studies related to upper limb rehabilitation is limited. Therefore, the aim of this review is to understand the effect of existing trainings on hand dexterity.

METHODS

The scoping review was based on a comprehensive literature search in PubMed, EMbase, Web of Science using key terms which included Parkinson*, hand function, dexterity, upper extremit*, upper limb*, fine motor, exercise*, and training. Studies were included if they (1)were written in English, (2)were original research articles, (3)randomly assigned the participants into groups, (4)recruited participants diagnosed with Parkinson's disease, (5)adopted exercise training for hands, (6)measured at least one outcome assessing hand dexterity, and (7)measured outcomes before and after intervention. Studies were excluded if the intervention was provided for only single session.

RESULTS AND DISCUSSION

Of the 290 studies retrieved from all databases, 8 studies met the criteria (Table 1). Five studies assess dexterity using Nine Hole Peg test, while three additional studies used the Purdue Pegboard test and Box & Block test. Different exercise types were adopted for intervention in these studies. According to one study, interactive video games for arm and hand exercises did not improve hand dexterity, despite improvements in game-playing performance. Other exercises including home-based dexterity exercise, virtual reality exergaming, Whqinxi exercise, Yang-ge dancing, and LSVT-BIG, have all improved hand dexterity in patients with Parkinson's disease.

Table 1: Exercises used for training in patients with Parkinson's disease

Study	Exercise type
Vanbellingen, 2017	Home-based dexterity exercise and Thera-band exercise
Allen, 2017	Exergames
Cikajlo, 2019	3D virtual reality and 2D non-immersive 2D exergaming
Wang, 2020	Wuqinxi exercise and stretching exercise
Choi, 2022	Task-based LSVT-BIG
Zare, 2022	Activity-based training and strengthening exercise
Hashemi, 2022	Upper limb virtual reality exercise
Li, 2022	Yang-ge dancing and conventional exercise

CONCLUSIONS

In recent years, there has been a growing body of research on exercise training to improve hand function in Parkinson's patients. From this review, we found that exercises involving finger movements have the potential to improve hand dexterity in people with Parkinson's disease. Therefore, there is still room for research to investigate which exercises, such as range of motion, stretching, coordination, and strengthening, will benefit patients more and make the outcomes durable.

Towards crutch-less exoskeleton-assisted geriatric sit-to-stand motions – an experimental and optimization-based study

Jan C. L. Lau and Katja Mombaur
Canada Excellence Research Chair Human-Centred Robotics and Machine Intelligence, Systems Design Engineering and Mechanical & Mechatronics Engineering, University of Waterloo, Waterloo, Canada.
Email: jan.lau@uwaterloo.ca, katja.mombaur@uwaterloo.ca

INTRODUCTION

Most lower-limb exoskeletons are only powered along the sagittal plane and must be used with crutches for stability. To avoid falling backwards, users must push themselves forward with the crutches. Long-term crutch use can cause upper-limb joint deterioration [1], so a way to perform sit-to-stand (Sit2S) without crutches was investigated. A healthy young subject showed the possibility to do so even with motors disengaged, and the joint torques can be computed as a least-squares optimal control problem (OCP). The first goal of this study is to investigate Sit2S biomechanics with an exoskeleton. The second goal is to obtain the total required torques from least-squares OCP for the device to do crutch-less Sit2S with a frailer older adult, who cannot stand up by themselves and requires support.

METHODS

A healthy 25-year-old experienced TWIN user was recruited to perform Sit2S with the device under different conditions. Made for people with paraplegia, TWIN exoskeleton weighs 25 kg and has 4 active DOF in the hips and knees [2]. Biomechanics of Sit2S were observed at seat heights equal to and higher than the user's knee height. The following data, which are part of a larger experiment, are analyzed. Passive means the exoskeleton's motors are disengaged.

1. Active with crutches at seat height of 46 cm
2. Passive without crutches at seat height of 46 cm
3. Passive without crutches at seat height of 55.2 cm

Sit2S motions are recorded with the Vicon motion capture system. Forces exerted by crutches or feet are captured with Bertec force plates. Proven possible to use least-squares OCP to determine the required kinematics and actuation for exoskeleton walking [3], the OCP is formulated as a least-squares problem on Bioptim [4] to track Sit2S from cases 2 & 3. The system's state vector $[q\ \dot{q}\ \tau]^T$ contains joint positions $q \in \mathbb{R}^{13}$, joint velocities $\dot{q} \in \mathbb{R}^{13}$, and joint torques $\tau \in \mathbb{R}^{10}$. The controls are the first derivative of joint torques $u \in \mathbb{R}^{10}$. The model describes an elderly woman lumped with TWIN and assumes symmetry in the lower limbs. Translational position values are scaled to account for the height discrepancy between the reference data (young adult) and lumped model (older adult).

RESULTS AND DISCUSSION

In case 1, a peak combined crutch force of 330 N occurred when the subject is standing up. In cases 2 & 3, the subject first swings their arms forward and imposes a large trunk bend right before standing up. The vertical force exceeds the total weight of the human and TWIN, meaning that one must accelerate upwards to stand up from sitting. Table 1 shows the maximum torques at the xiphoid and lower limb joints in case 3, though upper-body joint torques are also computed. Full experimental results will be presented at the conference.

Table 1: Magnitude of maximum joint torque values at xiphoid, lumped hips, lumped knees, and lumped ankles in case 3.

	Xiphoid	Hips	Knees	Ankles
Torque (Nm)	34	130	109	47

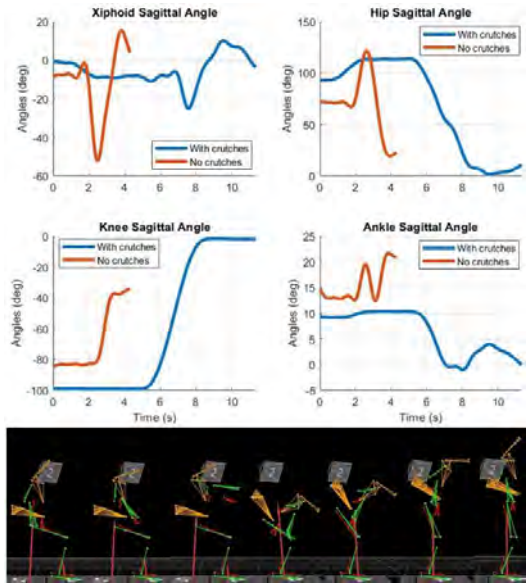

Figure 1 (Top) Joint angles of xiphoid, hip, knee, and ankle in cases 1 & 3. (Bottom) Motion capture recording of case 3.

CONCLUSIONS

The total torques computed would be the combined effort of the TWIN and older adult, and the split depends on the user's strength. This research is a preliminary step to obtain an optimal crutch-less Sit2S trajectory.

A Usability Evaluation of the Powered-Wheelchair for severely Disabled in Korea

Eung-Pyo Hong[1], Yong-Cheol Kim[1], Dae-Jin Jang[1], Jungsun Kang[1], Yunhee Chang[1] and Ki-Tae Nam[1]
[1] Medical Convergence R&D Team, Rehabilitation Engineering Research Institute, Incheon, Korea.
Email: ephong@comwel.or.kr

INTRODUCTION

Powered-wheelchairs(PWs) have been provided to the disabled since 2005 trhough National Health Insurance Service(NHIS) in Korea. Accord to the survey, currently 5.9% of people with physical disabilities and cerebral palsy require PWs, but only 3.2% of people actually use PWs[1]. Many people have PWs but do not use them because they are not suitable for their physical conditions[2]. And this is due to the fact that most of the customized high-functioning PWs required for severely disabled people are expensive foreigh-made wheelchairs, so the purchase cost is excessive and maintenance and warranty services are limited. Accordingly, Rehabilitation Engineering Research Institute (RERI) is developing a powered-wheelchair with customized chairs, tilt, and recline functions for the localization of high-end powered wheelchairs. In this study, usability evaluation of the PW was conducted for the developed wheelchair in indoor and outdoor daily living environments.

METHODS

Ten people (60.4±15.0 years, 168.0±8.1cm, 73.5± 14.9kg) with spinal cord injury (Level C4~7) participated in this study and a sufficient explanation of the purpose and process of the study, voluntary written consent was obtained (IRB number of RERI-221108-2). The developed wheelchair can adjust the seat to suit the user's physical condition, and is equipped with tilt and recline functions. For usability evaluation, it was compared with commercially available wheelchair (KP-45.5, Karma Medical, Taiwan). The usability of the wheelchairs in daily life was evaluated in the living Lab of RERI. And the assigned tasks were performed according to driving scenarios in indoor and outdoor driving environments (carpets, rough roads, ramps, and obstacles). After completing all driving of a PW, the questionnaire was evaluated, and after sufficient rest, the evaluation of the next wheelchair was conducted. The questionnaire evaluation was conducted based on QUEST (Quebec User Evaluation of Satisfaction with assistive Technology) 2.0, usability evaluation of PW mechanical parts, and driving usability. The evaluation metrics were satisfaction with safety, adjustability, and convenience.

RESULTS AND DISCUSSION

As a result of device satisfaction of QUEST2.0, both wheelchairs showed relatively high satisfaction with an average of 4 points or more. And convenience showed similar satisfaction, but safety and operation & functionality were equally evaluated at 4.31 points, 3.5% and 7.9% lower than comparable products. As a result of the mechanical part, the stability was 4.21 points, 3.9% lower than the comparative product's 4.38 points, but the convenience was evaluated as 4.44 points, which was 19.4% higher than the comparative product.

Figure 1. Image of the wheelchair tests.

CONCLUSIONS

Localized powered-wheelchair showed high satisfaction with customized chairs, tilt and recline convenience. However, the wheelchair users who participated in the study had high manipulative proficiency, so there was a demand for finer control of the steering devices, and in the case of heavy users, there was a demand for a large torque at low speeds. In order to improve the control function and riding comfort in the future, we plan to improve the completeness of the product with the opinions of users presented in this usability evaluation and additional user monitoring.

ACKNOWLEDGEMENTS

This research was supported by the Assistive Technology R&D Project for People with Disabilities and the Elderly funded by the Ministry of Health & Welfare, Republic of Korea (#HJ20C0017).

INTRODUCTION

The purpose of this study is to develop an intelligent wheelchair that improves the convenience of operation to enable autonomous driving for indoor mobility support and daily life assistance in public facilities such as hospitals and museums for people with upper limb disabilities who lack wheelchair operation ability due to spasticity, tremors, and weakness. Especially, It is a study for optimizing sensor system equipment to improve autonomous driving performance and stability.

METHODS

A self-driving wheelchair is composed of RGBD(Intel REALSENSE D435), Webcam, 2D LiDAR(SICK TIM571) and RGBD for sensing rear driving environment. The self-driving wheelchair is composed of a wireless communication module(CNR-L600 Router) and a data processing device(Mini PC & Control power board Assembly) for environmental information processing and driving control. We check the problems through the track test of the autonomous wheelchair and the indoor driving test of the hospital, and carry out the complementary design to improve the performance.

RESULTS AND DISCUSSION

The self-driving wheelchair was tested in a track test simulating the indoor obstacle environment[3] and the driving test was conducted in the hospital indoor environment. The track test satisfies the driving safety without collision as a result of performance evaluation with a fixed obstacle, a movable obstacle, and a driving track of about 40m, which simulates a human model.

Figure 1 Autonomous driving Wheelchair Hospital Indoor Driving Test

In addition, it was confirmed that there is a problem in the detection of the movement obstacle in the front left and right diagonal direction in the driving test in the hospital room, and it is judged that the reason for this result is due to the limitation of the detection range of the RGBD located in the center. In addition, the table configured to locate the sensor in the center is inconvenient for the user to board, and it is judged that it is necessary to supplement the safety of the user against sudden stop or collision.

CONCLUSIONS

The use of the table is excluded for the boarding discomfort solution and safety assurance of the wheelchair user. In order to at the same time sense the dead zone and front of right and left to supplement the square of the front driving environment sensitive area RGBD of 2 is constituted in right and left. At this time, the 2D LiDAR is configured on the opposite side to which the controller is attached. Through this configuration, it is possible to prevent the accident risk by increasing the recognition performance of the movement obstacle in the diagonal area as well as the front.

Performance and Usability Evaluation of an Intelligent Wheelchair

Ki-Tae Nam[1], Yong Cheol[1] and Eung-Pyo Hong[1]
[1] Medical Convergence R&D Team, Rehabilitation Engineering Research Institute, Incheon, Republic of Korea.
Email: nkt798@comwel.or.kr

INTRODUCTION

The Intelligent Wheelchair combines robotic technology with conventional electric wheelchairs to provide autonomous driving to a destination with a robotic function, while allowing joystick steering like conventional electric wheelchairs. People with severe disabilities may not be able to use their upper limbs properly, making accurate joystick steering impossible. Therefore, an intelligent wheelchair is required. The Rehabilitation Engineering Research Institute (RERI) is designing and developing an intelligent wheelchair with autonomous driving function. In this study, the autonomous driving performance and usability evaluation were conducted on the developed intelligent wheelchair.

METHODS

The autonomous performance evaluation was conducted in accordance with the recently written standard "The Performance Evaluation of Autonomous Navigation for Powered Wheelchair". The test route was divided into two sections: the first section was a complex 2-meter-wide corridor with fixed obstacles. In the second section, four different types of moving obstacles were placed. The total length of the two sections is approximately 40 meters [1].

For the usability evaluation, six rehabilitation professionals (therapists, etc.) (31.5±8.5 years, 173.7±9.4 cm, 71.1±13.3 kg) participated in the study and provided full explanation of the study purpose and process and voluntary written consent (IRB number KCIRB-2022-0011). Tasks were created based on usage scenarios, and subjects performed tasks on the intelligent wheelchair for approximately 60 minutes. The results were collected and the subject's subjective feedback was obtained. The tasks consisted of two tasks to read and understand the product's user manual and four tasks to use the actual wheelchair.

RESULTS AND DISCUSSION

In the autonomous performance evaluation, the wheelchair completed 200 laps around the constructed track and avoided all obstacles and collisions during the test.

In the usability evaluation, the task of understanding the user manual was mostly trouble-free, while the task of operating the wheelchair often caused problems when driving the designated route (about 22.2%).

Figure 1 Designed and developed intelligent wheelchair

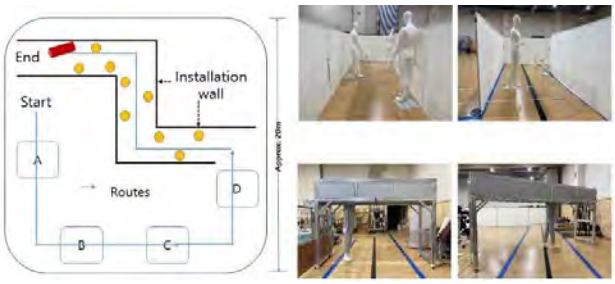

Figure 2 Autonomous Driving Performance Evaluation Track

CONCLUSIONS

Although the autonomous driving performance and safety of intelligent wheelchairs were satisfactory, they were often difficult to operate due to the complex user interface. Considering that the actual users of intelligent wheelchairs are severely disabled, there were many comments that a more intuitive and easy interface is needed. In addition, there were many comments that the table placed in front of the wheelchair made boarding inconvenient. In future studies, we plan to improve the product through additional user monitoring and feedback from usability evaluations.

A New Coupling Mechanics Model for Lower Limb Exoskeletons to Account for Initial Surface Forces

Christian Mele[1], James Tung[1], Katja Mombaur [1,2]
[1] Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, Canada.
[2] Systems Design Engineering, University of Waterloo, Waterloo, Canada.
Email: cmele@uwaterloo.ca

INTRODUCTION

Lower-limb exoskeletons are medical devices that aid in the ambulation of individuals with limited lower-limb mobility. To provide ambulatory assistance, force must be transferred from the exoskeleton to the user through coupling interfaces. These interfaces vary between devices and may contain materials that are rigid, soft, or a combination of the two. To predict and control the trajectory of the leg, the coupling mechanism must be well characterized [1].

Soft coupling mechanics are often represented as simple linear spring-damper systems that require experimental tuning or estimation to determine the coefficients. The least-squares fitting process leads to poor performance when predicting surface forces [1,2]. Recent studies also indicate initial strapping conditions influence reported coefficients [3]. This preliminary study details a new method of fitting spring coefficients in a piecewise approach for least squares approximation that does not sacrifice the simplicity and approachability that linear fitting provides.

METHODS

A case study was conducted to validate results from commonly used coupling models against experimental kinematic and force data collected at the exoskeleton's interface. We used a custom-made 3D printed mannequin leg to guarantee full predictability of the leg's behavior and the H3 exoskeleton (Technaid, Spain). VICON motion capture and Tekscan force-sensitive resistor (FSR) arrays were used to collect kinematic and force data, respectively (Fig. 1, bottom-left). Two models were simulated; the first operated using perfectly coupled assumptions (i.e. the mannequin leg and exoskeleton are assumed to move in union as one rigid body) and the latter assumed that the interface was represented by linear spring-damper.

A new framework of analysis was developed using results of this study to design a new simple spring-damper coupling equation, motivated by initial coupling forces and their influence on dynamics.

RESULTS AND DISCUSSION

Figure 1 (bottom-right) details the driving interface forces of recorded, commonly used linear-spring damper, and proposed coupled spring-damper. When in static contact, an initial pressure was observed that, a linear spring-damper model could not replicate. Figure 1 (top-center), highlights the difference between the old model and newly proposed model. This new model allows for initial coupling to influence mechanics.

The proposed model treats the system as starting initially coupled as a function of the combined spring coefficients. Separation occurs when the compressed surface reaches a displacement equal to the initial compressed length of the opposite surface, allowing for 4 total discrete phases (as opposed to the usual 2). When separation occurs, the system switches and is equivalent to the "Old" linear spring-damper. Dampening coefficient influence remain the same. Characterising this equation is slightly more complex, as direction is no longer the sole indicator for calculating coefficients. The simulated pseudo-static proposed model followed much closer to the recorded spring-values but could not account for drift likely caused by frictional influence.

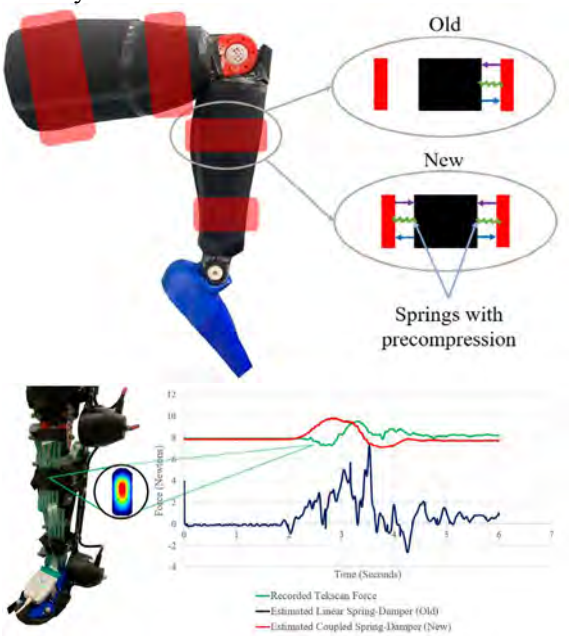

Figure 1 Graphic detailing the Proposed Coupled Spring-Damper model with loaded pre-compression against common models (Top). Testbench sensor setup (bottom-left). Recorded Tekscan force (Green) compared against highly stiff linear spring damper (Blue), and the proposed Coupled Spring-Damper (Red), (bottom-right).

CONCLUSIONS

The models used often in the characterisation of exo-user interactions lack the ability to describe non-linearities caused by initial coupling forces. The newly proposed model maintains the simplicity of linear spring-dampers, with consideration of multi-contact and single-contact stages to more accurately model force.

Biomechanical Evaluation of Difference Between Customized Angled Abutments and Commercial Angled Abutment for Dental Implant in Maxillary Incisor Region

INTRODUCTION

Angled abutment is often required to achieve good esthetic and biomechanical function in immediate implant placement especially in the maxillary incisor region. In this study, finite element analysis and an in vitro experiment were used to investigate the biomechanical effects of the angled abutments with customized angles and the commercial 15°angled abutment in implant and surrounding bone in the region of maxillary incisors.

METHODS

The customized angles for angle abutments was referred from another clinical study by measuring the cone-beam computed tomography (CBCT) images of inclination angle of the incisors and lateral incisors from Taiwanese population from China Medical University Hospital (CMUH108-REC3-168). Therefore, there are four kinds of customized angled abutments (21.9°, 24.15°, 20.22°, 33°) were analyzed including all patients, patients under 20-23, 24-39 and 40-65 years old as compared with a commercial 15°angled abutment. The 3D models of customized angled abutments and a commercial 15°angled abutment were constructed by computer aided design software. For the 3D maxillary bone models, they were created from CBCT images of patients with medical imaging software. Then the computer simulation-finite element analysis (FEA) and in-vitro strain gauge experiment were employed with applying 100N or 50N of a axial force or an oblique force to evaluate the difference in stress/strain values of implant and surrounding bone between customized angled abutments and a commercial 15°angled abutment.\

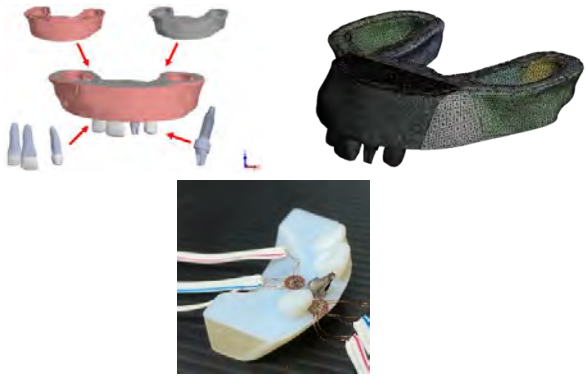

Figure 1. The left figure is the CAD models of maxillary bone (including cortical bone and cancellous bone), tooth and dental implant (including angled abutment and fixture) and the right figure is the mesh model for FEA. The middle figure is the sample for in-vitro strain gauge experiment.

RESULTS AND DISCUSSION

For the results of FEA, in the axial loading, because the angles of the customized angled abutments (21.9°, 24.15°, 20.22°, 33°) are relatively higher as compared with the commercial 15°angled abutment, the stress value in the dental implant and surrounding bone were also higher. However, in oblique loading the commercial 15° angled abutment showed higher stress value in implant and bone. For the results of the vitro experiment, there is no statically difference in bone strain between the customized 21.9° and the commercial 15° angled abutments. Nevertheless, in the oblique loading the use of a commercial 15°angled abutment induced the higher maximum and minimum principal bone strains.

Table 1. Maximum von-Mises stress of cortical bone, cancellous bone and implant under two kinds of loading conditions. (unit: MPa)

	Loading type	Abutment Angle	Cortical bone	Cancellous bone	Implant
All	Axial loading	15°	42.6	3.0	94.5
		21.9°	51.6	3.3	130.8
	Oblique loading	15°	55.8	4.2	327.2
		21.9°	51.1	4.0	223.3
20-23	Axial loading	15°	20.2	2.7	76.4
		24.15°	23.6	2.7	151.9
	Oblique loading	15°	38.1	3.3	301.5
		24.15°	37.8	3.1	204.0
24-39	Axial loading	15°	29.1	4.2	79.1
		20.22°	26.9	4.2	126.8
	Oblique loading	15°	43.4	4.3	302.3
		20.22°	45.0	4.1	201.1
40-65	Axial loading	15°	29.4	3.1	74.6
		33°	38.8	3.6	193.3
	Oblique loading	15°	116.79	7.69	400.1
		33°	100.23	6.89	223.4

CONCLUSIONS

The customized angled abutment show lower stress/strain in implant and surrounding bone in the oblique loading, but in the axial loading a commercial 15° angled abutment present higher stress/strain. It looks like that in terms of biomechanics, there seems to be no absolute benefit for using a customized angle abutment, and it is still related to the direction of the occlusal load.

GENERALISED LIGAMENT MODEL FOR FINITE ELEMENT MODELLING OF THE KNEE

Luca Kiener[1], and Michaela Nusser[1]
[1] Biomechanical Engineering, Zurich University of Applied Sciences/Institute of Mechanical Systems, Winterthur, Switzerland.
Email: luca.kiener@zhaw.ch

INTRODUCTION

A general ligament model for the tibiofemoral joint would pave the way for the use of finite element (FE) models in preoperative planning software as well as for the development of future implant designs for a variety of knee geometries. The aim was to develop a general ligament model applicable to knees from different specimens.

METHODS

A FE model of the knee was developed by segmenting MRI images containing the 3D geometries of the anterior and posterior cruciate ligaments (ACL, PCL) and the medial and lateral collateral ligaments (MCL, LCL). Beidokhti et al. [1] showed that modelling the ligaments as a continuum leads to more accurate contact modelling, which is important for the analysis of knee prostheses. The material model of the ligaments was a multilinear elastic model based on a tensile test on a LCL with a variable strain offset as calibration parameter. In addition, an initial strain was assigned to the ligaments to avoid compressive forces and provide stability to the knee. A holistic approach to the ligament model was to consider the ligament forces, which is the ligament's output affecting the tibiofemoral joint kinematics. Thus, the goal was to determine a set of forces as a general ligament model. Since there was only one calibration parameter per ligament, namely the strain offset, only one force value could determine this parameter. The target force for each ligament was defined during knee flexion from 0° to 90°. To obtain meaningful calibrating forces, they were selected in a position where the forces were high. The force set was based on seven different knee FE models that were independently calibrated based on robotic laxity testing of knee cadavers. The target forces were then applied to six new FE models.

RESULTS AND DISCUSSION

For the ACL, the LCL and the MCL, the calibration forces were defined at 0° flexion and were 15N, 49N and 23N, respectively. For the PCL, the force was 35N at 90° flexion. The target forces were iteratively calibrated for each FE model. Interestingly, the ligaments can exhibit large differences in forces at the flexion angles other than the one of calibration (Figure 1). There are several factors which may influence the behaviors of the ligaments. One factor being that the geometries of the ligaments may vary due to subject-specific differences and the challenges of proper segmentation. The definition of attachment points can also have an influence, as the definition is also subjective to a certain extent. Another factor is that the ligaments have different initial positions depending on the flexion angle during the MRI scan. A possible influence is also the position of the ligament within knee which means that for example larger knees produce a larger lever arm for the ligament. Although the calibrated force may be the same for the ligaments, the stresses in the ligament are higher the smaller the cross-section of the ligament is. This means that thinner ligaments have higher stresses and produce higher forces more quickly due to the curve behaviour. This may be a factor which determines if knee is generally stiff or loose. A viable strategy for preoperative planning would be to have a generative ligament geometry because segmenting the geometry is a time intensive procedure. This would be a compromise between subject-specific geometries and springs.

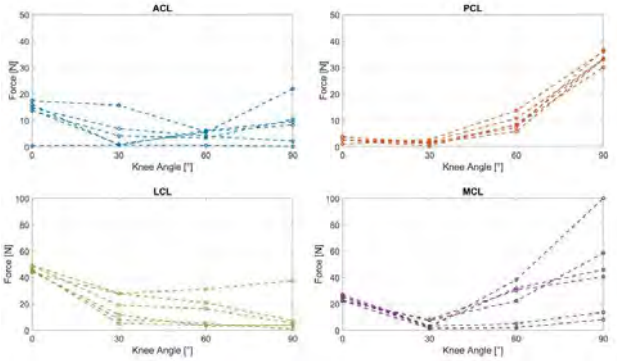

Figure 1 Ligament forces during a passive path flexion (0°-90°) of the ACL, PCL, MCL, LCL of six different FE models.

CONCLUSIONS

The pitfall of a generalized ligament model is that it is generalized and that it does not fit the subject as good as possible. Hence subject-specific properties need to be considered as it would improve the predicted kinematics already shown by Beidokhti et al. [1]. A possibility would be to have a loose and stiff ligament force set, which could be applied according to subject-specific laxity tests.

IS COMPUTER VISION-BASED MOTION CAPTURE APPLICABLE FOR MUSCULOSKELETAL SIMULATION ?

Ryotaro Numata[1], Yasuaki Tsuyuki[1], Ryo Ueno[1,2]
[1]Department of Research and Development, ORGO Inc., Sapporo, Japan
[2]Faculty of Health Sciences, Hokkaido University, Sapporo, Japan.
Email: numata@orgo.co.jp

INTRODUCTION

Usually, several optical motion capture cameras and force plates are needed for musculoskeletal simulation. However, it is expensive and needs preparation time for the measurement. Vision-based monocular 3D human pose estimation is a suitable approach to overcome the above problems. It needs a single RGB camera for kinematics acquisition without any measuring devices. Therefore, the Vision-based approach has the possibility of reducing the cost and measuring time for the musculoskeletal simulation. In this study, we evaluated whether the kinematics data obtained from monocular 3D human pose estimation is applicable to musculoskeletal simulation.

METHODS

An open dataset [2] that was measured from 9 healthy subjects was used. It contains simultaneously recorded 6 types of motion capture data, RGB video and electromyography (EMG) from 9 dominant leg muscles (Soleus, Medial Gastrocnemius, Tibialis Anterior, Semimembranosus, Biceps Femoris, Vastus Lateralis, Rectus Femoris, Vastus Medialis). EMG data was high pass filtered at 25 Hz to remove wire artifacts, full-wave rectified, low pass filtered at 6 Hz and normalized by the maximum value of each trial. Two types of motion (Jump, Squat) from 7 subjects were used because estimated kinematics from 2 subjects were unsuccessful and pose estimation did not perform well for treadmill data. HuMoR [1], a computer vision-based monocular 3D human pose estimation method, is used to estimate the human pose from RGB video. HuMoR fits a human 3D mesh model to the sequential image by optimization with a conditional variational autoencoder.RGB videos that were used for HuMoR were captured at the frontal plane of participants. Markers used for simulation were extracted from the surface of a 3D human mesh as same as in the markerset of the above dataset. Ground reaction force estimation and muscle activation computation were performed with CusToM [3] with the musculoskeletal model consisting of 33 degrees of freedom and 82 muscles from the kinematics data from HuMoR. Out of 9 EMG records, lateral gastrocnemius was excluded from the analysis since it was not implemented in the musculoskeletal model. Spearman's rank correlation coefficient was computed between activation and EMG to examine estimated muscle activations accuracies. To evaluate the applicability of muscle activation from HuMoR, it was compared to the muscle activation computed with the motion capture data.

RESULTS AND DISCUSSION

Figure 1 shows the mean activation of each method in the jump trial over all subjects. Focusing on the knee extensors (Vastus Lateralis, Rectus Femoris, Vastus Medialis) that primarily work for the squat and jump, r_s scores between activation with HuMoR and EMG are equivalent to r_s score by activation with Mocap and EMG (Table1).

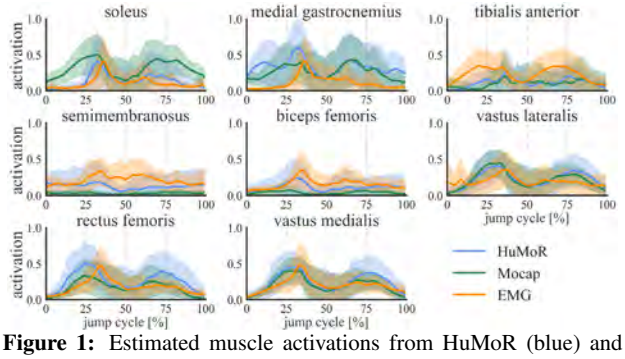

Figure 1: Estimated muscle activations from HuMoR (blue) and Mocap (green) as well as EMG (orange) averaged over the jump trials. The shaded area represents ± 1SD.

CONCLUSIONS

Preliminary results show the estimated kinematics from monocular video with a 3D human pose estimation algorithm is applicable for musculoskeletal simulation.

CRITICAL REGIONS IN THE MANDIBLE DURING MASTICATION AND BLUNT IMPACT

Samrat Sagar[1], Rupesh Ghyar[1], B. Ravi[1] and Darshan Shah[1]
[1] Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India.
Email: samratsagar@iitb.ac.in

INTRODUCTION

There is a rise in the use of custom implants for the reconstruction of mandibles affected by osteosarcoma in order to restore facial aesthetics and oral functions. Custom implants have been known to offer better biomechanical fit and postoperative outcomes when compared to stock implants. However, there have been instances of postoperative implant fractures due to fatigue, where cracks were identified at stress concentration regions [1]. Additionally, blunt force trauma often causes mandible fractures [2], which could be to detrimental to the implant. Characterising potential regions of high stress in the native intact mandible could potentially direct design considerations while developing a custom implant. The aim of this study was to identify and characterise critical stress concentration regions in an intact mandible for simulated loading conditions during mastication and trauma.

METHODS

A finite element analysis was conducted on an edentulous intact mandible subjected to tasks replicating loading conditions from mastication and blunt impacts using Workbench 2020 R2 (Ansys Inc., PA, USA). The material of the model was assumed to be homogeneous and isotropic cortical bone. The condyles of the mandible were rigidly fixed. Forces of jaw-closing muscles were appropriately simulated in magnitude and line of action. For simulating mastication, the model was loaded under six unilateral clenching tasks – intercuspal (ICP), incisal (INC), canine (CAN), molar (MOL), left group (LGC) and left group with molar balancing (LGC+MB) – and one molar chewing task (MOL chew) [3]. Fist punches were simulated on four principal locations of the mandible – symphysis (SYM), parasymphysis (paraSYM), body (BOD) and ramus (RAM).

The critical stress for failure (σ_{cr}) was considered to be the fatigue shear strength of cortical bone (24 MPa) and yield strength of cortical bone (114 MPa) for the mastication tasks and blunt-impact tasks, respectively. Regions on the mandible exhibiting stress values over the critical stress were identified as critical regions. Critical regions appearing around the condyles were neglected following the St. Venant's principle.

RESULTS AND DISCUSSION

For all mastication tasks, except LGC and LGC+MB, critical regions were observed around the respective clenching points (Fig.1). In contrast, critical regions for fist punching tasks were found at the ipsilateral and contralateral condylar necks, with maximum stress values 1.75 to 6 times higher than σ_{cr} (Table 1). These findings were in agreement with the previous studies [2]. Critical regions thus identified on a native mandible could predict potential failure sites on a custom implant meant to replace it, allowing for improved design considerations apriori. Further improvements on the model will be directed towards using a dentate mandible with cortical and cancellous material.

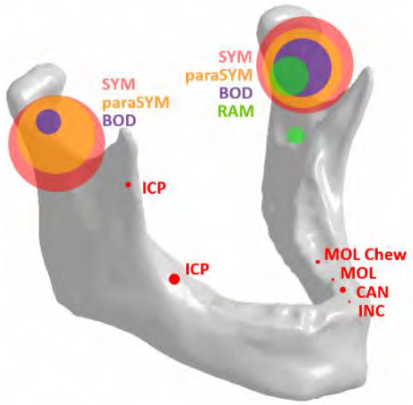

Figure 1 Critical regions on mandible for mastication and blunt-impact loads (circles indicate location and area of the critical region).

CONCLUSIONS

Critical regions during incisal clench, canine clench and molar chewing, which constitute the alternating bilateral mastication pattern [4], were predominantly observed on the body of the mandible. Therefore, while designing a mandibular implant for a body defect, designers should avoid stress concentration points, such as sharp edges or corners, which could lead to implant failure. In view of critical regions in condylar necks during blunt force trauma, similar care should be taken while designing temporomandibular joint implants.

APPROPRIATE METRICS TO EVALUATE SPRING ASSISTANCE TO LOWER LIMBS FOR IMPROVING HUMAN GAIT

Rajbeer Singh Anand[1], Neeta Kanekar[2] and Anirban Guha[1]
[1] Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India.
[2] Department of Biosciences and Bioengineering, Indian Institute of Technology Bombay, Mumbai, India.
Email: rajbeer2007@iitb.ac.in

INTRODUCTION

Gait impairments in older adults severely increase their risk of disability, morbidity, and mortality. Wearable devices have been suggested for their gait assistance. Among wearable devices, passive exoskeletons have some advantages over active devices like lower weight and independence from power source. Before fabricating these passive devices, a designer often performs simulations to judge the performance of multiple designs. For comparing results of different simulations, researchers have mostly used two metrics - the peak value and the average of a parameter of interest over the Gait Cycle (GC) [1,2]. However, the questions of whether the chosen metrics lead to similar conclusions and capture the effect of the device in different phases of the GC remain unanswered. This study addresses these questions by evaluating these metrics separately in different phases of the GC. It also introduces another metric which is likely to be more representative of the performance of a device over the entire GC than the peak and average.

METHODS

OpenSim 4.4 was used for the simulations. The parameters evaluated were total metabolic rate (TMR) and right ankle moment (RAM). 7 metrics were considered for this study, peak, average, and area under the curve over the entire GC, the phase wise values of these three metrics, and the average of phase wise peaks. The GC was divided into 4 phases: initial stance (IS, 0-10% GC), mid stance (MS, 10-30% GC), terminal stance (TS, 30-60% GC), and swing (SW, 60-100% GC). Torsion springs with spring wire diameters of 2mm (TS_2, spring constant, k=0.023Nm/deg.), 3mm (TS_3, k=0.164Nm/deg.), and 5mm (TS_5, k=1.005Nm/deg.) at the ankles and linear springs replicating the path of soleus muscles with spring constants of 7kN/m (LS_7), 11kN/m (LS_11), and 15kN/m (LS_15) were used. The subject in this simulation weighed 72.6 kg with a standing height of 1.8 m and walked at a comfortable speed of 1.2 m/s on the treadmill. The spring assistance conditions were compared to the no spring (control) condition.

RESULTS AND DISCUSSION

Table 1 shows percentage changes in the parameters with spring versus the control condition. Positive values indicate an improvement. The greater detail captured through the phase wise representation was obvious. The fact that the IS and SW phases can show a deterioration in RAM in spite of the overall peak or average based data leading to the opposite conclusion, was significant. The magnitude of improvement in TMR with the use of torsion springs was severely underestimated by the peak compared to the other two metrics. Overall, predictions through the average and area under the curve metrics (in green) were much more closely correlated than those with the peak (in red).

CONCLUSIONS

Commonly used parameter metrics such as peak value over the entire GC may not be the best indicator of assessing the effectiveness of a device and in certain cases could even be misleading. Phase wise metrics provide a more nuanced indicator of the assistance (or the lack of it) provided by a device in different phases of the GC and could be more appropriate for guiding device development. This consideration becomes particularly important in the design of passive exoskeletons that may not have phase-wise control and act through the entire GC.

INTRODUCTION

Biomechanical computed tomography analysis can predict the bone strength and vertebral fracture risk in patients with low bone density. To automatically create a finite element model with inhomogeneous bone materials, a customized (MATLAB) program was designed for pre-processing CT images of each patient. This study will compare the vertebral strain in two models generated by using a MATLAB program (high inhomogeneity) and CAE software (low inhomogeneity).

METHODS

When modeling with MATLAB, the CT images are first stacked into a 3D array, and the pixel values are converted into Hounsfield units based on the RescaleSlope and RescaleIntercept in the CT image tag. The PixelSpacing is used to determine the actual imaging size. Using the Volume Segmenter, the general location of the image is marked for cropping. The bone segment is then separated based on the Hounsfield units, and the largest voxel group is marked for isolation, to separate the vertebrae to be analyzed[1].

According to the order of intensity values, the coordinates of each voxel's eight nodes are numbered and stored in a cell, which are then converted into three-dimensional coordinates. The intensity is converted into apparent density and elastic modulus using an empirical formula[2]. The maximum and minimum values of the y-coordinate are stored in an additional array to establish the node set for the upper and lower plane of the vertebral body. Strain calculation was conducted by LS-DYNA (LSTC, Livermore, CA, USA). A compression force was distributed perpendicularly on the upper endplate of the vertebral body. All nodes in the lower plane of the vertebral body are restricted. After renumbering the nodes, the solver can be utilized for computation.

For comparison, CAE software was utilized to create a vertebral body model. The 2D mesh model was extracted from the CT image using RETOMO (BETA CAE Systems, CH-6039 Root D4, Switzerland). Further processing of the 2D mesh model was performed using ANSA (BETA CAE Systems, CH-6039 Root D4, Switzerland), where the model was divided into 30 different materials through material mapping.

RESULTS AND DISCUSSION

The models were generated by using two methods (Figure 1). The time spent was 30.65minutes (customized) and 50.27 minutes (CAE software). The maximum and minimum values of the 1st Principal Strain-Infinitesimal and the 3rd Principal Strain-Infinitesimal were different (Table 1). However, there were ignorable differences between their means. The vertebral strains were similar in both models.

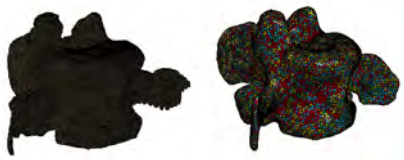

Figure 1 Left: customized; Right: CAE software

CONCLUSIONS

The modeling process used in this study can perform pre-processing and model meshing tasks automatically and saves time and labor costs in pre-processing. The result reveals that the customized program generates a model with more real bony distribution and similar strain as CAE model does. In the future, this modeling method can be used to predict the mechanical strengths and fracture risks of vertebrae.

The Study of Tip-over Stability Analysis for Sitting Position Transition Wheelchair

Dae-Jin Jang[1], Yong-Cheol Kim[1], Eung-Pyo Hong[1] and Gyoo-Suk Kim[1]
[1] Rehabilitation Engineering Research Institute, Incheon, Korea
Email: rehajang@comwel.or.kr

INTRODUCTION

The sitting position transition power wheelchair is a mobile device used by the disabled who have difficulty in daily life by themselves. The sitting position trnsition power wheelchair is capable of backward tilt, recline, elevating legrest, lift, forward tilt, and stand. These postures are important for the prevention of various diseases in wheelchair users [1]. Some power wheelchairs reduce the movement speed or limit some postures when changing posture. However, there is no known criterion for limiting the posture, and there have been few studies on the tip-over risk evaluation when changing posture in power wheelchairs. In this study, ADAMS, a multi-body dynamics analysis program, the force-moment stability measurement method is used to calculate a stability metric when the posture of a power wheelchair is changed and the risk of tip-over in various postures is compared and analyzed.

METHODS

Force-moment stability measurement [2] is determined by the moment due to the inertial force and the moment due to the ground reaction force occurring at the center of gravity when the electric wheelchair moves or changes posture. The moment axes refer to a line connecting two adjacent points among the ground contact points of the power wheelchair, and the moment axes are equal to the number of wheels of the power wheelchair.

The stability measurement is calculated by the difference between the moment due to inertia and the moment due to ground contact force, and the equation is as follows.

$$SM_i = H_i^* r_i - \sum_{j=1}^{n}\left((p_j - p_i) \times F_j\right) r_i \quad (1)$$

Where when there are n ground contact points, r_i is a line (tip-over axis) connecting the i_{th} ground contact point and the next point, p_i is a three-dimensional vector connected to the i_{th} ground contact point at the center of gravity, and F_i is the ground contact force at i_{th} point. H_i^* in Eq. (1) is as follows.

$$H_i^* = I_b\dot{\omega} + \omega \times (I_b\omega) + (\dot{c} - \dot{p}_i + \omega \times (c - p_i)) \times mv_c \quad (2)$$

Wher I_b is the moment of inertia, ω is the angular velocity, c is the position of the center of gravity, and v_c is the movement speed of the center of gravity.

The stability metric refers to the value when the power wheelchair has the minimum value for all tip-over axes based on the most stable position. Therefore, if the power wheelchair is stationary, the stability metric value always has a positive value because only the ground reaction force was applied. However, when excessive acceleration or an external force is applied, the stability metric can become a negative value, and at this time, it can be considered to be inverted.

RESULTS AND DISCUSSION

For stability metric calculation, a posture transition power wheelchair is developed. The wheelbase of the power wheelchair is 525 mm, the height before the seat is lifted is about 580 mm from the ground, and the total weight of the power wheelchair is about 163 kg. The human body model was 175 mm and used two dummies weighing 75 kg and 100 kg. Stability metric values were compared and analyzed for tilt, recline, and lift operations. In the 45-degree tilt simulation, the stability metrics were 0.53 and 0.46 for the 75 kg and 100 kg models, respectively, and 0.51 and 0.46 for the 75 kg and 100 kg models, respectively, for the 90-degree recline. The stability metrics during lifting up to 380 mm were 0.95 and 0.92 for the 75 kg and 100 kg models, respectively.

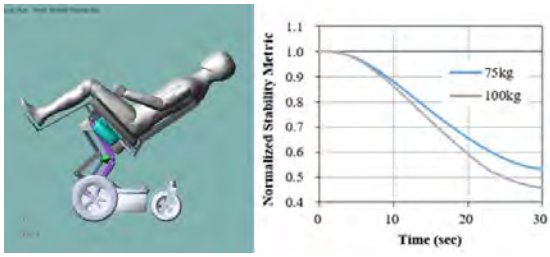

Figure 1 Stability metric in tilt simulation

CONCLUSIONS

As a result of the simulation, the stability metric was between 0.4 and 0.6 wheelchair during tilt and recline. This is not a condition for the wheelchair to overturn, but in this state, the wheelchair can be instantly overturned by losing the ground reaction force on either side due to a small stone, or outward extension of the user's arm. Under these conditions, the maximum speed of the wheelchair should be reduced and posture transition is restricted as a concerning step. In future research, we plan to compare the stability of wheelchairs by calculating the stability of each posture according to the movement speed of the wheelchair.

ANALYSIS OF POSTURE, SPINAL CURVATURES AND GAIT IN LUMBAR ARTHRODESIS PATIENTS

Guillaume Claus[1,2], Alessia Putzolu[3], Laurent Fabeck[3] and Véronique Feipel[1,2]

[1] Laboratory of Functional Anatomy, [2] Laboratory of Anatomy, Biomechanics and Organogenesis, [3] Department of Orthopaedics, Université Libre de Bruxelles (ULB), Belgium
Email: guillaume.claus@ulb.be

INTRODUCTION

The contribution of biomechanical analysis of the human spine regarding the diagnosis and therapeutic follow-up of patients suffering from low back pain is promising, but clinical studies supporting its relevance are rare. The aim of this study was to evaluate the clinical relevance of biomechanical parameters in persons with lumbar arthrodesis (LA) by studying static (vertebral curvatures) and dynamic (gait) parameters.

METHODS

A control group (CG, n=10) and an affected group with LA (n=13) volunteered aged 35 years and older for the study.

Data were collected using the A-palp technique [1] in a fourteen-camera optoelectronic system (T40s, VICON, Oxford, UK; sampling rate: 100Hz). Retro-reflective markers were placed on the anatomical landmarks organised for postural evaluation [2]. Additional landmarks were palpated according to a precise protocol [2] using the thermo-deformable splint of the A-Palp tool. This protocol allows to obtain a 3D model of the spine by continuously tracking the trajectory of the spinous processes from the external occipital prominence until the spinous process of S2. The landmarks were palpated in a controlled standing position. Lumbar lordosis (LL) and thoracic kyphosis (TK) were computed using the tangent method [2].

Consequently, participants walked barefoot on a 6m long ZENO instrumented walkway (ProtoKinetics, Havertown, PA, USA). Two trials were carried out at three randomized self-selected speeds (slow, fast and preferred [3]). Spatiotemporal variables were extracted using PKMas.

Mann-Whitney U tests and Pearson's correlation coefficients were used for statistical analysis.

RESULTS AND DISCUSSION

No group difference in LL and TK were found. During gait, the group with LA showed a greater toe out angle compared to CG. At preferred and/or fast speeds, step length, single support and gait velocity were lower, while stance phase, swing phase and step time increased in the LA group in comparison with CG.

These differences at preferred and fast speeds support that humans are better able to cope with postural instability and kinesiophobia at slow speed [4,5]. The use of adaptation mechanisms is stronger at higher gait speed.

In the CG, a strong negative correlation was found between LL and step length at fast speed (r=-0.77), indicating longer steps with lower LL. Moderate correlations existed between LL and stance, swing and single support phases at preferred speed in the CG (|r|≥0.50), increasing LL being associated with larger single support and swing phases and shorter stance phase. No correlation coefficient above 0.50 was found in the LA group, except for a moderate inverse relationship between TK and toe in/out angle (r=-0.53).

Table 1. Spatiotemporal gait parameters. Velocity in cm/s; Toe in/out angle in °; Step length, cycle length and step width in cm, Stance and single support phases in % of gait cycle. Significant different from CG in red.

Variable	**CG**			**LA**		
Speed	Slow	Preferred	Fast	Slow	Preferred	Fast
Velocity	72±25	120±12	171±20	73±27	110±22	139±35
Toe in/out angle	3±4	3±4	2±4	**9±5**	9±5	9±7
Step length	53±5	65±4	73±9	47±8	59±7	65±10
Cycle length	105±11	130±9	151±12	94±17	118±14	129±19
Step width	9±3	8±1	9±2	9±5	9±3	9±3
Stance phase	66±3	62±1	59±1	67±5	63±2	62±2
Single support	34±4	38±1	41±1	33±5	37±2	38±2

CONCLUSIONS

Patients with LA differed from controls in terms of spatiotemporal gait variables, but not of spinal curvatures. The absence of correlation between curvature and gait variables in the LA group and its clinical relevance needs further investigation, among others including larger samples.

Dependence of static compressive condition on breast support performance of sports bras during running

Yasuho Takii[1]
[1] Institute of Sport Science / ASICS Corporation, Kobe, Japan.
Email: yasuho.takii@asics.com

INTRODUCTION

The relationship between breast movement during running and breast support privided by sports bra has been studied previously. These studies have shown that the greater the support provided by a sports bra, the greater the reduction in breast movement during running[1,2]. In practical designing of sports bra, these research would be more fruiful if the detailed discussion as belows were added. (1)Comparison of breast movement in different sizes under the same compression of sports bra. (2)Understanding the critical contribution area in sports bra to controll the breast movement. (3)Relationshiop between breast movement and breast bounce perception.
Therefore, the aim of this study was to quantitatively examine the relationships between wearing compression of sports bras, breast movement during running and subjective breast bounce perception.

METHODS

Four females participated in this study (mean ± SD: 22.8 ± 4.6 years, 154.6 ± 2.7 cm, 46.4 ± 5.1 kg). Participants' breast sizes were 65A, 70A, 70C, 80C. Medium size bras were used for participants with 70C or 80C size breasts. Small size bras were used for participants with 65A or 70A size breasts. Six types of bras were used for this study. In these bras, two were low support types, one was medium support type, and two were high support types. Wearing compression was measured at ten points on each of their trunks in the static condition using an air-pack-type pressure sensor (AMI 3037-10, AMI Techno, Co., Ltd). Participants performed running trials (treadmill, 8 km/h), then 3D movement of the left nipple using the 3D motion analysis system (VICON Motion System, UK) and subjective breast bounce perception data during running using 10-cm visual analog scale were collected. The trajectory length in each bra condition compared to that of the nude condition was calculated as %Trajectory length (%Trj.). A multiple regression test was performed with %Trj. as the response variable and the pressure values at each point as the explanatory variables.

RESULTS AND DISCUSSION

The trajectory length of the left nipple during one cycle of running was longer for larger breast sizes and shorter for smaller breast sizes at all pressure levels. For each subject, there was a correlation between average pressure on the trunk and trajectory length. In terms of %Trj., values for all subjects were in the same range.
There was a correlation between average pressure on the trunk and %Trj. for each subject and for all subjects combined (Figure 1). The same level of breast bounce reduction was shown with increasing pressure. The multiple regression identified the pressure in the shoulder, lower breast and underbust areas to be important in describing %Trj. Subjects of all breast sizes had relatively low breast bounce perception when %Trj. was below 55%.
These results suggest that greater pressure is needed to bring the larger size breasts to the same level of breast bounce as the smaller size breasts. On the other hand, the rate of reduction in breast bounce required to feel less breast bounce and the wearing compression required to reach that rate of reduction are the same regardless of breast size. The results of the multiple regression analysis indicate a high contribution of forces controlling breast bounce in the vertical direction. This is a reasonable result given the large vertical displacement of the breast during bare-breast running[3]. Further analysis is needed to improve the accuracy of the multiple regression equation here, after adding information on the types of bra shapes and physical properties of the fabrics.

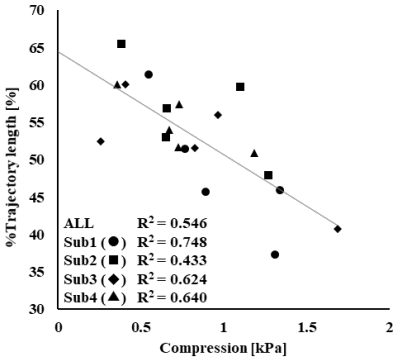

Figure 1 Relationship %Trj. and wearing compression.

CONCLUSIONS

For subjects with different breast sizes, it was required to provide higher wearing compression for subjects with lager breasts in order to achieve the same amount of breast bounce during running. If the rate of reduction in breast bounce was the same, the same wearing compression was required regardless of breast size. And pressure at the shoulders and lower breast area was important. Breast bounce perception was reduced when the reduction rate fell below a certain level.

INTRODUCTION

Idiopathic scoliosis is the most common form and is characterized by its occurrence mainly in adolescence [1]. In particular, adolescent idiopathic scoliosis (AIS) is more common in girls, and women are at a 10-fold higher risk of developing than men [2,3]. In the case of adolescent idiopathic scoliosis, interest in estrogen as a potential factor for AIS has increased while the exact cause has not yet been identified [3]. In particular, in the case of women, since the secondary growth of menarche appears physiologically during adolescence, it is necessary to study the scoliosis angle according to the presence or absence of menarche. Therefore, the purpose of this study is to find out the scoliosis angle according to the presence or absence of menarche.

METHODS

A total of 130 elementary school female students were recruited for this study, and the group with menarche (age 12.35±0.58 years, height 154.22±6.87 cm, weight 45.03±11.46 kg) and the group without menarche (age 10.48±0.65 years, height 138.42±5.48 cm, weight 33.00±5.98 kg) were recruited. All subjects utilized spinal structural analysis (Formetric 4D, Diers Biomedical Solutions, Germany) using the rastersterography method to measure spinal deformity. This device is known as a device used to evaluate spinal divisions, and its validity and reliability have been demonstrated [4-6]. For measurement, a halogen light source was aimed at it, and a 3D model used for spinal deformity evaluation was constructed based on the image obtained, and scoliosis angle values were extracted by triangulation. For statistical analysis, an independent *t*-test was used for comparison within groups using the SPSS 26.0 (IBM, USA), and all variables were calculated as mean and standard deviation. The statistical significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

The scoliosis angle showed a significant difference between the groups according to menarche status <Figure 1>. Menarche in women is determined by the secretion rhythm of the ovarian hormones, estrogen, and progesterone [3]. Abnormal estrogen levels cause delayed menarche, which delays bone development and maturation, increasing the possibility of spinal deformities [7]. In addition, a higher risk of AIS in women is associated with delayed menarche, suggesting that low estrogen is an important factor in the onset of AIS [7].

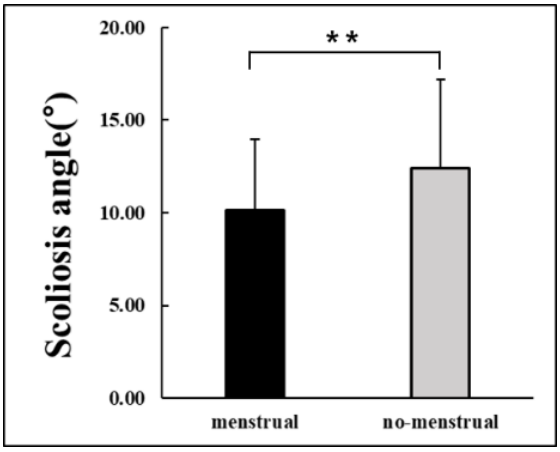

Figure 1. Result of scoliosis angle
Note. Data are mean ± standard deviation. Asterisk (**) indicates a significant difference between force level conditions at $P < 0.01$.

CONCLUSIONS

In addition to delayed menarche, one of the risk factors for AIS, the scoliosis angle was higher in the non-menarche group, which is highly likely to be due to abnormal estrogen levels, compared to the menarche group.

ACKNOWLEDGEMENTS

The authors would like to thank the participants for their time and commitment to this research. This study was supported by the University Innovation Support Project of Incheon National University.

Effects of varying in load weight on spine kinematics in Deadlift

Kazuma Shoji[1], Koichi Nakayama[1], Masayo Shiouchi[1] and Yoshiaki Manabe[1,2]

INTRODUCTION

Deadlift is a comprehensive training of the trunk and lower extremity muscles, and the load weight should be selected according to the targeted training effect [1]. Maximal and submaximal deadlift reported to have different lifting techniques and strategies [2]. However, no studies have yet comprehensive compared spinal kinematics of the spine between different load weights. In addition, the human spine, composed of 33 vertebral bones, has mobility, such as extension-flexion and rotation, similar to other joints. However, most biomechanical motion studies of deadlift simplify the human trunk to a single rigid-body segment, ignoring its motion. Recent studies have reported that using a segmented trunk model is able to measure detailed spinal kinematics [3]. This study utilized a trunk model with six rigid-body segments and compare spinal kinematic characteristics between different load weights.

METHODS

In this study, twelve university male track and field athletes performed traditional deadlifts. The maximum load weight (1RM: one repetition maximum) was estimated by a direct method for each subject, and the trials were performed at 60, 70, 80, 90% of the loads when 1RM was set at 100%. Using a 12-camera optical three-dimensional motion analysis (VICON MX, Oxford Metrics Group), we measured the three-dimensional coordinates of each reflective marker attached to a total of 27 physical feature points on the body. A force plate (Kistler) was used to simultaneously measure the ground reaction force. A link segment model, in which the trunk consisted of six regions, was constructed based on the method of Kudo et al. [3], and kinematic data for each region of the spine in the sagittal plane were calculated. Statistical processing was used for the statistical analysis software SPSS.26.0 (SPSS Inc., Chicago).

RESULTS AND DISCUSSION

The maximum flexion angle of the total spine angle was significantly greater for the 90% 1RM than for the other weights (60%: -52.05 ± 2.673deg vs. 70%: -53.47 ± 3.26deg vs. 80%: -55.19 ± 3.76 vs. 90%: -61.38 ± 3.96, P<.05). This result revealed that the increased load weight emphasizes the rounding of the trunk (Table 1). In particular, the differences in regional flexion angles of spine, when increased load weight, were significant at the lower regions of the spine (T12: at 0 to 100% normalized time, L3: at 0 to 60% normalized time, respectively; P <.05). And those increased flexion angles were found in the timing of the barbell passing through the knee (at 50% normalization time).

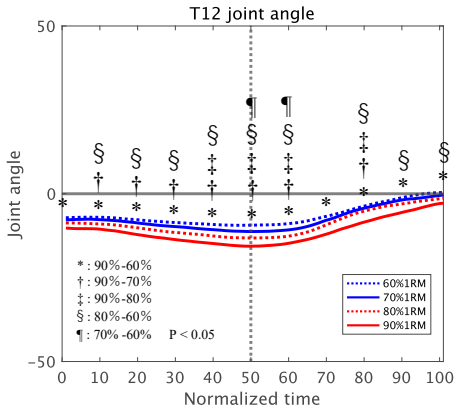

Figure 1 Time series data that show the lower thoracic spine angle during the ascending phase.

CONCLUSIONS

Concerning spinal kinematics in deadlift, we conclude that (1) flexion angle was larger with increasing load weight, (2) the difference in regional flexion angle, with increased load weight, were remarkable around the upper lumbar spine, (3) those region's flexion angle increased when the bar passes through the knee.

INTRODUCTION

Persistent shoulder pain involves a complex interaction between physiological and psychological factors. Still unknown is to what extent upper body movement behaviour in patients with shoulder pain is part of an ongoing nociception-based adaptive mechanism. The aim of this multicentre observational study was to observe the influence of immediate relief of nociception-based pain on shoulder and trunk kinematics during a semi-constrained painful overhead reach task in patients with ongoing shoulder pain.

METHODS

Symptomatic shoulders of 29 patients (mean age 59.0 SD 12.8 years; 16 males) were injected with corticosteroids and lidocaine by their attending orthopaedic surgeon. Immediately before and five minutes after the injection, patients had to reach ten consecutive times as high as possible to a target at the ceiling directly above. Pain intensity (VNRS-11) at each highest arm elevation, scapula, humerus and trunk kinematics (assessed using Xsens DOT, wireless inertial measurement units) were recorded. Shoulder motions were expressed as a helical angle rotation relative to their initial position. Pre- and post-injection motions were compared as the differences between those values.

RESULTS AND DISCUSSION

Generalized Estimating Equations analysis showed statistically significant reduction in pain during the reach task after the injection (n=27). Statistical Non-Parametrical Mapping did not identify differences in maximal shoulder and trunk helical angle contributions between conditions (Figure 1). Significantly lower angles for the post-injection condition were found for part of the descending phase (thoracohumeral [75.3%, 92.9%]; p<.001;scapulothoracic [73.7%, 93.1%]; p=.003; humeroscapular [71.4%, 92.3%]; p<.001).

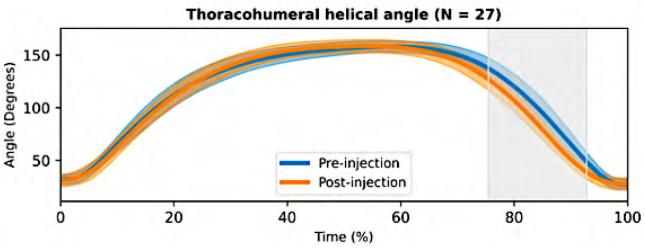

Figure 1 Results of Statistical non-Parametric Mapping (SnMP) of the elevation (helical) angle of the reach task within the normalized time domain (%). Mean (solid lines) and 95% confidence intervals (shaded band) of pre-injection are given in blue and post-injection in orange. Shaded grey areas indicate the significant differences.

CONCLUSIONS

Acute pain relief following topical anaesthetics does not result in immediate alterations in the maximal contribution of shoulder and trunk range of motion during a semi-constrained painful overhead reach task in patients with ongoing shoulder pain. At the group level, there appears to be no reason to alter shoulder and trunk kinematics when reaching for the target post-injection. However, there are small alterations in shoulder kinematics during the descending phase.

ACKNOWLEDGEMENTS

We thank all involved orthopaedics secretariats and colleagues of the Amphia Hospital, the Spaarne Hospital, the Bergman Clinics and the Onze Lieve Vrouwe Hospital (OLVG) for their help in organizing this study.

Motor unit behavior of the lower trapezius and serratus anterior in individuals with Scapular Dyskinesis

Masahiro Kuniki[1], Daisuke Kuwahara[1], Rei Konishi[1,2] and Nobuhiro Kito [2]

[1] Graduate School of Medical Welfare Sciences, Medical Engineering, Hiroshima International University / Hiroshima, Japan.

Email: n-kito@hirokoku-u.ac.jp

INTRODUCTION

Scapular dyskinesis (SD) is one of the factors that cause shoulder injuries [1]. Although the weakness of the lower trapezius and serratus anterior is associated with SD, these muscle thicknesses are not reduced in individuals with a shoulder injury, and muscle weakness due to muscle atrophy alone cannot explain the cause of SD. Muscle strength also depends on the number, size, and firing rate of recruited motor units (motor unit behavior, MU behavior) [2], but no studies have investigated MU behavior in the lower trapezius and serratus anterior of individuals with SD. The purpose of this study was to clarify the MU behavior of the lower trapezius and serratus anterior in individuals with SD.

METHODS

The Scapular Dyskinesis Test (SDT) was performed on 50 healthy young adults. The SDT is classified into Normal, Subtle, and Obvious by observing the scapular motion from the back during the raising and lowering of the upper limb [1]. The SDT results showed that 14 were Normal, 16 were Subtle, and 20 were Obvious. Of the Obvious, 9 who observed SD in the raising phase were considered as the SD group (SDG), and 11 who observed SD only in the lowering phase were excluded. Normal 14 was considered the Normal group (NG). The subject performed trapezoidal contractions with 70 % of the maximum voluntary contraction of the lower trapezius, serratus anterior at the position of manual muscle testing by Kendall. Muscle activity was measured with a Trigno Galileo sensor (Delsys, USA), and the EMG waveform was decomposed into MU action potential amplitude (MUAP-amp), mean firing rate (MFR), and recruitment threshold (RT) using a template-matching algorithm [3]. MFR was calculated as the mean of the firing rate during the 20-second plateau during trapezoidal contraction. The slope and y-intercept of the regression of MUAP-amp and MFR with RT were calculated. The MUs were divided into three groups by RT (< 20%, 20-40%, > 40%), and the average of MUAP-amp and MFR for each MU group was calculated. A two-sample t-test or Mann-Whitney test was used to compare each parameter between groups. The significance level was set at $p < 0.05$, and d or r was calculated as the effect size.

RESULTS AND DISCUSSION

The slope of the regression between MUAP-amp and RT was higher in the NG for both the lower trapezius (NG, 0.010 ± 0.003; SDG, 0.007 ± 0.002; $p = 0.010$, $d = 1.054$) and serratus anterior (NG, 0.009 ± 0.004; SDG, 0.004 ± 0.003; $p = 0.007$, $d = 1.272$). MUAP-amp of the lower trapezius is higher in the NG at all RTs, and the serratus anterior is higher in the NG at medium and high threshold MUs **(Figure 1).** The slope of the regression between MFR and RT was higher in the NG only for the serratus anterior (NG, 27.839 ± 3.515; SDG, 22.215 ± 5.069; p = 0.005, d = 1.347). In particular, the low firing rates of the medium and high threshold MUs **(Figure 1).** In addition to the size of the MU, the serratus anterior has a low firing rate, suggesting that the neural drive of the serratus anterior is reduced in individuals with SD.

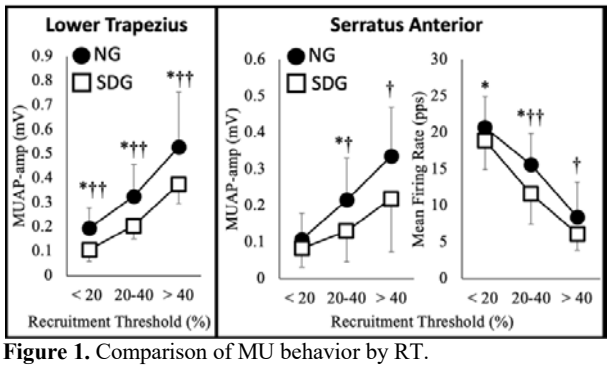

Figure 1. Comparison of MU behavior by RT.
* p <0.05; † medium effect size; †† large effect size
NG, Normal group; SDG, Scapular Dyskinesis group

CONCLUSIONS

Individuals with SD differ from individuals with normal scapular motion in MU behavior of the lower trapezius and serratus anterior. SD may be caused not only by muscle weakness due to muscle atrophy but also by neurophysiological factors such as recruited MU size and firing rate of the lower trapezius and serratus anterior.

ACKNOWLEDGEMENTS

The authors thank all individuals who participated in this study.

INTRODUCTION

Ulnar neuropathy is a common cause of medial elbow pain. Furthermore, valgus instability is known to be related to ulnar neuropathy. However, previous studies have not examined the effects of level of competition. Therefore, the purpose of this study was to examine the effect of level of competition on ulnar neuropathy.

METHODS

The subjects were 76 baseball players (32 professional baseball players and 44 amateur baseball players). The ulnohumeral joint space was measured at rest and during valgus stress loading using an ultrasonography. In addition, the presence of osteophytes on the medial epicondyle and sublime tubercle which was called insertion of the ulnar collateral ligament (UCL) was confirmed. Relative to the medial epicondyle, the arcade of Struthers was 5 cm proximal, the cubital tunnel was the posteo-medial part, and Osborne's ligament was defined as 3 cm distal. For statistical analysis, subjects were classified according to with or without of medial elbow pain. The CSA ratio were calculated as the CSA of the throwing side relative to the non-throwing side, respectively. The subjects were classified into four groups according to their level of competition and with or without of medial elbow pain. The ulnohumeral joint space and CSA ratio was compared among the four groups using a one-way analysis of variance and a multiple comparison test. The relationship between level of competition or medial elbow pain and osteophytes was examined using the X_2 test.

RESULTS AND DISCUSSION

Professional baseball players had 10 players with pain and 22 players without pain. Amateur baseball players had 24 players with pain and 20 players without pain.
The ulnohumeral joint space at rest was significantly wider in the professional with pain group than in the without pain group. The ulnohumeral joint space was significantly wider in the with pain group than in the without pain group in both professionals and amateurs during valgus stress. The CSA ratio of the ulnar nerve was significantly swelled in the with pain group compared to the without pain group in both the professional and amateur groups.
The relationship between medial elbow pain and osteophytes was significantly more in the with pain group. There was no significant difference between the level of competition and osteophytes.
Previous studies have reported ulnar neuropathy as a result of increased valgus instability and osteophytes in the ulnohumeral joint. Excessive valgus stress continues to be applied to the medial elbow, and repetitive mechanical stress of the UN increases. Osteophytes in the ulnohumeral joint may increase frictional stress on the ulnar nerve. These factors suggest that swelling of the ulnar nerve at the cubital tunnel and Osborne's ligament and osteophytes at the ulnohumeral joint are likely to be a factor in medial elbow pain.

CONCLUSIONS

Valgus instability, Osteophytes of the ulnohumeral joint and swelling of the ulnar nerve are factors for medial elbow pain. There was no significant difference between professionals and amateurs.

Effect of Multiplane Arm Elevations on Glenohumeral Kinematics and Contact Patterns

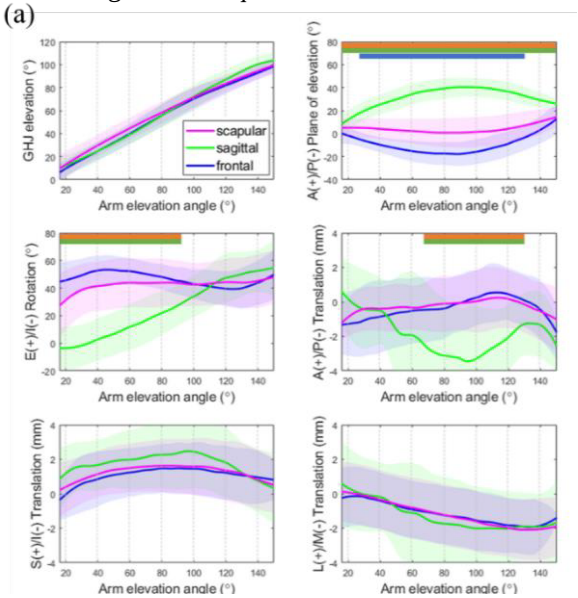
INTRODUCTION

The glenohumeral (GH) joint consists of the humeral head and the glenoid cavity of the scapula [1], however, previous studies have only been able to illustrate the rigid body kinematics of the GH joint without the contact pattern due to the lack of availability of a cartilage model [2]. The purpose of this study aimed to use 3D fluoroscopy and the virtual cartilage method to calculate the *in vivo* 3D GH rigid-body kinematics and the joint articular contact patterns during multiplane arm elevation.

METHODS

Twelve healthy adults (age: 25.5 ± 2.7 y/0; BMI: 23.8 ± 2.1 kg/m^2) performed arm elevation in the sagittal, frontal, and scapular planes under the surveillance of a biplane fluoroscopy system. A CT scan (Brilliance iCT 256, Philips) was firstly taken for each individual in supine to obtain subject-specific models of the humerus and scapula. By using 3D fluoroscopy to register the model projections to the corresponding x-ray images, the poses of the shoulder bone models were established [3]. The thickness of the virtual cartilage was defined as the mean distance of each vertex between the surface models of the glenoid and humeral head in the resting position. The contact region was then defined as the penetrated area between the glenoid cartilage and the humeral head cartilage. The contact point was established using the depth-weighted average over the contact region technique.



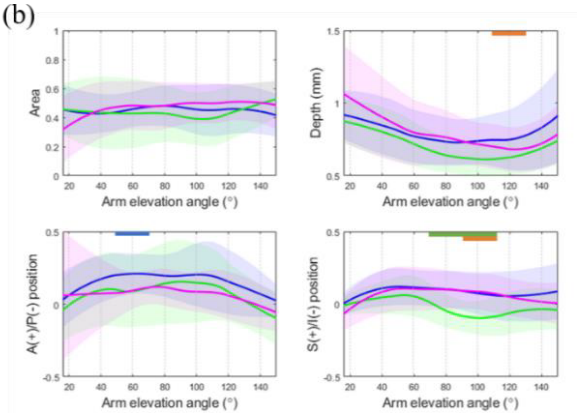


Figure 1 Means and standard deviations of the GH joint's (a) kinematics, (b) contact areas, depths and points during multiplane arm elevations. The orange horizontal line indicates a significant difference between the frontal plane and the sagittal plane; the blue horizontal line indicates a significant difference between the frontal plane and scapular plane; the green horizontal line indicates a significant difference between the sagittal plane and scapular plane.

RESULTS AND DISCUSSION

The greater anterior rotation was found during arm elevation in the sagittal plane, compared to that in the frontal or scapular plane (Fig 1a). Comparing arm elevation in the sagittal plane to that in the scapular or frontal planes, a larger external rotation was observed. The contact point of the GH joint typically remained in the immediate area (25% length of the glenoid) during arm flexion between 20° to 100°. The mean contact depth decreased during arm flexion between 20° to 100° but increased when arm flexion is greater than 100° among the three planes, which showed a similar trend of the contact area in the sagittal plane (Fig. 1b). The mechanical behaviour of the articular cartilages during arm elevation activities can be investigated by quantifying the interactions between the convex and concave surfaces of the GH joint.

CONCLUSIONS

This study successfully quantified the normative 3D GH kinematics in healthy young individuals and showed the coupled motions of the GH joint during multiplane arm elevation, which could serve as a recommendation for clinical practice guidelines.

PILOT FOLLOW UP OF A PATIENT WITH POST-STROKE HEMIPARESIS USING THE SSULF SCALE IN COMPARISON WITH OTHER CLINICAL ASSESSMENT.

Paris J Velasco Acosta[1,2], Leonardo E Anaya Campos[1], Ana Guadalupe Ramírez Nava[1], Ivett Quiñones Uriósteguí[1], Valeria Polet Olivares Gonzales[1, 3], Virginia Bueyes Roiz[1]

3 Universidad Nacional Autónoma de México, Mexico City, Mexico
E-mail: parisvelasco.inr@gmail.com

INTRODUCTION

The use of clinical assessments, evaluation scales or metrics by physicians is one of the tools for the diagnosis of motor disabilities and for the preparation of a rehabilitation plan (1). These assessments (i.e. Ashworth, CUE-T, Grasp & Release, Fugl Meyer, Action Research Arm Test (ARAT), to name a few)(2) measure parameters like motor control, pain, movement range, coordination, strength, grip, object manipulation, etc.(3)(4), but that depend entirely on the training and ability of the physicians qualified to diagnose, rehabilitate, and treat patients with motor impairment.
From previous projects performed at the Instituto Nacional de Rehabilitación Luis Guillermo Ibarra Ibarra, an scale from collected SALM scores into 5 significative levels has been made, so patients can be classified by degree of impairment. Using the results from fuzzy classifiers The Smoothness-based Scale for the Upper Limb Function (SSULF) has been created, identifying level 1 as an unimpaired limb increasing the level of impairment until a level 5 being a severe impaired limb.

METHODS

The recruitment of a 68 year old male patient with right hemiparesis due to middle cerebral artery stroke of 2 years of evolution. Patient had a history of Diabetes Mellitus 2 and Hypertension of at least 10 years of diagnosis. During a period of six months the subject followed a rehabilitation program implemented by the group of Neurological Rehabilitation Physicians of the Institute. Along with this program the patient was evaluated with clinical scales; such as: ARAT, Motricity Index (from which only the superior extremity was accounted) and Modified Ashworth Scale; The methodology of the Sorting Block Box (SBB) system to acquire the smoothness data needed to obtain its SSULF score was also implemented.
The evaluations were placed at the beginning of the treatment, 3 months after its initiation, and at the end of the 6 months period.

RESULTS AND DISCUSSION

Each score obtained by the patient during the protocol was recorded to be compared within all the clinical scales performed, these values are show in Table1. The table shown has the values register by the SSULF classifications, ARAT, Motricity and Modified Ashworth. Scale.

CONCLUSIONS

The first Pilot using the SSULF scores to classify the function of the impaired limb of a patient being treated at the Institute showed that a correlation can be seen within the already performed scales by the group of Physicians, although an acknowledgment of the different skills needed for each clinical scales to be performed must be made to correlate the data along with a bigger sample of patients.
The continuation of testing the SSULF on as many patients as possible, must be an ongoing project to create a significant correlation of the scores obtained by this new tool.

USING OUTDOOR CYCLING POWER OUTPUT AND HEART RATE TO ESTIMATE MAXIMAL OXYGEN CONSUMPTION

Tzyy-Yuang Shiang[1], Ting-Yu Yeh[1], Yin-Shin Lee[1] and Chen-Chang Tsai[2]
[1]Department of Athletic Performance, National Taiwan Normal University, Taipei, Taiwan
[2]Lifestyles of Health and Sustainability Executive Master of Business Administration, National Taiwan Normal University, Taipei, Taiwan
*E-mail: tyshiang@gmail.com

INTRODUCTION

Directly measured maximal oxygen consumption (VO_2max) was considered as the golden standard of performance and cardiorespiratory endurance. [1] However, measurement of VO_2max requires maximal efforts, which may pose health risks and also is restricted in laboratory condition [2]. Numerous submaximal cycling work tests exist for estimation of VO2max, such as the nomogram of Åstrand (*Å*-test). Much of the submaximal cycling tests have been performed indoors in laboratories, whereas little research has been performed outdoor cycling. Therefore, the purpose of the study was to investigate whether outdoor cycling data can be used to estimate VO_2max or not.

METHODS

In the study, nineteen male volunteers (6 non-experienced, 4 experienced and 9 professional) participated in 2 experimental trials consisting of 1 laboratory and 1 outdoor session and completed in two visits, at least 48 hours of rest between. They performed a graded exercise test (GXT) at first visit. After 5 minutes warm-up with 100W, power output increased 10W every minute until dropout [3]. The first visit aimed to obtain VO2max and the association between power output, heart rate and VO_2max. At the second visit, subjects performed outdoor cycling 20-kilometer time trial test with their maximal effort.

Data Analysis

In the indoor graded exercise test, power output and heart rate in the last 15 seconds of each stage of the official test were captured and conducted regression analysis. The slope of regression line was defined as indoor power/heart rate, (P/H) index. Since indoor P/H index had high correlation with VO2max, the index was fitted into regression equation to estimate VO_2max.

In the outdoor 20-kilometer time trial test, we removed the data that power is 0, power and heart rate were averaged over 60 seconds as output per minute. Linear regression was conducted between the power and heart rate per minute and the slope of the regression line was defined as outdoor P/H index. The outdoor P/H index were calculated to fit into regression equation to obtain predict VO_2max.

RESULTS AND DISCUSSION

VO_2max had high correlation with indoor P/H index ($r = 0.72$, $p < 0.01$). Standard error of estimation between estimated and measured VO_2max is 6.44 (ml/kg/min).

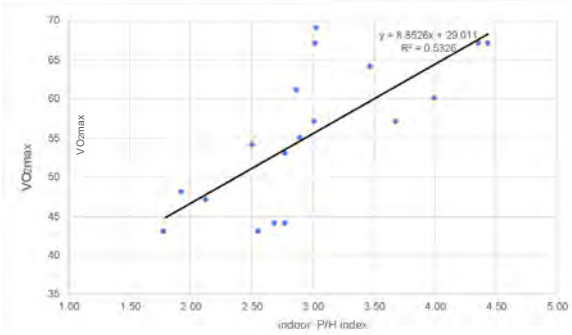

Figure 1 The linear regression of indoor P/H index and VO_2max

The predict VO_2max obtained from outdoor P/H index had medium correlation with VO_2max from indoor GXT ($r = 0.5$).

As the completing time of outdoor cycling varied among different subjects, the amount of data to derive outdoor P/H index also varied. Furthermore, since outdoor cycling test were largely influenced by the environmental conditions and cycling technique, more precise data cleaning or several times tests may be needed.

CONCLUSIONS

The predict VO2max obtained from outdoor P/H index had medium correlation with VO_2max from indoor graded exercise test. Hence, outdoor 20km cycling test may be used as the submaximal test to estimate VO_2max.

ACKNOLEDGEMENTS

The research was funded by Technology Development Program of Ministry of Economic Affairs.

Integrated Gaze Tracking and Motion Analysis During Walking

Zhaoyuan Wan[1], Xiaocheng Zhang[1], Yi-Xing Liu[1], and Ruoli Wang[1]
[1] Department of Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden.
Email: zhaoyuan@kth.se

INTRODUCTION

Vision plays an important role in guidance for efficient human movement that often involves complex sensory integration, spatial orientation, balance, proprioception and haptic feedback [1]. With the development of mobile eye-tracking techniques, measurements of gaze patterns during movements have become more practical. However, most of the existing research analysed gaze and motion data separately due to the extra temporal and spatial synchronization has to be established, which is not always trivial [2]. In this study, we presented an integrated solution of a relatively low-cost eye tracking system and a marker-based Mocap system. Simultaneously recorded gaze data and gait patterns in different walking conditions were investigated.

METHODS

Five able-bodied participants with normal visual ability took part in the measurement. Participants were instructed to walk at their comfortable pace in two different settings: a plain path (level ground) and a complex path. The complex path consisted of a ramp, a plateau and a stair. Participants were asked to walk in both directions: from ramp to stair (RS), and from stair to ramp (SR). Reflective markers were placed on the bony landmarks according to CGM2.3 marker set. Ground reaction forces were also recorded. Gaze data was recorded by an eye-tracker (Pupil Core), which consists of one world camera (30Hz@1080p) and two pupil cameras (200Hz@192x192px). The marker trajectories were recorded with a 10-camera Mocap system (Vicon at 100Hz). The recorded gaze data was then transformed from the coordinate of the world camera to the global coordinate of the Mocap system using a marker cluster attached on the eye tracker. Arduino UNO was used to acquire time stamps for the eye tracker and the Mocap system, in order to achieve the temporal synchronization. The average gaze time distribution (proportions of gaze points falling in different areas) and gait parameters, i.e., step length and step time were calculated from 3 repeated trials and compared among different conditions.

RESULTS AND DISCUSSION

Regardless of the settings, the participants in general spent less than 50% of time looking at the walking path (Figure 1). Among 3 conditions, participants spent more time looking at the path during the RS trials. In particular, the plateau and stair attracted more visual attention than the ramp. During SR trials, the ramp occupied most of the gaze. As expected, gaze was always focused on the upcoming path, especially the downward path, possibly for better navigation and planning. Coupled with more gaze time on the pathway, participants had the longest step time and shortest step length in the RS trials, which led to the lowest walking speed (Table 1).

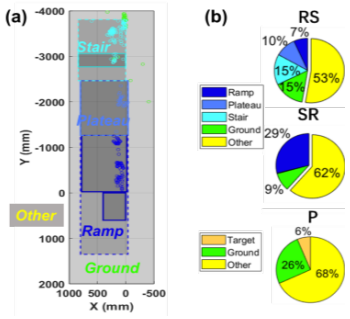

Figure 1 (a) Top view of transformed gaze points (circles) on the complex path from one example trial. Other refers to gaze points outside the walking path. (b) Average gaze time distribution from all participants. RS: from ramp to stair. SR: from stair to ramp. P: plain path (only 3 participants).

CONCLUSIONS

We proposed a feasible solution for simultaneous eye-tracking and motion analysis. Gaze point and motion data can be successfully synchronized spatially and temporally. Our preliminary results showed that people tended to look at the upcoming path during walking. As expected, gait parameters were found coupled with gaze time distribution, i.e., walking more slowly when looking at pathway more. The proposed integrated system can potentially benefit both research and clinical evaluation of sensory integration, spatial orientation, and proprioception during locomotion.

INTRODUCTION

Observation of running performance with inertial mesurement units (IMUs) has become more popular in recent years. Monitoring runners during their training and races could be useful for improvement of runnning performance and reduction of running injury. The purpose of this study was to estimate the changes in spatiotemporal parameters during long distance running using a foot-mounted IMU.

METHODS

One university runner (female, 19 yrs, 1.63m, 50.9 kg) performed a 60-minute running trial at a self-selected speed (7 laps of a 1.8 km loop course). Linear accelerations and angular velocities of the right foot were measured with an IMU (Casio, Tokyo, Japan, 200 Hz) fixed to the dorsum of the foot.

Stride frequency and contact time were calculated from initial contact and toe-off events detected using acceleration data [1]. Additionally, stride length throughout the running trial was calculated [2]. Running speed of each stride was calculated from stride frequency and stride length. Calculated spatiotemporal variables of the 60-minute running trial were averaged for each of seven laps.

RESULTS AND DISCUSSION

The total number of detected strides in this study was 4689. Table 1 shows the average running speeds calculated from lap times and IMU data for seven laps. The results of this study demonstrate that gait events and stride lengths can be accurately estimated from IMU data during running.

Figure 1 shows changes in running speed, stride length, stride frequency and contact time during the 60-minute running trial. Running speed increased from 5th lap to 7th lap, and stride length also increased in this phase. Stride frequency increased and contact time decreased throughout the running trial, however the magnitudes of these changes were relatively small. These results indicate that the subject increased running speed during the latter part of running by increasing stride length.

CONCLUSIONS

This study attempted to estimate changes in spatiotemporal variables during long distance running. The results support the potential of monitoring runners and collecting longitudinal data during their training and races using IMUs.

INTRODUCTION

Artifical turf has been widely used in sports and has the advantage that the characterists of the turf can be modified to alter performance [1] and injury risk [2]. Due to the demands of practicing sports such as soccer, the participants are required to change their direction in response to external stimulus which could lead to increased loading rates. To quantify this, inertial sensors have been used in running [3] but the application in other sports contexts have been poorly described. Thus, the objective of this study was to investigate if altering the properties of artificial turf could attenuate peak accelerations measured with inertial sensors on the heel and shank segments when performing an agility test.

METHODS

Nineteen healthy males (age: 29.2 ± 6.0 years, height: 1.8 ± 0.1 m, body mass: 78.6 ± 9.4 kg) participated in this study after giving written consent. Two artificial turf conditions (FieldTurf, Tarkett Inc., Montreal, QC, Canada) installed in the laboratory were tested: 1) Control turf (shockpad: none; carpet fiber: poltethylene slit-film, infill: bottom = 1.0lbs/sqft sand, middle = 5.2lbs/sqft sand+2.6lbs/sqft 14-30 rubber, top = 0.4lbs/sqft 10-14 rubber) and 2) Shockpad (shockpad: 12mm thick Therma-plastic, carpet fiber: polyethylene monofilament, infill: bottom = 1.0lbs/sqft sand, middle = 5.2lbs/sqft sand+2.6lbs/sqft 14-30 rubber, top = 0.4lbs/sqft 10-14 rubber). All participants wore the same model of football cleats which were available in multiple sizes (Nike Vapor Edge Speed 360). During the data collection, each participant was required to perform a maximal effort agility test (3m-6m-3m) with athlete performance measured with photocells. The first cut of the agility test was considered for further analysis.

To measure the accelerations, two inertial measurement units (IMU, BlueTrident Vicon, Oxford, UK) at 225Hz were placed on the right heel cup of the shoe and right shank (shin bone). Additionally, ground reaction forces were measured with a force platform (Kistler) at 2400 Hz. The signals were filtered using a 4th order low-pass Butterworth filter at a cut-off frequency of 60-Hz. Maximum acceleration of the heel and shank, and maximum vertical ground reaction forces were selected for further analysis. Additionally, performance time was quantified based on the photocells. Paired *t*-tests were used to detect differences between the turf conditions (α=0.05). All data processing and statistical analyses were performed in Python.

RESULTS AND DISCUSSION

Comparing the two turfs, no difference in athlete performance was present (p=0.60). The shank medio-lateral acceleration (p<0.01); and both the heel (p=0.01) and shank (p<0.01) resultant acceleration presented lower values on the Shockpad turf compared with the Control turf (Figure 1).

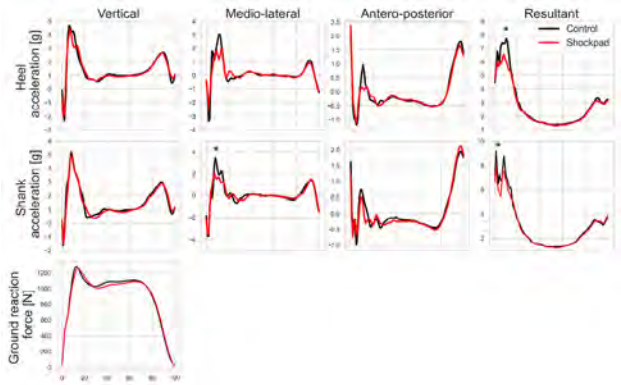

Figure 1 Ensemble average time-series across subjects of the heel and shank accelerations, and vertical ground reaction forces of the Control and Shockpad turf conditions

CONCLUSIONS

This preliminary study highlighted that the Shockpad artificial turf decreased the peak acceleration, particularly, in the shank segment. Altering components of artificial turf can influence acceleration of the body and might positively decrease the risk of injuries. Further studies with larger sample size and different drills are needed.

DEVELOPMENT OF AN INSTRUCTIONAL SUPPORT SYSTEM FOR SKIING USING GNNS DATA

Hiroshi Hoshino[1] and Hidehiko Hayashi[2]
[1] Department of Economy, Hokusei Gakuen University / general education unit, Sapporo, Japan.
[2] Department of Economy, Hokusei Gakuen University / Institute of Management Information, Sapporo, Japan.
Email: h-hoshi@hokusei.ac.jp

INTRODUCTION

The utilization of Global Navigation Satellite System (GNSS) data in sports has increased rapidly in recent years. GNSS data for performance and team feature analysis is especially effective for ball game sports. GNSS data are commonly used to digitize the tracking information obtained by GNSS to aid in visualization.
The present study aimed to develop a ski instruction support system for technical alpine skiing training scenarios, in which the routes and speeds obtained from the GNSS tracking information were added and synthesized to video recordings of the trainees' skiing practice.

METHODS

1. Participants
The participants in this study were two adult males, one of whom (aged 58, 169 cm, 88 kg) passed the Level 2 Ski Test certified by the Ski Association of Japan (SAJ). The other (ski instructor: aged 56, 171 cm, 83 kg) had basic ski instructor certification. The participants were instructed to ski freely, as they would normally.The data obtained in this study were organized for use as basic references in the instruction scenarios as additional sensor visualizer items.
2. Ski Instruction Support System Development
(1) The ski instruction support system we are developing in this study aims to provide trainees with feedback images in which GNSS-derived speed and route data are added as sensor visualizer items on the skiing practice video recordings to create synthesized feedback for training. One of the advantages of this ski instruction support system is its instantaneous user (trainee) feedback. They can visually receive synthesized feedback from the video image and sensor information, while their kinesthesia from practice is still fresh. This would also enable them to share technical issues and progress in skill acquisition with the instructor.
As stated above, we are developing an effective tool for ski instruction. Here, we attempted to utilize GNSS and gyro sensors built into mobile terminals (smartphones) [1], which have recently become popular, to collect data during skiing practice. Two AQUOS sense 3 lite mobile terminals were used in this experiment. A preinstalled smartphone application was used. The system was modified to synchronize the video and sensor information obtained from the two mobile terminals automatically using GPS time.
(2) Participants placed the mobile terminal (AQUAS sense3 lite), which was pre-installed with the ski instruction support system, into their ski suits to collect the practice data. It was confirmed that wearing the device inside their clothes did not interfere with their performance or posture during skiing practice.

RESULTS AND DISCUSSION

A verification test of the ski instruction support system using GNSS data is conducted in this study. Figure 1 shows an example of the operation of the ski instruction support system. The image on the left (A) indicates the scenario of providing the participant with a practice image containing sensor visualizer items after practice. As shown in the image on the right (B), the recording was provided as a synthesized image of the participant's video recording, with data on speed, height evolution, body sway, and route.

CONCLUSIONS

As stated above, the ski instruction support system developed in this study provided users with video images containing sensor visualizer items immediately after skiing practice, suggesting that the use of GNSS data in the ski instruction support system is effective.

INTRODUCTION

The loadsol insole is a commerical device used to measure in-shoe vertical ground reaction force (GRF). Traditionally, biomechanics research is conducted using force platforms or plantar pressure insoles/mats that require additional wires attached to equipment and usage of a laptop. This wireless insole enables free movement of the user without being restricted by wires. The reliability of the loadsol has not been examined in cycling [2]. The loadsol may be beneficial for clinical use because of its portability and cost reduction compared to a standard plantar pressure system. Therefore, the purpose of this study was to evaluate the reliability of GRFs measured by the loadsol device and vertical pedal reaction force (PRF) measured by the instrumented pedals during stationary cycling at different workloads.

METHODS

Ten healthy college aged students (age=22±4 years, height=1.70±0.1 m, mass=75.6±12.6 kg) were recruited from a local college campus. Customized instrumented 3D force pedals (1200Hz, Kistler) were used to measure PRF and vertical PRF was also concurrently measured with a 3-region, loadsol insole (100Hz, vertical force only, Novel) placed in a standard lab running shoes (Air Zoom Pegasus, Nike). Data collection was synchronized to Vicon Nexus by using loadsync device. Participants cycled on a stationary ergometer (Ergomedic 828E, Monark) at three workload conditions (1kg, 2kg, 3kg) at a cadence of 80 revolutions per minute for two minutes in each condition. PRF data were collected for the final 10 seconds of the two minutes and analyzed as a block consisting of the whole 10-second trial. Intraclass correlation coefficients (ICC) were computed using a Two-Way Mixed Effects model for Consistency with a 95% confidence interval (IBM Statistical Package for Social Science [1].

RESULTS AND DISCUSSION

The results showed that the loadsol consistently underestimated vertical peak reaction forces and produced systematically lower impulse values (Figure 1). ICC values ranged from 0.325 to 0.954 (Table 1). Overall, it appears that the loadsol showed better consistency with the instrumented pedals on peak vertical PRFs (ICC: 0.454 - 0.954, Table 1) as opposed to vertical PRF impulse (ICC: 0.325 – 0.850) for stationary cycling. PRFs are lower in cycling compared to other movement tasks with high loading such as jumping. The small differences measured by the two devices here may not be as easily identified in studies involving movements with high GRFs.

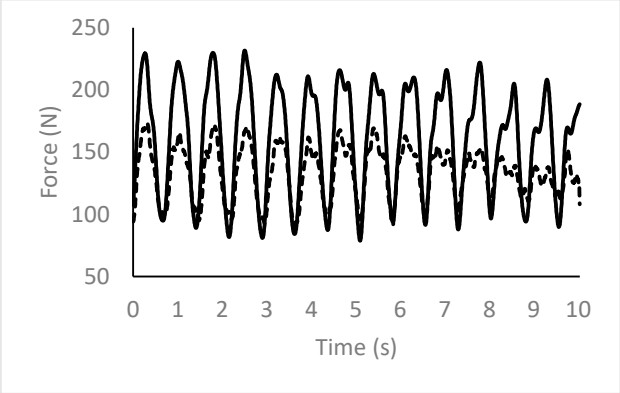

Figure 1 Ensemble reaction force curves for the right 3kg workload condition. Solid line represents instrumented pedals; dashed represents loadsol.

CONCLUSIONS

The loadsol can have wider clinical use for measuring patient kinetics without requiring specialized equipment, laboratory spaces, or highly trained personnel. This study provides evidence that the loadsol is consistent and reliable at measuring kinetics through a range of workloads for stationary cycling although it may underestimate peak forces. Further research may involve application to specific patient populations, especially those engaging in cycling activities as part of prevention or rehabilitative protocols.

INTRODUCTION

A lower limb prosthesis is an indispensable device for lower limb amputees. It replaces the lost functions of the lower limb by combining and coordinating various parts such as the prosthetic foot, pins, pipes, and socket. The performance and user convenience of lower limb prostheses have improved with technological advances [1]. However, dissatisfaction among users remains[2, 3]. Because existing methods of evaluating lower limb prosthesis satisfaction are based on subjective elements such as user perception and psychological factors, quantitative evaluation is difficult. In particular, the socket, which connects the wearer of the lower limb prosthesis directly to the prosthesis frame, have a major influence on the satisfaction of prosthesis users. This study developed and evaluated a pressure sensor system for measuring interface pressure between the lower limb prosthetic socket and stump using up to 16 force-sensitive resistors (FSR).

METHODS

The developed pressure sensor uses 16 FSR channels and is aimed at enhancing user convenience through wireless communication, a data storage function, and a GUI. The gait simulator is designed to simulate the stance-phase motion. The movement of the gait simulator was limited to the anterior–posterior direction to observe the correlation between the tilt angle and sensor data, and the tilt angle ranged up to ±25°.

RESULTS AND DISCUSSION

The load change according to the tilt angle is shown to be out of phase in the C and G sensors, placed parallel to the gait simulator's direction of motion (Figure 1(A)). In contrast, the data for the A and E sensors, attached perpendicular to the direction of motion of the gait simulator, are in phase (Figure 1(B)). In addition, the difference between the maximum and minimum loads increased with an increase in the tilt angle (Table 1).

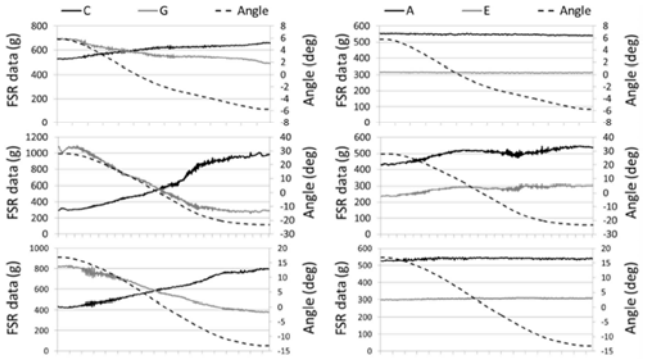

Figure 1 *The motion of the gait simulator at maximum tilt angles of ±5°, ±15°, and ±25°. (A: parallel sensor C and G, B: perpendicular sensors A and E).*

CONCLUSIONS

The lower limb prosthetic socket is pivotal in determining the comfort of the pros-thesis fit and its performance. The proposed pressure sensor system is designed to be worn with the prosthesis. Because it can measure changes in in-socket pressure during everyday use, it is expected to provide data that can be used to evaluate the wearer's intent or the walking environment.

WEARABLE INTRA-FOOT TEMPERATURE GRADIENTS DURING FREE-LIVING CONDITIONS

Emily Matijevich[1,2]

Email: em.matijevich@gmail.com

INTRODUCTION

Core body temperature has long been considered a key vital sign – an objective measure of an individual's physiological status. Distal skin temperatures have also been shown to reveal health insights. For example, foot temperatures assessed with thermography have been used to evaluate foot health in individuals with diabetes [2]. While single time point, static thermograms have proven clinically useful, the development of sensory insoles embedded with temperature sensors allows for continuous foot temperature monitoring. Prior to continuous foot temperatures being leveraged for digital health monitoring opportunities, a fundamental understanding of foot temperatures during free-living conditions is necessary.

Intra-foot temperature gradients have been well characterized during static thermograms; a decrease in temperature moving from proximal to distal is observed in healthy feet [3]. However, it is not well established how this relationship changes throughout the day, and if this relationship is individual specific. Therefore, the purpose of this pilot study was to evaluate intra-foot temperature gradients across healthy individuals during ambulatory, free-living conditions.

METHODS

Five healthy volunteers participated in a 2-week wear session. Participants wore a sensory insole (Orpyx® SI) in a self-selected footwear 5+ hours per day during their free-living activities. The sensory insole measured temperature at five foot locations (heel, metatarsal 1, 3, and 5, and the big toe, **Figure 1**) at a rate of 1/60 Hz. An individual's intra-foot temperature gradient was evaluated as the difference in temperature versus the metatarsal 3 temperature (the most central location).

RESULTS AND DISCUSSION

As expected, across all five individuals, the heel was typically warmer than the metatarsal 3 (1.2±0.6 ºC for the left foot), the big toe was typically cooler (-1.8±0.8 ºC), and metatarsals 1 and 5 were similar in temperature to metatarsal 3 (-0.4±0.3 -0.5±0.3 for metatarsal 1 and 5, respectively). Foot temperature gradients were similar between the left and right foot (**Figure 1**). However, the magnitude of this intra-foot gradient varied across individuals. For example, in one individual (P04) the big toe was typically 0.9 ºC cooler, whereas in another individual the big toe was typically 3.1 ºC cooler (P05). Results suggest individuals have a personal foot temperature "fingerprint".

In these healthy participants, intra-foot temperature gradients remained consistent throughout free-living conditions (**Figure 1**). While activity and behaviour will change the absolute magnitude of foot temperatures, the intra-foot temperature gradient is likely consistent.

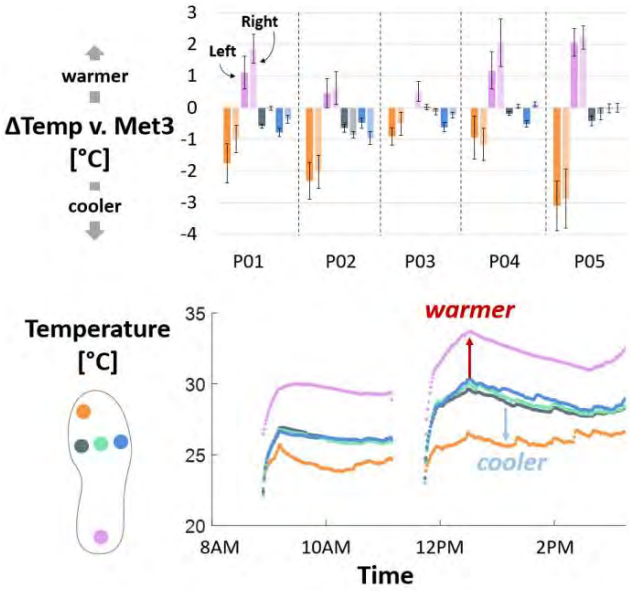

Figure 1 Upper: Intra-foot temperature differences versus metatarsal 3 (Met3) across five participants. Bars = average, error bars = standard deviation across days. Lower: Example of time-series foot temperature

CONCLUSIONS

Wearable, effortless distal skin temperature monitoring is an exciting, emerging digital health opportunity. During free-living conditions, healthy participants exhibit an expected proximal to distal foot temperature decrease, but the magnitude of this gradient is individual specific. Absolute foot temperatures vary throughout the day, but the foot temperature gradient likely remains consistent. These preliminary findings in healthy individuals may guide interpretation of both healthy and pathological time continuous foot temperatures.

Is a wirelessly-charged implant safe?

Maedeh Amirpour[1], Eryn Kwon[2], Kristi Fechney[1]

INTRODUCTION

Subdermal wirelessly-charged implantable sensors and devices induce electromagnetic waves between the charging and receiving systems, causing damaging effects on the tissue in-between. The electromagnetic energy is converted to thermal energy, which increases the tissue temperature. Heat transfer and its effect on tissue is unknown as it involves a range of varying physical parameters and the tissue complex morphology. We aim to understand the thermal response of tissue with different morphologies to mitigate tissue overheating during wireless charging process. The tissue thermal insult will be modelled by a multi-physics bio-heat mathematical formulation and validated against computational models.

Heat dissipation in living tissues undergoing wireless radio frequency electromagnetic field is a complex phenomenon since it highly depends on tissue size and involves multiple physics such as the heat conduction in solid tissue, heat convection between fluid (blood) and solid tissue, internal heat generation during electromagnetic loss and blood circulation[1-2]. This coupled multi-physics challenge prevents the widespread adoption of Wirelessly-charged implantable devices and sensors which operate under radio frequency electromagnetic field (kHz-MHz). One of the biggest barriers is the danger of tissue overheating from heat dissipation during wireless charging process. We hypothesise that tissue with its full complexity at various scales, from capillary vessels to large tissue layers such as muscle, play a major role in thermal dissipation. However, understanding of the multi-physics nature of heat dissipation including thermal, electromagnetic, structural, fluid and blood flow interactions within tissue underlying wireless electromagnetic stimulation is still unknown.

METHODS

The research will be carried out in two phases. In the first phase, we will generate biofidelic anatomical models with a range of tissue layers and blood vessels based on Magnetic Resonance Imaging (MRI) scans of human tissue with different sizes that encompass reasonable range of typical implant recipient. The second phase will extend the author's previously developed multi-physics, 3-dimensional, high-fidelity finite element (FE) model for high frequency electromagnetic stimulators. The computational model will first apply high frequency electromagnetic fields on the tissue model developed from the phase one to quantify key parameters of thermal dissipation. Moreover, tissue hot spots and temperature distribution will be modelled as electromagnetic loss within tissue leads to temperature rise. In this project, we will answer the below research questions to generate knowledge on a bio-heat mathematical model with considering diffrent tissue morphologies:

1. How does the geometry, size and density of tissue impact the tissue thermal insult?
2. What is the relationship between factors like temperature, pressure, electromagnetic field, strength and chemical potential of living tissue undergoing radio frequency electromagnetic stimulation?
3. How does the interaction between the factors above determine heat dissipation in tissue?

RESULTS AND DISCUSSION

In the first phase, MRI scans and image processesing of a chest area of a 32-year old man was perfromed in order to derived a 3D cad model for the next step which is multiphysics computational simulation of the tissue under wireless elactromagnetic charging (Figure 1).

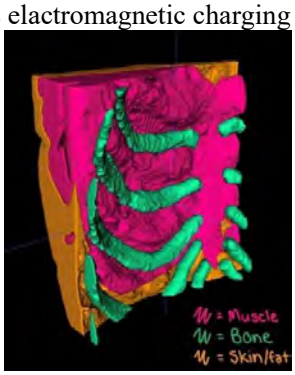

Figure 1: 3D cad model of MRI scan and image prosessing of a right chest area

CONCLUSIONS

This project will give clear insight into the heat dissipation mechanism in variable tissue morphologies undergoing high electromagnetic field exposure and thermal impact.

INTRODUCTION

Wearable sensors including inertial measurement units (IMUs) allow in-field monitoring and produce an affordable alternative to three-dimensional optical motion capture. Accurate detection of gait events (GEs) is critical for analyzing running biomechanics. Foot mounted IMUs have been used to perform GE detection [1], however it is unknown whether GE can be determined using only a sacral mounted IMU. The purpose of this study was to develop and validate an initial contact (IC) detection method using a sacral mounted IMU. Additionally, we developed a technique to determine whether the IC is from the left or the right foot, based on angular velocity of the sacral mounted IMU. We compare the new method against an IC detection method using foot-mounted IMUs while running on a force instrumented treadmill across a range of speeds and grades.

METHODS

Ten healthy recreational runners (8 F, 2M, 23 years, 169 cm, 59 kg) were equipped with IMUs (Casio, Tokyo, Japan) mounted bilaterally on the dorsal aspect of the foot and at the sacrum. Each participant ran on a force instrumented treadmill (Bertec, Columbus, OH, USA) at three grades: level ground (LG), incline (INC) and decline (DEC) at ±7.5 deg. The total range of speeds across participants was 2.55–4.48 m s−1. For the IMU-based algorithm, first, maxima and minima of sacral angular velocity about the anterior-posterior axis (Sacral ω_y) is found. Then the location of the first maximum and first minimum is compared to determine the sign of the first extrema. Once sign is defined, the second extrema is determined within a 3 ms window. The maximum allowed time between two successive minima / maxima was set to a criterion value of 5 ms. Left initial contact (LIC) was identified as the first peak of the sacral resultant acceleration (Sacral Res Acc) after the minimum of Sacral ω_y. Right initial contact (RIC) was identified as the first peak of Sacral Res Acc after the maximum of Sacral ω_y.

RESULTS AND DISCUSSION

Wada et al [2] compared pelvic orientation angles using a single lower back-mounted inertial sensor during sprinting with a 3D motion capture system. They noted that mediolateral pelvis angles increased at the beginning of the right leg support phase, and started to decrease at the left leg support phase with a difference of 4.1 ± 1.2 deg. Our results (Figure 1) show that during the right impact, sacral angular velocity increased, and the RIC was identified as the first peak after maximum Sacral ω_y. During the left impact, sacral angular velocity increased in the negative direction, and the LIC was identified as the first peak after minimum Sacral ω_y. The time difference between RIC, LIC Foot and Sacrum was between 6.1 ± 2.2 and 2.8 ± 1.6 ms for right side and between 5.8 ± 1.8 and 3.1 ± 1.5 ms for left side (Table 1).

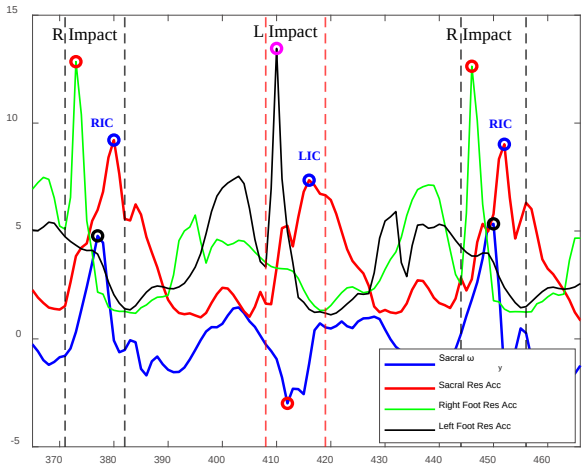

Figure 1 RIC and LIC identification from Sacral Res Acc using the maximum and minimum Sacral ω_y.

Table 1: Time differences between RIC and LIC Foot and Sacrum (ms); Mean ± SD.

	LG	INC	DEC
Right	3.7 ± 1.7	6.1 ± 2.2	2.8 ± 1.6
Left	3.8 ± 1.8	5.8 ± 1.8	3.1 ± 1.5

CONCLUSIONS

The results of this study support the idea that a single inertial sensor at the sacrum can be used to detect initial contact and distinguish between left and right contacts. The algorithm developed in this study will be expanded to include toe off from sacral IMU as part of GE detection in indoor and outdoor running.

INTRODUCTION

For years, robots have played a role in society, handling tasks from manufacturing and industry to delicate medical procedures. The safety restrictions and physical limitations of robots have hindered their potential. keyboard and mouse are the standard means of human-computer interaction [1]. Wearable haptic gloves based on flexible sensors are used lately to control similar robotic hands however, they are costly and may not be comfortable for every user. This paper presents an easier method to control a robotic hand using hand gestures by utilizing computer vision (CV). The open-source framework MediaPipe is used to detect human hands through a webcam[2].MediaPipe employs image processing and machine learning to infer landmarks of the real-time captured hand, once the hand model is captured, it can be used to control the robotic hand.

METHODS

CV captures input data at 24 frames per second. The user controls the robotic hand using hand gestures, CV collects the user's hand coordinates, and based on the user's hand motion the robotic hand is controlled. The robotic hand has 6 Degrees of Freedom (DOF), and each finger can move independently as well as the wrist. Arduino chip is used to control the motors of the robotic hand. Since the MediaPipe program was written in python code, Pyfirmata (a python interface) is used to establish a connection between CV & Arduino therefore, Arduino will receive orders from CV based on the detected user's hands to actuate the motors that will allow for the robotic fingers and wrist motion. Once the user's hand is detected by the webcam, CV will automatically display the overlay of the hand and execute the orders according to our algorithm. By displaying their right hand to the webcam, the user can independently control each robotic finger by flexing and unflexing their own fingers. The user can twist the robotic wrist to 170 deg from its origin by contracting their left hand. The Robotic fingers and wrist are controlled at the same time when both hands are displayed.

RESULTS AND DISCUSSION

A recently published paper discussed a robotic hand control system using flexible sensors attached to a haptic glove [3]. Both projects serve a similar purpose however, our system has more DOF, since not only the fingers are controlled but the wrist as well. Our system is less complex and more user-friendly as it has fewer components. It doesn't require any signal transmission modules to provide a wireless connection and no wearable devices are used. As shown in Figure 1. The system has little equipment (a computer that can be replaced by a Raspberry pi board, and a robot). The method was manually evaluated by various users and found to be user-friendly. The accuracy of the system is influenced by the camera quality however, thanks to the MediaPipe framework, it achieved an average accuracy of 95% when standard webcams were employed.

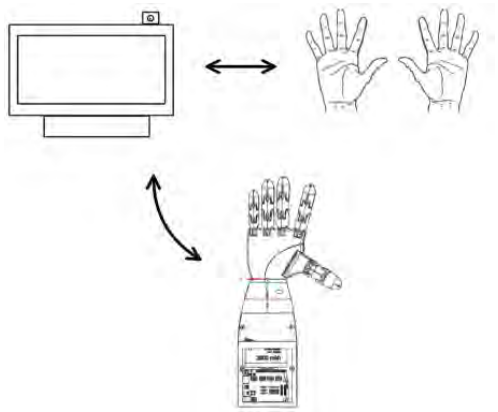

Figure 1 System of CV-controlled robotic hand.

CONCLUSIONS

Gestures can make robots accessible to people with disabilities and can be used to control robots wirelessly. This technique is very simple and easier to control than other complex control systems. More features have been developed and are now being processed in patent work. These features will allow the user to have a more human-like finger motion experience as well as the ability to control the robotic hand with the help of virtual reality (VR).

WHOLE-BODY KINEMATICS PREDICTION WHILE WALKING AND RUNNING USING A VIRTUAL ACCELEROMETER ON VARIOUS POSITIONS

Gunwoo Park[1], Seungbum Koo[1*]

[1] Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea.
Email: skoo@kaist.ac.kr

INTRODUCTION

In addition to transportation, the purpose of locomotion is various such as recreation, sports, or therapy. Poses during walking and running, represented by kinematic gait parameters, affect the performance or injury risk. Previous studies predicted lower body joint kinematics using an inertial sensor on the lower back [1] and shank [2]. The studies showed the feasibility of using a single sensor and artificial neural network (ANN) for specific motion in a database. Nevertheless, further research about the effect of the sensor position is needed. This study is about predicting three-dimensional motion of a whole body with an accelerometer. We compared three sensor positions, left wrist, lower back, and right shank.

METHODS

The motion capture dataset includes data from 198 subjects, 157 males and 41 females (mean and standard deviation of age 28.0 ± 9.8). Motion capture was done on a treadmill with four walking and running speeds, 4 km/h, 8 km/h, 10 km/h, and 12 km/h. Using the inverse kinematics function in OpenSim [3], 28 gait parameters were calculated. Accelerations were calculated at the three body segments, left radius, pelvis, and right tibia. The virtual accelerometer measures three-dimensional acceleration of each segment as a wearable sensor does. The gait parameters were segmented into a gait cycle using ground reaction force and temporally normalized to 100Hz. The dataset was split into training, validation, and test set with 160, 19, and 19 subjects. We trained ANN with two linear layers to predict a gait parameter from a virtual accelerometer data (Figure 1). The ANN has batch normalization with a momentum of 0.9 at the input layer and a dropout function with a probability of 0.5 at the hidden layer.

RESULTS AND DISCUSSION

We compared root-mean-squared error (RMSE) from three positions with an analysis of variance and Tukey's test (Table 1). P-values were obtained for each pair of sensor positions.

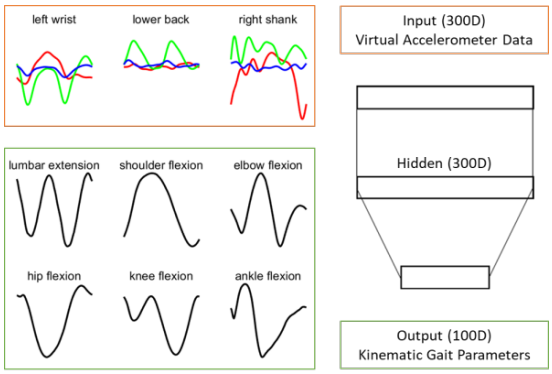

Figure 1 ANN description with input and output.

The sensors were effective in predicting the motion of adjacent joints in the kinematics tree. Upper and lower body movements are mutually related while walking and running [4]. It may be possible to predict a whole-body movement with a single sensor. The virtual accelerometer method may be applied to any motion capture dataset without sensor data.

CONCLUSIONS

This study found an effect of the sensor position on prediction accuracy. Our results will benefit selecting devices to implement the ANN for motion prediction.

REAL-TIME MUSICAL FEEDBACK FROM PRESSURE-SENSING INSOLES FOR ANKLE FRACTURE REHABILITATION: A CASE REPORT

Markus A. Wimmer[1], Luisa Cedin[1], Christopher Knowlton[1]
[1] Department of Orthopedics, Rush University Medical Center / Chicago, United States.
Email: markus_a_wimmer@rush.edu

INTRODUCTION

Ankle fracture often leads to gait impairments in kinetics, kinematics, and temporospatial parameters several months later[1]. Patient adopts an avoidance behaviour which may cause detrimental impact on contralateral limb and body stability. Gait retraining can be challenging due to continuous therapist guidance. Biofeedback could offer uninterrupted instruction while allowing patients to perceive their performance and adjust it accordingly. Studies have shown that auditory feedback is a promising approach to rehabilitation and gait retraining [2,3], however, they offered only negative stimulus and no engagement. Our aim was to target ankle fracture rehabilitation and gait retraining by using a musical, progressive, and reward-based auditory feedback based on a wireless pressure-sensing insole.

METHODS

A 56-year-old male who suffered a trimalleolar fracture on the right ankle was recruited two months post-op after being released for full weight-bearing. Lack of mobility during walking was evident. Real-time pressure data from sensors under the hallux and second toe and total force were obtained with Insole3 (OpenGo, Moticon) - a 16-sensor pressure insole with an embedded six-axis inertial measurement unit - and transmitted to Max 8 (Cycling '74). A 50N threshold of total force triggered a Musical Instrument Digital Interface chord to play, followed by a second chord when the pressure of the toe sensors exceeded a pre-adjusted threshold (Pachelbel's *Canon in D* four-bar progression). Listening to whether the second chord played would indicate the patient if he applied sufficient pressure on his toes; timing between heel-strike and toe-off would cue the rhythm of the chords. Training consisted of 6 sessions of 12 min, preceded by 5-min warm-up and practice. Health limb practice demonstrated how the music should sound. 3D gait analysis (Qualisys) was conducted at baseline (BL) and after one month of practice (1M) at a self-selected speed to evaluate ankle and foot kinematics. Ankle joint ankle and was determined on Visual 3D (C-Motion).

RESULTS AND DISCUSSION

Higher cadence (BL = 47.7 strides/min; 1M = 50.6) and longer stride lengths (Table 1) were seen after practice. Mean fraction of stance phase was significantly different ($p < 0.001$) between limbs and significantly increased on the affected leg after training ($p = 0.003$). Less plantar flexion during swing phase on the affected side at baseline and range of motion seems more closely related to healthy side after training (Figure 1). Mean pressure under toes nearly doubled on the affected side after training and was distributed more evenly in-between sides but did not reach the level of the healthy limb.

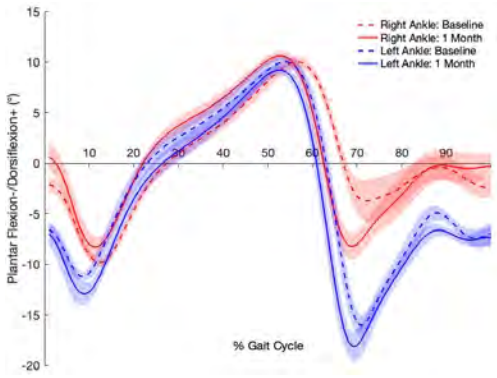

Figure 1 Ankle joint angle at baseline and after one month of training.

CONCLUSIONS

Reward-based and progressive musical auditory feedback resulted in more resemblance on kinematics and symmetric distribution of forces and less pressure avoidance of toe region. Our developed technology has potential to be an evaluation, intervention, and compliance monitoring tool in real-world settings. Further studies are in progress to validate and demonstrate its effects on other clinical conditions.

INTRODUCTION

Monitoring dynamic balance during gait is critical for fall prevention in the elderly. A well-developed method is by quantifying the inclination angles (IA) of the body's centre of mass (COM) relative to the centre of pressure (COP) and their rates of change (RCIA) in standard gait laboratories [1]. Inertial Measurement Units (IMUs) have become more widely used for gait monitoring in domestic environments owing to the reduction in size and costs [2]. For IA and RCIA, several IMUs would be needed for the complete measurement of the body segments, making it infeasible for daily monitoring. Artificial neural networks (ANN) can potentially reduce the number of sensors, but multiple sensors are still needed in estimating gait parameters [3]. Monitoring balance and spatial-temporal parameters during gait using a single sensor remains challenging. The current study aimed to develop a new approach based on a long short-term memory network (LSTM) and an ANN for predicting IA and RCIA and spatial-temporal parameters using a single waist-worn IMU and to evaluate its accuracy against data obtained using 3D motion analysis systems.

METHODS

Ten healthy young and ten older adult males wearing 50 skin markers and an IMU on the waist walked on a 10-meter walkway while the ground reaction forces were measured with four forceplates and marker data by a motion capture system. The body's COM position was calculated as the weighted sum of the positions of the COM's of all the body segments using the marker data and segmental inertial properties. The COP position was calculated using forces and moments measured from the forceplates. These data were used to calculate gold standard IA, RCIA [1], and spatial-temporal parameters over a gait cycle, which, together with the low-pass filtered IMU data, were used to train the proposed hybrid LSTM-ANN model (Figure 1). The two LSTM layers extracted the IA and RCIA features, which were passed onto the ANN layers with data on body height and leg length to estimate the spatial-temporal parameters. Data from 229 gait cycles were used to train the LSTM-ANN model, and 10% of trials were used to test the model. The model predictions were compared to the gold standard, giving percentage relative root-mean-squared errors (rRMSE). Independent t-tests were used to compare the groups for measured and model-predicted parameters, respectively.

RESULTS AND DISCUSSION

The means (standard deviations) of the rRMSEs of the sagittal IA, sagittal RCIA, frontal IA, and frontal RCIA were 4.17 (0.90), 8.35 (1.40), 6.10 (2.20), 4.60 (0.90), respectively. Those for stride length, speed, cadence and contralateral toe-off and contralateral heel-strike and toe-off were 4.42 (4.30), 7.57 (7.56), 6.86 (6.17), 1.78 (1.63), 1.45 (1.34), 1.52 (1.39), respectively. The proposed LSTM-ANN model accurately predicted balance parameters, giving rRMSE of less than 5% and 8% for sagittal and frontal IA and RCIA, respectively (Table 1). It was also very accurate in predicting gait events and spatial-temporal parameters (Table 1). Such error levels were smaller than between-group differences reported in the literature [1]. Similar between-group effects were also obtained using measured and model-predicted data. Further training of the new model with a bigger dataset, including people with fall risks, will be helpful to improve the prediction accuracies and its application in balance monitoring and fall prevention.

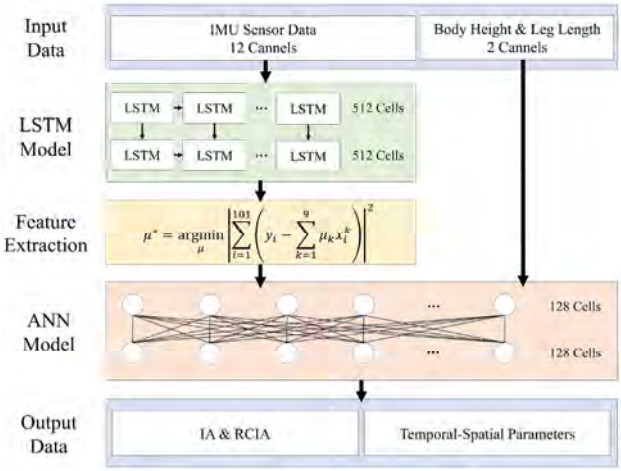

Figure 1 The structure of the proposed LSTM-ANN neural network model.

CONCLUSIONS

This study was the first in the literature to show the feasibility of predicting whole-body balance variables and spatiotemporal parameters during gait based on a single IMU on the pelvis. The current LSTM-ANN model was shown to have reasonably high accuracy and great potential for real-life monitoring of dynamic balance in people with fall risks.

PROPHYLACTIC CERCLAGE FIXATION FOR PREVENTION OF PERIPROSTHETIC FEMORAL FRACTURES: THE SIGNIFICANCE OF CABLE LOCATION

Kartik I. Reddy[1], Jonathan E. Gold[1], Sabir K. Ismaily[1], David Rodriguez-Quintana[1], and Shuyang Han[1]

INTRODUCTION

Periprosthetic femoral fracture is a common complication of total hip arthroplasty (THA). Prophylactic cerclage cable has been advocated for preventing propagation of cortical cracks during THA and postoperative activities [1,2]. Clinical studies have recommended placement of prophylactic cables at levels ranging from 0-20mm below the fracture, while definitive biomechanical data guiding the location of prophylactic cables is still lacking. Therefore, this biomechanical study was performed to examine two research questions:

(1) What is the acceptable cerclage cable location in order to effectively prevent fracture propagation?
(2) How does the cable tension change during loading?

METHODS

Femoral shafts of five fresh-frozen cadavers were prepared in this study. In each femoral shaft, five tests were performed sequentially with a CoCr prophylactic cable placed at varying distances (i.e., 5mm, 10mm, 15mm, 20mm, and cableless) from a longitudinal fracture. The fracture was initiated prior to each test using a surgical saw. The cerclage cable was outfitted with a compressive load cell in order to achievethe same cable tension across different tests and to measure the cable tension changes during subsequent loading.

To prepare for testing, the femoral canal was reamed, and then a 4° taper was advanced with an MTS machine at a rate of 10mm/min (Figure 1A). The test was terminated when crack propagation occurred or at 15mm displacement. The fracture was stained with blue ink to facilitate visualization. The ultimate force and cable tension were compared between different groups with a repeated measure ANOVA and post hoc analysis using Fisher's PLSD test.

RESULTS AND DISCUSSION

Compared to the control group, a cerclage placed at 5mm below the initial fracture increased the ultimate force by 2.4-fold to about 3 times the bodyweight (p=0.02). As the cerclage was placed further away, the ultimate force continuously decreased. When the distance reached 20mm, the cerclage did not provide any resistance to fracture propagation (Table 1).

The cable tension changed in different patterns between groups. With the cable at 5-10mm, the tension first remained flat and then increased rapidly in the late stage (Figure 1B). However, when the cable was 15-20mm below the fracture, there was minimal change in the cable tension throughout the test (Figure 1C), indicating that the cable was not effective.

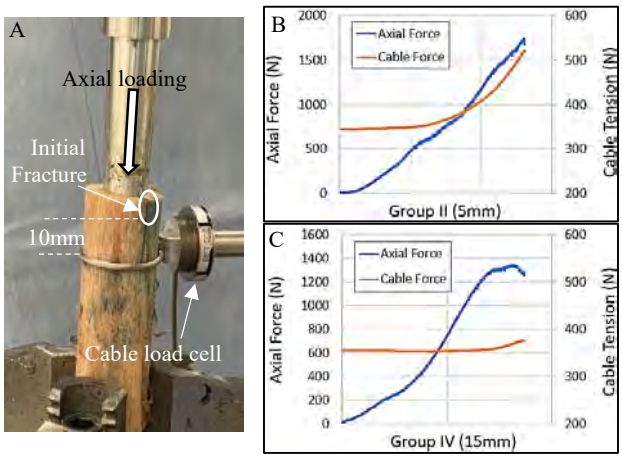

Figure 1. Test setup (A) and typical graphs (B and C) showing variations of the axial force and cable tension during loading.

CONCLUSIONS

The results of this biomechanical study supported the use of a prophylactic cerclage cable for periprosthetic femoral fractures. More importantly, the closer the cerclage to the fracture, the better the performance for preventing fracture propagation. When a prophylactic cerclage cable was placed 20mm below the fracture, the biomechanical response of the bone was similar to that without a cerclage.

ACKNOWLEDGEMENTS

The cerclage cables were donated by ZimmerBiomet.

INTRODUCTION

High-collar shoes should provide enough collar stiffness (CS) to protect the ankle during high-demand activities such as running. The primary purpose of this study was to introduce a high-collar running shoe that allows regulating CS and a new method to measure CS.

METHODS

To fabricate a flexible running shoe (figure 1, C), neoprene fabric was used for the upper part, and thermoplastic polyurethane and rubber were used for the midsole and outsole, respectively. Two Boa® ratcheting reels (Boa Technology Inc, USA) were implemented on the lateral sides of the collar wired to a 3D-printed top cover which allowed adjusting CS (figure 1, A & B). To measure passive CS, the force generated by a 200W motor at a constant velocity of 10 cm/s was applied to the shaft of a foot prosthesis (figure 1, D). Starting from 90°, the motor pulled the shaft to 60° and 110° for dorsi-flexion and plantar flexion, respectively. By reaching the end range angle, the motor released the wire with the same velocity to measure collar recoil movement. An IMU sensor (MTi-630, Xsens, Netherland) controlled the motor by measuring the shaft's angular position. The force in the wire was measured using a load cell (LSB205, Futek Inc., USA) synchronized with the Vicon motion capture system that tracked collar movement and wire angle by reflective markers.

At the 90° shaft position, two pressure-measuring sensors (Kikuhime, TT Medi Trade, Denmark) were placed at the level of the medial and lateral malleolus of the prosthesis. Then, the Boa® ratcheting reels were regulated until both sensors reached the same levels of 10-, 30-, and 60-mmHg, representing the low, medium, and high CS conditions, respectively.

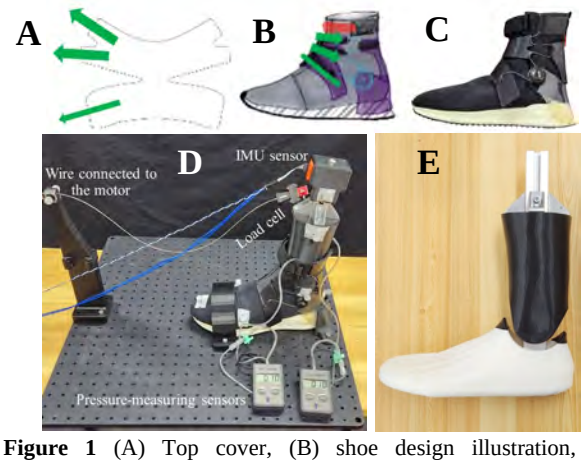

Figure 1 (A) Top cover, (B) shoe design illustration, (C) manufactured prototype of the custom-designed high-collar shoe, (D) collar stiffness measurement setup, and (E) foot prosthesis.

All data were filtered using a fourth-order low-pass Butterworth filter with a cut-off frequency of 10 Hz. The moment-angle curve was calculated using the component of the wire's force perpendicular to the shaft. The slopes from 90° to 60° and 110° characterized the dorsiflexion and plantar flexion CSs, respectively [1]. The area between the pulling and recoiling curves indicates the mechanical energy lost [1].

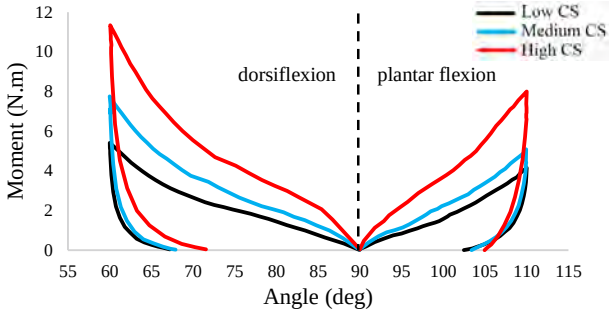

Figure 2 Moment-angle diagram for three CS conditions.

RESULTS AND DISCUSSION

The stiffness characteristics for three CS conditions are presented in Figure 2. The CS ($Nm.deg^{-1}$) for low, medium, and high conditions were -1.8, -2.57, and -3.78 for dorsiflexion and 2.04, 2.53, and 3.98 for plantar flexion, respectively. Also, energy loss (%) for low, medium, and high CS conditions were 90.2, 89.9, and 85.8 for dorsiflexion and 82.1, 84.3, and 87.5 for plantar flexion, respectively.

The main issue with similar studies that tried to measure CS is that they did not solely measure the CS but the whole shoe's bending stiffness [2], applied a range of constant forces to the shaft that makes it unclear how the high-collar reacted during different ankle angles [3] or applied the force to the shaft manually [1]. The presented method addressed these problems.

CONCLUSIONS

Mechanical testing of the high-collar shoe revealed nonlinear moment-angle relations for all conditions, which is typical for the material used for the high-collar shoe. Compared to the low CS condition, the stiffer collars required higher forces to deform to the same end range and returned lower percentages of energy for dorsiflexion and higher percentages for plantar flexion during recoiling.

MOUSE HORIZONTAL AIMING PERFORMANCE BETWEEN TWO GAMING MICE OF DIFFERENT SLANTED DESIGN

INTRODUCTION

In the past, studies pointed out that lightweight mouse may effectively optimize performance while minimizing discomfort [1][2]. However, the shape of the mouse is the first point of contact with the human body, and it is the key that directly affects the feel of the movement. But how the shape of the gaming mouse affects the horizontal target acquisition skills is unknown. Therefore, the purpose of this study was to explore the difference of slanted design in gaming mice which e-sport players use. In this study, it was hypothesized that all variables in given e-sport players would be significantly different between the two designs.

METHODS

Eight male e-sport professional players of first-person shooter game volunteered as participants. The data collection was done in an indoor experimental area with a dedicated "ZOWIE ZONE" gaming table. The kinematics data include hand horizontal velocity, and metacarpophalangeal (MCP) and proximal interphalangeal (PIP) angle of index finger, which were detected by Motion Analysis System with Cortex 9.0.0.44. The muscle activation signals of the 1st dorsal interossei (1st DI), 4th dorsal interossei (4th DI), abductor digiti minimi (ADM), extensor indicis (EI), flexor carpi radialis (FCR) and extensor carpi ulnaris (ECU) were recorded with the Delsys-16 EMG system. A nonparametric statistical procedure Wilcoxon was used to test differences.

RESULTS AND DISCUSSION

This study shows that the MCP joint angle of the index finger and the other parameters between two slanted design during horizontal task were not significantly different (Table 1). The MCP joint angle of the index finger, which may affect the comfort of moving your palm horizontally and clicking, indicates the angle between the first knuckle of the index finger and the palm when the palm rests on the back of the mouse. In horizontal target acquisition skills, reaching the target quickly and accurately are achieved by muscle coordination and joint movement from upper arm to forearm, and finally to the mouse. There was no significant difference in hand velocity and upper extremity muscle activation signals between the two design during horizontal aiming task. The reason may be that not all players' movements are consistent. For example, the wrist-aiming gamers have more wrist angular displacement, while the arm-aiming gamers use more upper arm and forearm to move quickly.

CONCLUSIONS

The kinematic data in this study shows that the MCP joint angle of the index finger and the horizontal aiming performance were affected by mouse slant. It is recommended to investigate whether other shape designs of the mouse have impacts on performance in the future, which could help know more clearly how to effectively design the shape to enhance the performance.

INTRODUCTION

Distal radius fractures (DRF) are one the most common upper limb injuries requiring open reduction and internal fixation in an orthopaedic setup. Over the last decade, volar plating has become the treatment of choice for such fractures, as it results in better functional outcomes with greater fragment stability and low complication rates as compared to other means of management. The pronator quadratus (PQ) muscle covers the distal radius metaphysis and needs to be released from the radial end to visualise the fracture and subsequent fixation of the volar plate. Considerable controversy exists if post-fixation, the muscle needs to be repaired or not. Clinicians have reported contrasting opinions, with some favouring PQ repair while others demonstrating no beneficial role of the same. The purpose of this study was to evaluate and compare the clinical efficacy of volar plating with PQ preservation versus PQ repair or transection for DRF in different age groups.

METHODS

In this study, (a) range of motion (ROM) and (b) grip strength meter (TTM, Tokyo, Japan) were used.

(a) ROM was performed as long as there was no pain, and ROM of palm flexion, dorsi flexion, radial flexion, ulnar flexion, internal rotation, and external rotation was evaluated in the sitting position.

(b) In an upright position, the patient gripped the grip strength meter and adjusted it so that the second joint of the index finger was at 90 degrees. The upper limbs were held in a posture with the upper limbs drooping toward the body, and the measurement was performed without swinging the grip strength meter. Since grip strength is affected by body size and other factors, the value on the affected side was divided by body weight to obtain the body weight ratio.

All consecutive fractures of the distal radius surgically treated with the Vollard plate were assigned to a group with PQ preservation versus PQ repair or transection and grouped according to age. Groups were divided into 60s, 70s, and 80s (Group A: 60-69 years, 5 patients, Group B: 70-79 years, patients, Group C: 80-89 years, 6patients). 22 patients had complete 4 week follow-up (1,2,3,4 weeks) and were included in this study. 22 patients who were between September 2018 and December 2022, there with DRF underwent open reduction and internal fixation using the volar locking palmar plates (Synthes or MEIRA companies). Written informed consents were obtained from all subjects prior to the experiments. The range of motion and grip strength at each week were compared between groups with and without PQ restoration by age.

RESULTS AND DISCUSSION

ROM and grip strength for each group at each week were determined using a t-test. There were no differences among the groups in the 60s. In the 70s, range of motion was better in dorsiflexion and palmar flexion at 1 week in the PQ muscle preservation group (Table 1). In the 80s, the grip strength to body weight ratio was stronger in the PQ muscle preservation group in grip strength at 1, 3, and 4 weeks (Table 1).

CONCLUSIONS

In this study, dorsiflexion and palmar flexion was better at 1 week in the 70s PQ muscle sparing group, and grip strength to weight ratio was better at 1, 3, and 4 weeks in the 80s PQ muscle sparing group. The results of this study revealed that age influences the decision to preserve or not preserve the PQ muscle for DRF in the early postoperative period.

Table 1: Comparison of ROM and grip strength between volar plating with PQ preservation versus PQ repair or transection for DRF in different age groups

	PQ preservation	PQ repair or transection	*p-value*
Group B dorsal flexion (1week)	29.167° ± 6.6646°	47.500° ± 10.607°	$p = 0.024$
Group B palm flexion (1week)	34.167° ± 5.845°	50.000° ± 14.142°	$p = 0.049$
Group C grip strength (1week)	0.067 ± 0.054	0.161 ± 0.038	$p = 0.033$
Group C grip strength (3week)	0.111 ± 0.055	0.227 ± 0.070	$p = 0.028$
Group C grip strength (4week)	0.122 ± 0.063	0.282 ± 0.066	$p = 0.009$

The optimal tunnel entry point in cranial cruciate ligament reconstruction for dogs: a simulation analysis for femoral tunnel placement

Ching-Ho Wu[1], Tsai-Yu Lee[1], Shih-Wen Wang[1], and Cheng-Chung Lin[2]
[1]Institute of Veterinary Clinical Science, National Taiwan University, Taipei, Taiwan
[2]Department of Electrical Engineering, Fu Jen Catholic University, New Taipei City, Taiwan
Email: chinghowu@ntu.edu.tw

INTRODUCTION

Intraarticular reconstruction of the cranial cruciate ligament (CCL) aims to repair stifle stability and physiological function in dogs. However, to date, its poor postoperative outcomes made it less favorable among veterinary surgeons, and tunnel malpositioning was one of the most common causes of complications [1]. For instance, insufficient tunnel length was shown to result in weak fixation strength [2]. There is no consensus on the position/orientation of tunnel placement in canine CCL reconstruction. Thus, the study aimed to explore the potential femoral tunnel entry points (FTEPs) on the lateral femoral condyle by simulation analysis of commonly utilized criteria for human ACL reconstruction, namely femoral length, footprint coverage, and tunnel-face angle.

METHODS

The computed tomography (CT) scans of hindlimbs from 10 median-breed adult dogs (7 females and 3 males; body weight: 15.2–22.6 kg) were collected, from which 18 femoral bone models, free from bone and articular abnormalities, were reconstructed (9 left and 9 right). The FTEPs were determined on femoral model surfaces using an approach modified from the study by Hodel et al. [3](Figure 1A). The simulated femoral tunnels were placed by creating 4.5-mm diameter hollow cylinders from the candidate FTEPs toward the centroid of the CCL footprint on the femur. The femoral aperture was defined as the intersection area between the simulated tunnel and the medial surface of the lateral femoral condyle. The tunnel length was defined as the distance between the centroid of the femoral CCL footprint to the FTEP. The footprint coverage was defined as the similarity between the CCL footprint and the apertures as follows:

$$\text{Similarty} = \frac{\text{intersection of areas}}{\text{union of areas}} 100\% \quad (1)$$

The tunnel-face angle was defined as the angle between the central axis of the tunnel and the tangent surface at each FTEP.

RESULTS AND DISCUSSION

The results showed that the FTEP A7 has the highest footprint similarity (Figure 1B). The more cranial FTEPs possess longer tunnel lengths. Since a tunnel length <15 mm was found to affect graft strength [2], the FTEPs caudal to A4, B5, C5, D5, E4, and F3 should be avoided (Figure 1B). In clinical practice, a smaller tunnel-face angle is challenging to drill tunnels even for experienced surgeons. An adequate tunnel-face angle was never suggested in the literature. In the present study, to our surgical experience, we recommend a tunnel-face angle >30° to ensure successful tunnel drilling. As a result, the FTEPs other than A11, C9, C10, D8, D9, and E8 were feasible for tunnel placement (Figure 1B). In summary, FTEP A7 gives the highest footprint similarity and satisfies the demands for sufficient tunnel length and tunnel-face angle.

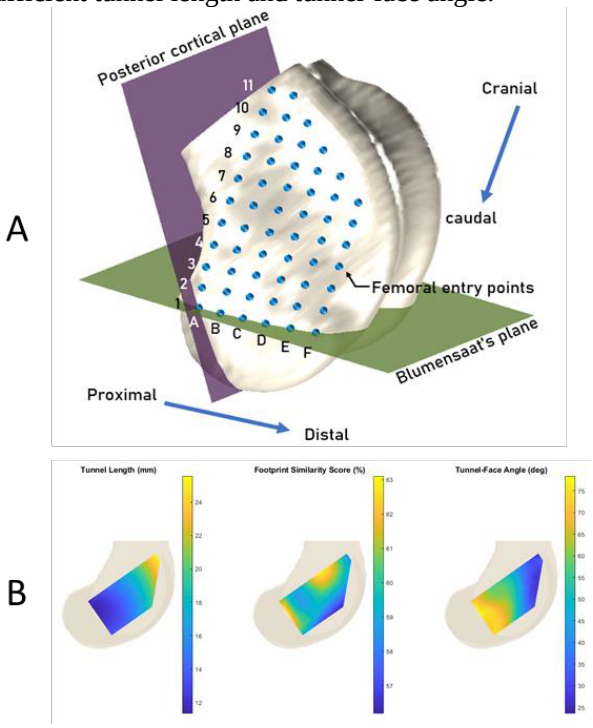

Figure 1 (A) The candidate FTEPs (B) Heatmaps on the lateral condyle show averaged tunnel length (mm), footprint similarity (%), and tunnel-face angle (°) of each FTEP.

CONCLUSIONS

The study recommends the FTEP, A7, for the outside-in drilling of the 4.5-mm-diameter femoral tunnel on the lateral femoral cortex in canine CCL reconstruction as it can yield the highest footprint similarity and satisfy the criterion of tunnel length and tunnel-face angle.

CHANGES IN LOWER LEG KINEMATIC FREQUENCY CONTENT DURING PRE-GROUND CONTACT AND WEIGHT ACCEPTANCE PHASES OF ACL INJURY RISK SCREENING TASKS

Simon Augustus[1] and Neal Smith[2]

[1] Applied and Human Sciences, Kingston University, London, UK.
[2] Institute of Sport, University of Chichester, Chichester, UK.
Email: s.augustus@kingston.ac.uk

INTRODUCTION

Change of direction (COD) and single leg drop jump (SLDJ) tasks are often used to assess non-contact ACL injury risk. Kinematic and force data are combined in 3D motion analysis to derive biomechanical proxies of injury risk (e.g. peak knee abduction moment during weight acceptance; WA). However, the extent to which foot-ground collisions induce expansion of lower leg frequency content is unknown. Understanding these changes is important if researchers are to optimise use of contemporary low-pass filter techniques that vary the magnitude of noise reduction over different phase of a task (i.e. transition from aerial to ground contact) [e.g., 1,2]. The aim of this study was thus to assess changes in foot and shank marker frequency content during the pre-ground contact phase, WA and post-WA phases of COD and SLDJ tasks.

METHODS

Three-dimensional lower limb kinematics were collected from 16 recreational athletes (77 ± 12 kg, 1.76 ± 0.09 m, 26.8 ± 4.5 years) performing unanticipated COD (approach velocity = 4-5 m/s) and SLDJ (drop height = 0.3 m) tasks (250 Hz; Oqus 300, Qualysis Medical AB, Sweden). Marker trajectories from the ground contacting leg (Table 1) were exported to Matlab (R2022a, Mathworks, USA) where frequencies corresponding to 95% cumulative signal power were determined for each: pre-ground contact (peak vertical position to vGRF > 10N), WA (vGRF > 10N to first trough following the vGRF impact peak) and post-WA phases (first trough following the vGRF impact peak to vGRF < 10 N). This analysis was performed in each X (medial/lateral), Y (anterior/posterior) and Z (vertical) planes and comparisons between phases made using pairwise effect sizes (Cohen's *d*; 0.2 - 0.5 small, 0.5 - 0.8 medium, > 0.8 large).

RESULTS AND DISCUSSION

COD and SLDJ tasks both showed large expansions in marker frequency content between pre-ground contact to WA, then reductions between WA and post-WA (d = 0.5 – 4.0; Table 1). This was likely due to the sudden deceleration of the markers after foot-ground collision. For COD, while frequencies expanded in all planes following ground contact, this was most pronounced in the vertical plane (d > 2.0) and these changes were similar irrespective of marker location. For SLDJ, frequency content was generally lower than for COD, and thus expansion and reduction was less pronounced (d = 0.3 – 3.0). This was likely due to a slower ground-contact velocity. However, like COD, the largest expansions during WA were in the vertical plane and were most evident for the foot markers (Table 1).

CONCLUSIONS

COD and SLDJ ACL injury risk screening tasks induce abrupt expansion and then reduction of lower leg kinematic frequency content following foot-to-ground collision. Given proxies of injury risk are often derived after transition to the higher frequencies during WA (e.g., peak knee abduction moment), researchers might consider using low-pass filter methods that vary the magnitude of noise reduction in different phases of a movement [e.g., 1,2]. The data presented here can help inform cut-off frequency selection and optimise signal-to-noise ratios when using such methods for COD and SLDJ tasks. However, it remains to be seen whether adopting such techniques would offer improvements for identifying individuals at risk from non-contact ACL injury.

INTRODUCTION

The initial ball velocity can be enhanced in tennis by increasing the racket's momentum at ball impact. However, due to the game's characteristics, increasing the racket's momentum by increasing the racket's mass would not always provide an advantage for players.
At the moment of ball impact in tennis, the racket's momentum is imparted to the ball where a part of the racket's mass is utilized as effective striking mass. Currently, many amateur tennis players tend to select a racket of 300g because the mass has been recognized as the "gold standard". However, it is still unknown whether the gold standard racket is the best in terms of effective striking mass. Thus, the purpose of this study was to clarify whether the mass of the gold standard racket (300g) is a reasonable mass for tennis rackets from the perspective of effective striking mass.

METHODS

Twenty-three experienced and right-handed tennis players (19 males and 4 females, height: 170.91 ± 8.81cm, weight: 62.96 ± 6.93kg) participated.
Rackets with five different masses (Racket_1(272g); Racket_2(285g); Racket_3(300g); Racket_4(315g); Racket_5(330g)) were prepared and the subjects were instructed to strike six balls delivered from a ball launcher (Slinger Bag, Slinger Inc.), as hard as possible so that the ball goes into the opponent's court.
An eight-camera motion capture system (Vicon Vero, Vicon Ltd.) was used to capture the subject's body and racket movements at 250 fps. The initial velocity of the ball after ball impact was measured using a TrackMan (TrackMan Inc.).
Of the five markers attached to the racket, the midpoint of two markers on either side of the racket was used to define the point where the participants hit the ball.
Applying the law of conservation of momentum with the assumption of the centrifugal collision happens between the racket and ball, effective striking mass during tennis hard strokes was calculated.

RESULTS AND DISCUSSION

We aimed to clarify the effect of gross racket mass on effective striking mass to examine whether the gold standard racket has some rationale from the perspective of effective striking mass.
On average, the striking masses of Racket_1–5 corresponded to 76.18 ± 6.90%, 75.86 ± 6.40%, 74.41 ± 6.42%, 73.44 ± 6.96%, and 72.10 ± 5.49% of the racket masses, respectively. The racket masses always exceeded the striking masses in all conditions (Figure 1). This finding supported the previous finding [1] and indicates that the mass required for ball impact (striking mass) can be provided by the mass of the racket alone under the given conditions in this study. In this study, we could not find any scientific rationales for the gold standard mass (300g) generally applied for conventional tennis rackets, suggesting tennis rackets could be lighter.

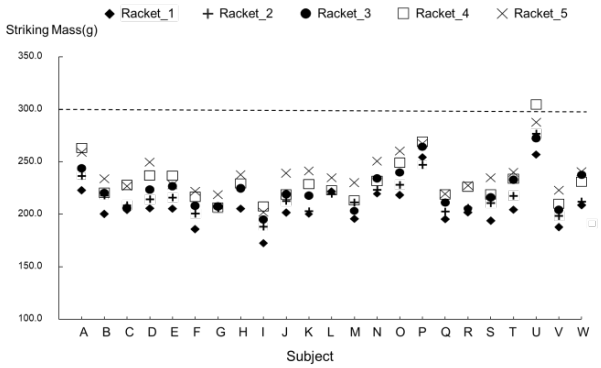

Figure 1. Effective striking masses during groundstrokes in tennis.

CONCLUSIONS

For tennis groundstrokes (hard shots), effective striking mass was found to be lighter than the racket's "gold standard" (300g), suggesting that tennis rackets could be even lighter.

INTRODUCTION

The population of older people has been increasing in Japan. As a result, an increasing number of elderly people are caring for other people of the same generation. How safe it is for elderly caregivers to operate a wheelchair on mainly barrier-free roads is unknown. The purpose of this study is to investigate the wheelchair operating capabilities of elderly people based on their body function.

METHODS

A total of 56 community-dwelling women participated in this study. Of this, 36 were considered elderly (average age: 79.4±3.8 years, height 149.5±5.4 cm, and weight 51.8±7.1 kg), and 20 were young adults (average age 18.9±1.0 years, height 159.8±4.8 cm, and weight 54.8±6.9 kg). The study was approved by the ethics community of Tokyo International University. All participants gave written and signed informed consent. We evaluated participants using the two-step test, stand-up test, and 25-question Geriatric Locomotive Function Scale to detect locomotive syndrome, which the Japanese Orthopaedic Association defines as a condition of reduced mobility. We also evaluated normal and fast walking times over a 5-m distance with and without a 75 kg dummy-weighted wheelchair, Timed Up and Go test (TUG), timed one-leg stand (eyes open and closed), grip strength (both hands), wheelchair operation test (time to tip caster to 10-cm height, travel up a 4.39-m longitudinal slope, go through a left-inclined 4.14-m course, and recovery from one forward-wheel dropping). For the statistical analysis, we used the Mann-Whitney *U* test or a two-sample *t*-test to compare performances between the two groups. Additionally, we used multiple regression analysis for wheelchair operation ability and logistic analysis for the property of tip caster (stepwise selection method).

RESULTS AND DISCUSSION

Of the 36 older people, 24 had Stage 1 locomotive syndrome, six people had Stage 2, two people had Stage 3, and four people did not have locomotive syndrome. The Stage of locomotive syndrome increases as mobility decreases. The older participants scored lower than the younger adults in 5-m walking time (fast), one-leg stand, TUG, grip power of both side strength, and wheelchair operation (Table 1). Eight (22%) of the older participants were unable to tip the caster up to a 10 cm height. From the multiple regression analysis, the grip strength of the left hand and the stage of locomotive syndrome predicated the longitudinal walking time and slope traversing ability. We were unable to determine a prediction factor using logistical analysis for the ability to tip a wheelchair back. We hypothesized that weak grip strength and locomotive function of elderly people influences wheelchair operating ability. Furthermore, tipping a wheelchair back needs not only muscular strength but also the acquisition of how to use power.

CONCLUSION

Most elderly people (over 75 years) have locomotive syndrome, which influences their ability to operate a wheelchair. In addition to barrier-free roads, we suggest that older caregivers use assistive technology when operating a wheelchair. In addition, they are needed to improve their body function.

ACKNOWLEDGEMENTS

This study received funding from the Foundation for Promoting Personal Mobility and Ecological Transportation.

INTRODUCTION

Dr. Robert Hickson [1] demonstrated impaired strength gains with traditional concurrent strength and endurance training the "interference effect". There are most of studies confirm that gains in muscle hypertrophy and strength are compromised when strength- and endurance-based training are undertaken concurrently. However, the interference effects of high-intensity aerobic exercise (HIAT) combined with high-intensity resistance exercise (HIRT) on strength development and endurance performance are unknown. The purpose of the study was to investigate the responses to eight-week of concurrent and traditional training on physiological and cardiovascular function, and one-repetition maximum [1-RM] strength capacity in sedentary adults with suboptimal health.

METHODS

Forty-one unhealthy and sedentary adults were recruited to complete this eight-week concurrent training or traditional training study in randomized order. After a familiarization trial, all participants performed a graded exercise test for determining VO_{2max}. Participants were assigned to either for eight-week training: (1) Concurrent training A (CTA)- Two bouts of HIAT (12 movements at 80–90%HRmax) before a single bout of HIRT (8 exercises at 20% – 60% of 1-RM) a day three time a week. (2) Concurrent training B (CTB)- A single bout of HIRT before two bouts of HIAT a day three times a week. (3) Traditional training (TT)- Two bouts of HIAT a day three times per week and two bouts of HIRT a day two times per week. A single bout of HIAT consists of 3 sessions, each separated by 1-min of the rest; each session includes four segments. Each whole-body exercise in a segment was done for 30-s at high effort, followed by 15-s of downtime, then repeated. Participants were evaluated on cardiovascular parameters, energy expenditure and maximal muscular capacity. The level of statistical significance is set at $p < 0.05$.

RESULTS AND DISCUSSION

There were significant increases in VO_{2max}, VE at VO_{2max}, O_2 plus, and endurance time on the ergometer in CTA and CTB groups ($p < .05$), with higher decreases in body fat percentage in CTA and CTB groups ($p < .05$). Only VE at VO_{2max} and endurance time increased in TT group ($p < .05$), with no significant difference among three groups. Furthermore, there were significant increases in energy expenditure and excess post-exercise oxygen consumption during post-exercise 30 minutes in CTB group compared with CTA and TT groups ($p < .05$). Significant increases in maximal strength after training in bench press of 1-RM (Figure 1) and back squat of 1-RM (Figure 2) among CTA, CTB, and TT groups, as well as increase by 9.2% – 12 .7% in the hand grip strength ($p < .05$). The interference effect of this study was not existed likely explained by methodological differences [2].

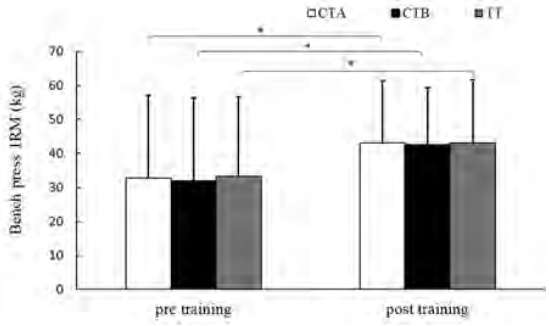

Figure 1 Change in bench press of 1-RM before and after training.

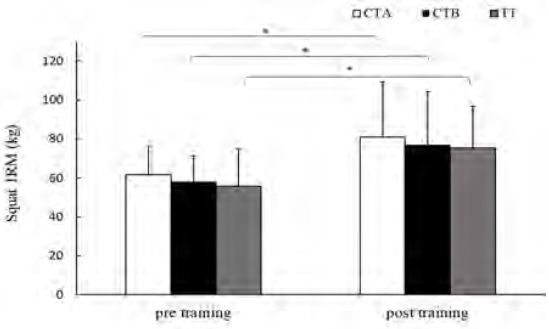

Figure 2 Change in squat of 1-RM before and after training.

CONCLUSIONS

In sub-healthy sedentary individuals, TT improves chest, hands, and leg muscle performance. However, concurrent HIAT combined with HIRT further improves body fat percentage, cardiovascular function at VO_{2max}, and muscle strength performance.

INTRODUCTION

In contemporary dance, the natural movement patterns of the body and its relation to gravity had been incorporated into dance. The movement called the swing which could be often seen in Limón Technique would be one of basic movement in modern or contemporary dance. Limón Technique by José Limón is one of common basic modern dance techniques originated from 20th century. Previous study reported that strong associations between higher beauty scores and certain kinematic parameters, especially those related to amplitude of movements in contemporary dance (Torrents et al.,2017). Although dance students perform the swing movement in their classes as well as rehearsals, kinematic characteristics of the swing movement are still unknown. So, the purpose of this study was to investigate the swing movement in contemporary dance by 3D motion analysis and its relation with the qualitative evaluation of the movement by experienced dance instructors.

METHODS

Twenty young female dancers participated in our study. Their mean age was 20.9 years old with 7.1 years of contemporary or modern dance training as the average. Dancers were asked to perform the swing movement to the right side which could be frequently seen in modern or contemporary dance such as Limon technique. The swing motion (Fig. 1) was captured with 8 optical cameras at 120 Hz. Three-dimensional motion analysis system (VICON, Motion Analysis, USA) was used to calculate the center of mass (COM) and other kinematic variables. After motion analysis, we also investigated how three experienced dance instructors perceived the swing movements by using VAS scale as well as impression of gravity, relaxation and COM displacement viewing the images of the stick pictures from the movement analysis.

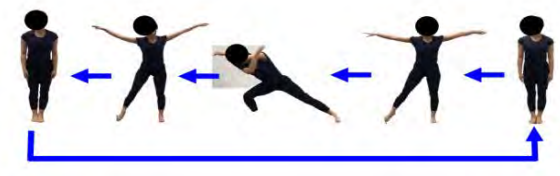

Figure 1 The images of one sequence of the swing movement.

RESULTS AND DISCUSSION

Average score of the swing movement was 6.52 ± 0.56 ranged from 5.3 to 7.3. Then, dancers were divided into two groups by the average score. Significant correlations were obtained between VAS scale of the swing movement and the impression of relaxation, that of gravity (Fig.2), that of downward displacement of COM, and that of movement amplitude evaluated by big to small. During the swing movement, lateral displacement to the right side of COM appeared with downward displacement of COM. High score group (HG) showed significant greater displacement of the head, the neck, and the shoulder compared to Low score group (LG). HG also showed significant larger angle of trunk lateral rotation on both sides, thoracic lateral tilt angle on both sides, elbow flexion/extension angle, and right hip angle of adduction/abduction. There was no significant difference in COM displacement between two groups. As for movement speed, during first half of the movement, HG showed significantly faster velocity of the head and the neck displacement as well as faster angular velocity of hip flexion. During latter half of the movement, HG also showed significantly faster velocity of the head, the neck and the shoulder as well as faster angular velocity of lateral tilt of the trunk.

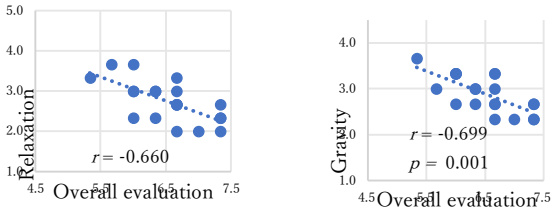

Figure 2 Correlations between impressions of relaxation and that of the gravity by the movement and overall evaluation of the swing movement

CONCLUSIONS

From the results of this study, it is indicated that dancers evaluated as high presentation in the swing movement would perform the swing movement with larger displacement of the upper body, while there was no significant difference in COM displacement between high- and low-score swing movement.

INTRODUCTION

Bone quality evaluation is essential for dental implant programs. Dental cone-beam computed tomography (CBCT) is suitable for jawbone quality assessment. Many scholars have used dental CBCT or medical CT to measure cancellous bone density.[1-2] However, there has yet to be a unified measurement method in the past, and there needs to be a discussion on the correlation between different measurement methods. The aim of this study is to investigate the relationship between two different measures of cancellous bone density by using dental cone-beam computed tomography.

METHODS

Two hundred preoperative dental CBCT images, which were obtained from China Medical University Hospital, were input into the medical image software MIMICS.
To establish 3D virtual dental implants at the potential implant sites. The length and diameter of the virtual cylinder were set as 11mm and 3.5mm. Different regions of interest (ROI) were used in two measurement methods, "inside cylinder" and "outside cylinder," was used to measure cancellous bone density. The repeated measures ANOVA was conducted to analyze the difference between the different methods. The Pearson correlation coefficient was used to analyze the correlation between the two methods.

RESULTS AND DISCUSSION

The results showed that the measurement result of the "outside cylinder" (527.03±227.97 grayscale value, GV) was significantly higher than that of the "inside cylinder" (496.53±233.52 GV). According to the Kolmogorov–Smirnov normality test analysis, the three measurement results showed normal distribution (P value>0.05). In addition, there was a high correlation between the two methods (r=0.970; p<0.001).(Table 1.)

The bone density measured in the "outside cylinder" group was significantly higher than in the "inside cylinder" group. We speculate that the main reason is that the ROI of the "outside cylinder" is more peripheral than the "inside cylinder." These may cause the cortical bone area to be included in the ROI, resulting in overestimating the cancellous bone density. Although the "outside cylinder" is the bone area actually connected with the dental implant, the cortical bone should be excluded when the cancellous bone density measurement is performed. Cortical bone and cancellous bone have different effects on implant stability, the two of which should discuss separately.[3] According to the above research results, if the "outside cylinder" is used for density assessment, more careful evaluation is required to avoid overestimating bone density.

CONCLUSIONS

Two measurement methods of cancellous bone density did not affect the magnitude trend of the results. The "outside cylinder" was significantly higher than the "inside cylinder."

INTRODUCTION

The special education population exhibits great individual differences. Effective training for this population needs to be personalized with specific movement indicators. They are also less motivated to participate in activities, hence adaptive games with diversities are needed to attract their attention. To date, with many intelligent movement evaluation and training systems available for typically developed individuals, a system specially designed for the special education population is scarce. The current multidisciplinary project aims to construct a digital, diverse, assemblable intelligent movement evaluation and training system for individuals with disabilities. This project was divided into three stages: 1. Evaluate the needs of the target group, analyze functional indicators to create the decision tree, and design the multi-functional assemblable modules; 2. Carry out content and structure planning, define movement parameters, and introduce AIoT technology; 3. Identify featured characteristics, plan for data collection and inclusive training activities (Fig. 1).

METHODS

To identify the unmet needs of this group, the team performed a literature review with keywords including "assistive devices, physical and mental disabilities, motion analysis, machine learning, system development", etc., summarized the pros and cons of the current-available functional assessment tools and devices, and ran them through multiple expert meetings. The performance indicators of the target population and the needs of special education schools were then identified.

The project is expected to design and develop an integrated assessment and training system for institutions with individuals with physical and intellectual disabilities. The assemblable system includes functional assessment modules for both the upper and lower limb (U/E and L/E). These modules are capable of measuring the control of arms and legs, eye-hand/foot coordination, attention. The module is equipped with a control circuit with a wireless transmission function. Sensors including micro switches, accelerometers, gyroscopes, and pressure gauges are installed on the circuit.

RESULTS AND DISCUSSION

Here we present 1. The prototype of the plug-in geometric block module and its corresponding application for the U/E. There are several different shapes of bases and plugs on the panel, and the participant must pair all specific shape plugs into the same shape base to complete the test. This is the most direct way to test the shape identification and manipulation function of the hand, including pickup, rotation, and eye-hand coordination. The app will first beep first at the start, and when the participant finishes pairing the last plug with the base, it will be considered as the stop of the test. 2. The prototype of the smart ball module and the smart mat for the L/E. Data will be collected and transmitted via wifi to the integrated system. The participant performed several desired movements according to the instructions on the screen of the assessment system. The signals measured by the sensors inside the smart ball and the smart mat collected the performance parameters via a self-developed signal collection gateway, processed, and sent to the computer for real-time calculation. School teachers and sports coaches can use mobile phones to receive data and upload the signal-processing results to the cloud for storage and formulate training plans accordingly.

Figure 1 The purposed assessment and training system

CONCLUSIONS

The intelligent system developed can not only objectively and efficiently evaluate the target population and provide specific features for personalized training design; moreover, through the diverse, assemblable design, it can facilitate the participation of these individuals and encourage them to interact with the peers. Results can also be used for reference by related professionals for teaching/rehab program design, scientific communication, product development and technology transfer, etc..

INTRODUCTION

The music performance by professional pianists is remarkable from the perspectives of aesthetics, i.e., beautiful sounds, and human movement science as well. In particular, the complex and dexterous actions by the hands and fingers during a piano performance are feasible due to the structural advantage of the hands and fingers, such as high mechanical degrees of freedom. In other words, high-quality piano performance may be associated with the ability to coordinate high-dimensional elements, including hands, fingers, and trunk. By general consensus from the current control theories, the strategy of the central nervous system (CNS) toward the high dimensionality of the elements is to reduce the degrees of freedom in such a way that the elements are classified into a limited number of groups (i.e., dimension reduction) that are latent variables as to the performance skills or coordination [1]. The purpose of this study was to examine the patterns of coordinative patterns and dimension reduction of a piano performance by a professional pianist.

METHODS

One professional pianist who has worked performer and instructor for at least 20 years participated in this study. The participant played a Computer Controlled Piano (Disklavier C7, Yamaha Inc., Hamamatsu, Japan) for 30 repertories which were composed of four techniques. (1) pulling arm legato: up, down, pronation and supination motion of wrist with released in the shoulder, (2) upper-arm gravity drops: a portion of the pulling arm cycle with a low- and high-wrist form, (3) forward gravity drops-rebounds: control of lower arm to maintain wrist height, and (4) hand bounce: produce faster and lighter repetitions of hands [2]. Spherical reflective markers were attached to the hand and each finger joint. Kinematics of upper body segments were captured using eight infrared cameras at 100Hz (OptiTrack, Natural Point Inc., Corvallis, OR). The geometric model consisting of 24 segmental angles was used for the quantification of mechanical properties of body kinematics. Principal component analysis (PCA) was performed to investigate the strategy of dimension reduction during the piano performance.

RESULTS AND DISCUSSION

(1) In pulling arm legato technique showed that the wrist, thumb, and little fingers were performed in one mode. (eigen value=14.99, variance=34.95%) by PCA. Also, upper limb elements were grouped into one mode (eigen value=1.89, variance=4.39%). These results suggest that the group of thumb and little finger and fixed upper arm play a role in the frame for hand circle motion. (2) upper arm gravity drops were shown that upper limb elements were separated into different modes. This technique is characterized by controlling the wrist movement with the motion of the upper arm. That is, it is shown that harmony can be played continuously by using the coordination of the upper and lower arm to control the movement of the wrist. (3) Forward gravity drops-rebounds showed that the wrist and forearm were one mode (eigen value=16.13, variance=37.50%), and the index-middle, ring-little, and thumb fingers of both hands represented as independent groups. It suggested that wrist and forearm motion and finger independence play an important role in short continuous hitting motions. (4) Hand bounce was shown that the index, middle, and ring fingers of each hand were played in one mode (left hand: eigen value=11.46, variance=26.64%; right hand: eigen value=9.68, variance=22.51%). This result reflected that the character of this technique which is by playing notes quickly and lightly for a long time while fixed wrist position.

CONCLUSIONS

The current results showed the existence of a common mode (i.e., latent variable) across different piano techniques. Further, the kinematics of the thumb, little finger, and wrist joint played a significant role in the overall frame. To sum up, the control ability of wrist position and independent motions of fingers may be a contributor to the professional piano performance, albeit these should not be all about the “beauty” of the piano performance.

PROGRESSIVE ENERGIZATION EVALUATION AND BENEFITS OF GROUP EXERCISE SESSION FOR SENIORS – POST-EVENT MOVEMENT OBSERVATION AND ANALYSIS METHOD

INTRODUCTION

According to the definition of the World Health Organization (WHO), when the population over 65 years old exceeds 14%, it is called an Aged Society. Taiwan is estimated to enter a super-aged society by 2025, making health and aging issues urgently needed to be taken seriously. As the elderly grow older, their physical functions gradually decline, including decreased muscle strength, decreased cardiorespiratory endurance, decreased nerve conduction velocity, decreased muscle flexibility, and decreased activity, which in turn leads to decreased physical fitness. Therefore, this study aimed at enhancing physical activity through group exercise instruction in the elderly population.

METHODS

The target population of the current study was the elderly who are over 65 years old and rarely do exercise. First, a doctor will diagnose and confirm whether the physical condition is suitable for participation. After the diagnosis, There were 15 people (age: 71.53±5.06) met the inclusion criteria; then, a qualified group sports coach provided group sports guidance. The courses were held 4 times a week, two hours each time, for a period of three months, with a total of 48 training sessions. The content of the courses were listed as follows: Weeks 1 to 4: Warm up with low-impact aerobics (20 min), operate a series of isokinetic training machines (50 min), stand balance (20 min), and flexibility (20 min); weeks 5 to 8: high-low impact aerobic (50 min), muscle strength and coordination training (20 min), chair yoga (40 min); weeks 9 to 12: high-low impact aerobic added agility and interval running training (50 min), combined with cognitive function and memory training (30 minutes), chair yoga (30 minutes). The evaluation method of this study adopts the post-event movement observation based on recording video, and three observation time points (the first week, the sixth week, and the 12th week) were used to evaluate and analyze the movement ability Four perspective of cardiorespiratory, resistance, flexibility and balance divided into 21 indicators were scored.

RESULTS AND DISCUSSION

Analysis of the movement ability in the three periods showed that all the indicators in the 6th week were significantly better than the 1st week; all the indicators in the 12th week were significantly better than the 1st and 6th weeks (p<0.001), and all indicators had the greatest effect (3.18~5.18). (Table 1) only lists the index results with effect size >4. **Important findings:** (1) Immediately hear the rhythm and respond to the action, (2) Being able to correct themself when there is a wrong rhythm, (3) Capable of memorizing the action to achieve the ability of the action combination, (4) After coordination and agility training, flexibility and dynamic balance ability were improved. This gradual and diversified guidance to safely and effectively enhance the physical activity ability of seniors, could be an appropriate method.

CONCLUSIONS

This study demonstrates that the physical function and cognitive function of the participants could be improved through progressive energy enhancement, Keeping up with the rhythm of the music as a whole, combining high and low impact, forward and backward and sideways movement, and dynamic and static balance control, intermittent intensity are the keys to improve heart rate and agility performance, and flexibility. A documentary is attached to this study for future relevant professionals to serve as a reference for the guidance of senior sports.

INTRODUCTION

An appropriate vertical center of mass (CoM) displacement during walking allows efficient mechanical energy exchange and reduces the amount of mechanical work demands. However, older adults tend to have flatter and smaller vertical CoM displacements than younger adults. Knee and ankle dynamic joint stiffness, which is defined as the change in joint moment divided by the change in joint angle [2], are important for providing body support while preventing excessive downward CoM motion [1]. However, little is known about the age-related changes in knee and ankle DJS during walking. Thus, the aim of this study was to investigate the differences in vertical CoM displacement and knee and ankle DJS between the young and the older adults.

METHODS

We used a public dataset from the National Institute of Advanced Industrial Science and Technology Gait Database 2019 [3]. From the Gait Database, 107 healthy young adults aged 20 to 39 years old (44 men and 63 women) and 129 healthy older adults aged 65 years or older (69 men and 60 women) were used for the analysis. The marker trajectories and ground reaction forces were collected using 15 infrared cameras and six force plates. Then, inverse kinematics and kinetics were analysed by a house development software 'DhaibaWorks'. The vertical CoM displacement during early to mid-stance was calculated, and normalized subject's body height (%BH). Knee and ankle DJS were expressed by the linear regression slope of the flexion-extension moment vs. flexion-extension angle during the power absorption phase. Analysis of covariance was performed to compare the CoM displacement and the DJS of the knee and ankle between the young and the older adults using walking speed and gender as covariates.

RESULTS AND DISCUSSION

Our results showed that older adults had significantly smaller knee DJS and vertical CoM displacement (Figure 1). In contrast, there was no difference in ankle DJS between the young and the older adults (Figure 1). Knee joint in early stance to mid-stance plays a role in elevating CoM. However, older adults may be unable to shift their CoM upward in this phase due to small knee DJS. On the other hand, ankle DJS did not appear to be an age-related change.

CONCLUSIONS

Our study indicates that older adults have a small knee DJS with a flat CoM displacement during walking. Our findings suggest that interventions to increase knee DJS in the early stance are necessary to improve vertical CoM displacement in older adults.

INTRODUCTION

Many patients with knee osteoarthritis walk with their knees flexed greatly. Physical therapists may employ verbal commands to extend the patient’s knee in some cases. The verbal instruction seemed to be effective as the patient's knee was extended. Although the knee is extended, ankle and hip may lead to an unexpected change in motion. Because the knee joint is formed by the thigh and shank, change in knee joint motion is always accompanied by changes in either or both hip and ankle joint motion. The thigh and shank tilt directly affect the hip and ankle angle, respectively. Based on this concept of multi-joint kinematics, similar changes can be observed by instructing hip extension. Verbal movement instructions are commonly used in clinical practice; however, there are few reports on their effectiveness.

It has been reported that when walking on a split-belt treadmill at different walking speeds, the knee at the side of the slower speed flexes in the early stance phase [1]. Therefore, this study examined how lower limb joint motion was changed by the verbal instructions of “knee extension” and “hip extension” during knee-flexed gait using a split-belt treadmill.

METHODS

The subjects were twenty three healthy young adults (mean age:20.5 years). This study was approved by the Research Ethics Committee of the University. Eighteen reflex markers were attached to the subjects according to the plug-in-gait lower limb model. The VICON motion analysis system was used to measure three-dimensional motion data. The subjects walked on a split-belt treadmill with two ground floor reaction forces (Kistler). Initially, walking at 1.0 km/h for both sides was measured (normal gait: NG), and subsequently, speed was increased to 1.5 km/h only on the left side (baseline split-belt gait: BS). Next, the participants were instructed verbally to extend their right knee after heel contact (knee extension gait: KE) and to extend their right hip after heel contact (hip extension gait: HE), in random order.

The joint angles and body joint moments normalized by body weight (BW) were calculated. One-way ANOVA and multiple comparisons (Bonfferoni) were used to compare the peak values at each gait phase for the three conditions BS, KE, and HE.

RESULTS AND DISCUSSION

Peak knee flexion at the early stance was 15.0° in the NG and 19.9° in the BS, simulating the flexed knee gait on the split treadmill. Peak knee flexion was 11.7° in KE and 15.5° in HE, with significant differences among all three conditions (BS, KE, and HE). As expected, the knee was extended by both verbal instructions. Peak ankle dorsiflexion and hip extension in the late stance showed significant differences among the three conditions. These results indicate that hip extension instruction facilitated more hip extension in the late stance phase than knee extension instruction, while strongly limiting ankle dorsiflexion.

Knee extension moment showed significant differences among all three conditions (SG:8.6 Nm/BW, HE:5.7 Nm/BW, KE:7.3 Nm/BW). The knee extension moment decreases when the knee is extended.

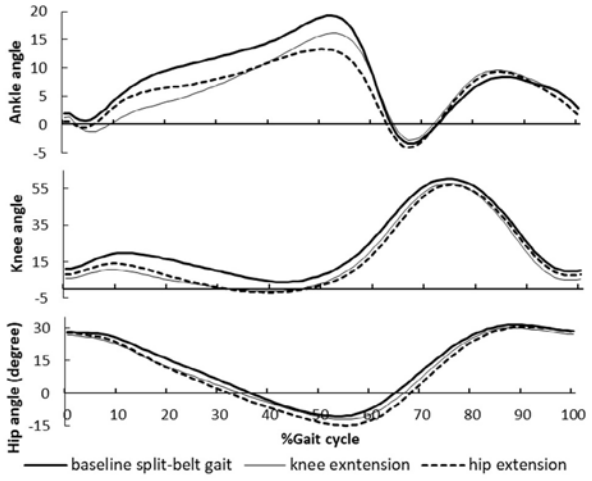

Figure 1 Joint Angle in 3 gait conditions.

CONCLUSIONS

Appropriate verbal instruction differs depending on whether the aim is to encourage more hip extension or maintain ankle dorsiflexion as much as possible.

INTRODUCTION

Loss of motoneurons with aging is associated with decreased muscle fiber number and size and leads to reduced muscle function (MF). MF is a comprehensive measure of muscle strength, power, and fatigue and can be assessed for decreased gait ability, which contributes to decreased physical performance as well as sarcopenia. However, few studies have investigated the association between MF and gait variables, and it is limited to preferred speed gait test. Therefore, it is necessary to examine the association between MF with gait ability at continuous and various speeds using inertial sensors in older women over 75 years.

METHODS

The participants of this study were 144 older women aged≥75 years. MF measure was performed five times sit-to-stand test. The gait test was performed at three speeds by modifying the preferred walking speed (PWS; slower walking speed [SWS, 80% of PWS]; faster-walking speed [FWS, 120% of PWS]) on a straight 19 m-overground walkway. Multicollinearity was used to select gait variables related to muscle function, and linear regression analysis was performed to identify the MF that explains the decrease in gait ability. Furthermore, gait variables were classified into quantile, and binary logistic regression analysis was performed to determine the classification between groups 1 (first quantile) and 3 (third quantile), according to MF. To investigate the classification accuracy of groups 1 and 3, areas under the curve (AUCs), sensitivity, specificity, and cut-off values were calculated using receiver operating characteristic curve analysis.

RESULTS AND DISCUSSION

MF was significantly associated with step length at SWS (R^2=0.266) and FWS (R^2=0.298), single support phase at PWS (R^2=0.196) and FWS (R^2=0.245), total steps at PWS (R^2=0.145), and stance phase at PWS (R^2=0.242) and FWS (R^2=0.269). As binary logistic regression of groups 1 and 3, MF of group 3 exhibited 2.8 times in step length at SWS (R_N^2: 0.459; AUC: 0.758), 3.5 times in step length at FWS (R_N^2: 0.432; AUC: 0.794), 2.8 times in single support phase at PWS (R_N^2: 0.441; AUC: 0.713), and 2.8 times in single support phase at FWS (R_N^2: 0.343; AUC: 0.746), which was greater than group 1 (Figure 1). In previous studies, changes in step parameters in older adults were associated with impaired balance and compensation for lower limb muscle weakness during gait, leading to shorter single support and longer stance phases to maintain dynamic stability[1]. Furthermore, it is suggested that older women with reduced MF are challenged to maintain symmetry to secure dynamic stability when gaiting under objective and various speed conditions[2].

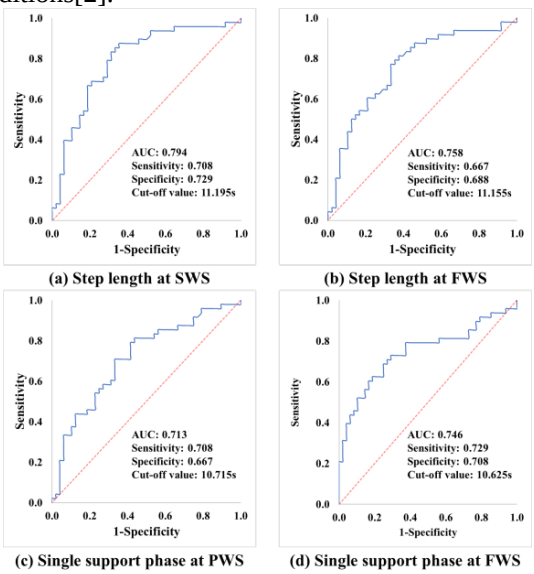

Figure 1. Receiver operating characteristic (ROC) curves for classification between groups 1 and 3

CONCLUSIONS

Our study indicated that a decrease in MF is associated with a decrease in gait ability, and MF in older women over 75 years may predict a reduction in step length at SWS and FWS and single support phase at PWS and FWS. Therefore, we suggest that MF is useful for evaluating gait tasks under continuous and various speed conditions, which are essential for the daily life activities of older women and assessing health status.

GENDER DIFFERENCES IN TRUNK AND LOWER EXTREMITY KINEMATICS DURING HURDLE STEP AND SQUAT LIFTING

Ganbat Danaa[1], Batlkham Dambadarjaa[2], Tserenchimed Purevsuren[1], Munkh-Erdene Bayartai[2] and Batbayar Khuyagbaatar[1]
[1]Department of Technical Mechanics, Mongolian University of Science and Technology, Ulaanbaatar, Mongolia

INTRODUCTION

Movement pattern differences exist between sexes and influence the rates of musculoskeletal injuries as well as treatment and rehabilitation strategies [1]. The deficiencies in the trunk and lower extremity movement can be examined by functional tasks, where squatting is the most commonly used while the hurdle step (HS) movement provides unique contrast relative to the squat because it tests bilateral functionality [2]. However, there are few studies have investigated gender differences during functional activities. In this study, we compared the trunk and lower extremity kinematics between males and females during the squat lifting (SL) and HS movements.

METHODS

Thirty-six healthy Mongolian adults (14 males, age 23.7±6.4 years, height 168.8±6.0 cm, weight 62.7±11.1 kg, and 22 females, age 25.1±8.6 years, height 160.3±7.1 cm, weight; 58.1±9.4 kg) were recruited. The Xsens wearable motion capture system (MVN, Xsens technologies, Netherlands) was used to record full body movements during the HS and SL at 120 Hz. Participants completed 3 repetitions of the HS, followed by 3 repetitions of the SL. The trunk and right lower extremity joint angles in the sagittal plane were calculated, normalized, and averaged for male and female groups. The trunk joint angle was calculated using a relative orientation between the pelvis and thorax segments. An independent sample t-test was used to compare the mean values of joint angles between the groups.

RESULTS AND DISCUSSION

The trunk, hip, knee, and ankle joint angles were compared between males and females during HS and SL (Figure 1). The hip, knee, and ankle flexions were similar, while the trunk flexion was significantly different between the males (4.9±7.7° in HS; 10.2±16.7° in SL) and females (2.3±5.1° in HS; 2.4±11.3° in SL) regardless of functional tasks ($p<0.001$). It was similar to previous studies, where they reported that trunk motion was significantly larger for men during the lifting movements [3]. The current results showed that gender differences in trunk mobility and men tend to bend more forward during both HS and SL.

CONCLUSIONS

The results demonstrated the gender difference in the trunk and lower extremity kinematics between males and females during HS and SL. A significant difference was observed for trunk flexion between males and females but no differences for hip, knee, and ankle joint angles during functional tasks. Therefore, different trunk kinematics between males and females should be considered during clinical examination and functional activities.

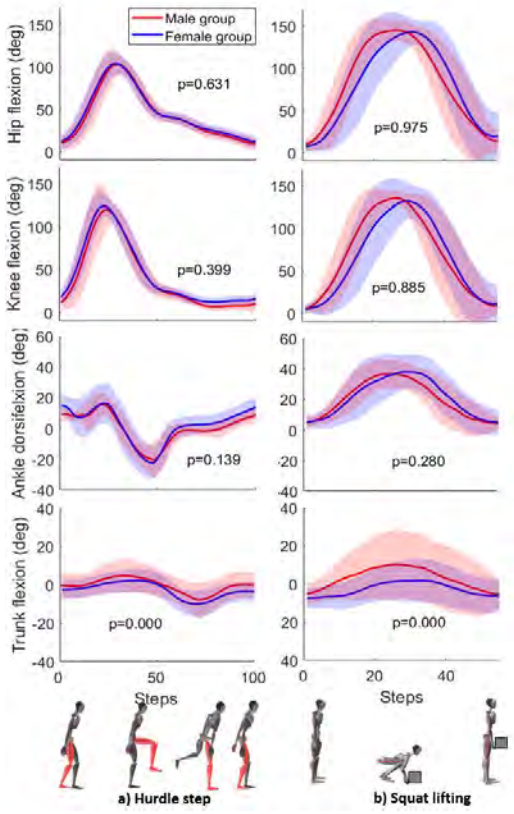

Figure 1 Hip, knee, ankle, and trunk flexion during HS and SL.

Effect of lower limb joints pain on toe area of foot pressure during walking in the elderly

Kazuya Imaizumi[1], Yumi Iwakami[1]
[1] Tokyo Healthcare University, Tokyo, Japan.
Email: k-imaizumi@thcu.ac.jp

INTRODUCTION

Gait is one of the most basic physical movements for human. Declining gait function impacts not only to various physical functions but also activities of daily living and quality of life for the elderly. In our previous study, we developed an evaluation method for toe function based on the plantar pressure distribution while walking and revealed the relationship between age-related decline and gait parameters [1]. In this study, we will examine the relationship between lower extremity pain and the plantar pressure parameter, which is thought to be related to the decline in gait function.

METHODS

Plantar pressure data were obtained from 33 female and 10 male adults more than 65 years who reported having no difficulty walking without support in Japan. Experimental setup and data analysis were conducted according to the previous study [1]. Toe Are Ratio (TAR) was calculated as the quotient of the toe area divided by the whole foot area. General gait parameters were also obtained using the attached software.

Participants were asked to respond to pain on a scale of none, mild pain, moderate pain, and severe pain in low back, knee, and foot.

Correlation analysis was conducted to evaluate the relationship between the plantar pressure parameter and various gait parameters. Ordinal logistic regression analysis was also used with the objective variable as pain in each part. A probability level of 0.05 was considered to indicate statistical significance.

RESULTS AND DISCUSSION

For 43 elderlies, 46.5% had pain in low back, 55.8% had in knee, 20.9% have in foot (Table 1).

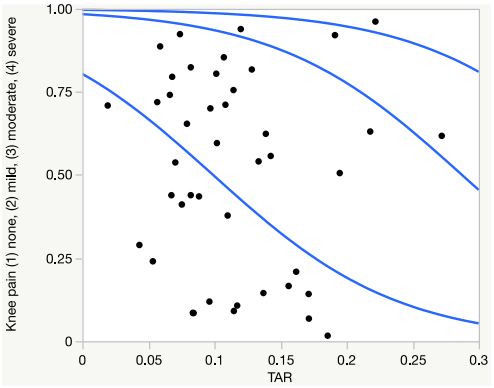
The results of correlation analysis indicate that the TAR had moderate positive correlations with walking speed (r=0.411, p=0.0069) and weak positive correlations with step length (r=0.334, p=0.0029) and stride time (r=0.336, p=0.027).

Figure 1 shows the logistic regression plots of pain in low back and knee. The results of the logistic regression had significant effect on the degree of knee pain (p=0.0189), and back pain (p=0.007).

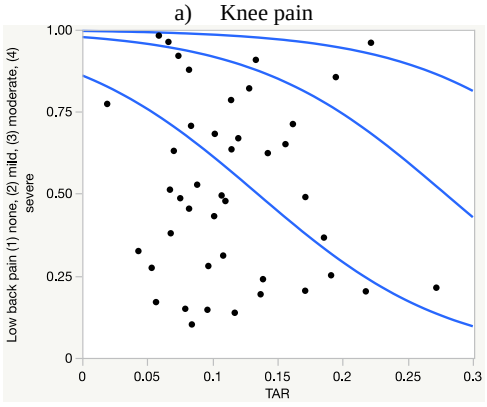
As a consideration, the TAR was correlated with three gait parameters which reflect age-related decline in gait function. Furthermore, the TAR may be affected by changes in gait due to lower extremity pain. On the other hand, as no significant effect on the TAR was observed for foot pain, so further investigation is needed.

Table 1: Number of participants with back, knee, and foot pain

	Low Back	*Knee*	*Foot*
Pain	**Number (%)**	**Number (%)**	**Number (%)**
No	24 (54.5%)	20 (54.5%)	33 (75.0%)
Light	15 (34.1%)	19 (34.1%)	7 (15.9%)
Moderate	4 (9.1%)	4 (9.1%)	1 (2.3%)
Severe	1 (2.3%)	1 (2.3%)	1 (2.3%)



a) Knee pain



b) Low back pain

Figure 1 Logistic regression plots of TAR and pain in low back and knee.

CONCLUSION

The toe ratio parameter may be useful in assessing the impact of pain on gait in older adults with reduced gait function.

Effect of light touch on inappropriate mediolateral foot placement

Toyoda Y[1], Iwamoto Y[1,2], Ishii Y[1,2], Mizutani M[1], Ono I[1], Takahashi M[1,2]
[1] Department of Biomechanics, Graduate School of Biomedical and Health Sciences, Hiroshima University / Hiroshima, Japan.

INTRODUCTION

Stable gait requires an estimation of the kinematic state of the body centre of mass (CoM) and a corresponding control of the mediolateral (ML) foot placement. Proprioceptive information derived from the hip abductor muscles (HA) of the stance leg contributes to the estimation of the CoM state. Perturbing proprioception from the hip abductor muscles due to muscle vibration can lead to misidentification of CoM, resulting in inappropriate foot placement [1]. Light touch may be beneficial for inappropriate foot placement that occurs in this way. Light touch adds somatosensory information, which may improve the accuracy of CoM estimation and correct for the foot placement. In this study, we investigated whether light touch is effective against inappropriate foot placement caused by perturbing proprioception from the HA.

METHODS

Eight healthy young adults volunteered to participate in this experiment. Participants walked on treadmill with comfortable speed. They walked under 4 conditions: normal gait (N), vibration gait (V), light touch gait (LT), and vibration gait with light touch (VLT). In V and VLT, vibration was applied to the left HA during the left stance phase, which was intended to perturb proprioception from the HA. To quantify the dynamics on the frontal plane during walking, the foot placement, the CoM displacement and the margin of stability (MOS) were calculated. In the two conditions with vibration, the right heel contact after the vibratory stimulation was defined vibration step and before the vibratory stimulation was defined non-vibration step. The difference of each parameter of the non-vibration step with vibration step was calculated. For all parameters, the Shapiro-Wilk test was used to check for normality of the data. As normality was observed for all parameters, paired t-test was used. Sequential Bonferroni correction coefficients were used to adjust alpha levels for multiple comparisons. The significant level was set at 5%.

RESULTS AND DISCUSSION

In V, the vibration step was placed more medially than non-vibration step (Figure 1), but the displacement of CoM was not altered (Table1). This caused reduced the MOS (Table 1). In VLT, there was no significant defeference in dynamics on the frontal plane (CoM displacement, foot placement, MOS) compared vibration step to non-vibration step (Figure 1, Table 1). Thus, the HA vibration caused an illusory shift of CoM and foot was placed more medially [2], but the ML foot placement was modified by light touch. This suggests that by obtaining information about their position in the external environment through light touch [3], which corrects the error in displacement of CoM recognition caused by the HA vibration and the foot was properly placed.

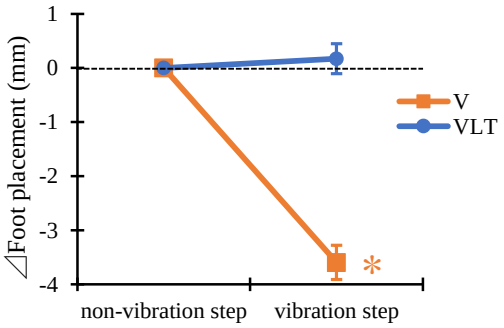

Figure 1 Effect of vibration on foot placement. The asterisk (*) indicates significance ($p < 0.05$).

CONCLUSIONS

We found that light touch can correct inappropriate foot placement caused by perturbing proprioception from the HA. Light touch may be a effective approach for in individual with walking balance deficits.

CLASSIFICATION OF YOUNG ADULT MOTOR FLUCTUATION PHENOTYPES IN GAIT

Christopher A. Bailey[1], Alexandre Mir-Orefice[1], Julie Nantel[1] and Ryan B. Graham[1]
[1] School of Human Kinetics, University of Ottawa, Ottawa, Canada.
Email: cbailey2@uottawa.ca

INTRODUCTION

Stride-to-stride motor fluctuations (i.e. motor variability) are natural in human gait. Excess or insufficient fluctuations in gait are well-linked to fall risk, yet, even healthy young adults show high inter-individual variability in motor fluctuations [1]. In materials handling tasks, the inter-individual variability can be explained by different motor phenotypes (i.e., low fluctuation "repeaters" and high fluctuation "replacers") with trait-like similarity over time [2,3]. This suggests that similar motor fluctuation phenotypes could exist in gait, although this remains untested. The purpose of this study was to determine if gait motor fluctuation phenotypes exist in young adults.

METHODS

Young adults (N = 51, 27 females) completed seven-minutes of constant-speed treadmill gait at their preferred speed. Marker-based inverse kinematics during 200 consecutive right-leg strides were computed in OpenSim 4.2 using a full body model [4]. Three motor fluctuation features were quantified from 32 degrees of freedom (3D angles of the lower and upper limb joints, trunk, pelvis): (i) magnitude of variability (mean standard deviation [meanSD]); (ii) local dynamic stability (local divergence exponent [λ_{max}]); (iii) regularity (sample entropy [SaEn]). Principal components (PCs) of features were computed by principal components analysis. PCs were interpreted by the loading vectors, then input into machine learning-based clustering using the k-means method for 5000 iterations to test cluster sizes of 1 to 15. The optimal number of clusters across iterations was selected by the number that was the most common elbow in the k-means inertia curve. Cluster differences in PC scores were analyzed using one-way ANOVAs.

RESULTS AND DISCUSSION

Two PCs explained 32.3% of variance in the 96 motor fluctuation inputs. Higher PC1 score was interpreted as more fluctuation across all joints (e.g. significant positive loadings showing higher meanSD of hip and wrist flexion) and higher PC2 score as more fluctuation of upper limb joints with less fluctuation of lower limb joints (e.g. significant positive loading showing higher wrist flexion meanSD and significant negative loading showing lower hip flexion meanSD). Using the k-means method, PC scores were optimally partitioned into 4 clusters for 98.4% of iterations (Figure 1). Table 1 shows that clusters differed by PC1 score ($p < 0.001$; Cluster 1 < Cluster 2 < Cluster 3 < Cluster 4) and PC2 score ($p < 0.001$; Clusters 1,2,4 < Cluster 3). Unlike in materials handling [2,3], 4 motor fluctuation phenotypes characterized gait. We interpret these as “full-body repeaters” (Cluster 1), “full-body replacers” (Cluster 4), “moderates” (Cluster 2), and “upper limb replacers, lower limb repeaters” (Cluster 3).

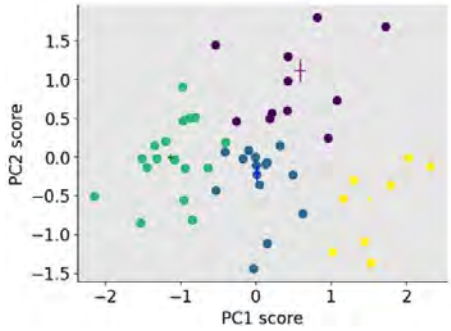

Figure 1: Clusters (k = 4) identified by the k-means method. Cluster centroids and standard deviations (+) are shown.

CONCLUSIONS

Young healthy adults can be classified into four distinct motor fluctuation phenotypes during treadmill gait at preferred speed. Further work is needed to see how these extend to other populations and locomotor tasks, and whether phenotype can help better assess fall risk.

VERY SHORT BOUT DURATIONS DECREASE THE EFFICIENCY OF WALKING UP STAIRS

INTRODUCTION

The metabolic demands of locomotion are generally examined at steady-state conditions, which last several minutes; however, in everyday life, people mostly walk for shorter bouts [1]. Previous research hinted that shorter bouts of walking up stairs may have a lower ratio of mechanical to metabolic power, also known as locomotor (apparent) efficiency, compared to longer ones [2]. As mechanical power in stair climbing is primarily done to raise and accelerate the body center of mass [2], this is a suitable model for studying the efficiency of short bouts of walking while minimizing the bias due to elastic storage, negative power, and internal power. The aim of the present study was to examine how an extensive combination of standardized bout durations and power outputs impacted locomotor efficiency.

METHODS

Mechanical power. Three participants (1 female; age 27±5 years; mass 73±12 kg; mean±SD) walked on a Technogym Climb Excite escalator at incline 78% and diagonal speeds of 0.20, 0.25 and 0.36 m/s while an eight-camera Vicon system recorded the position of 18 bilateral markers. Total mechanical power (P_{mech}; W kg^{-1}) was calculated by summing the power to raise and accelerate the body center of mass and the power to swing limbs [3].

Metabolic power and efficiency. Eight participants (4 female; age 26±5 years; mass 72±14 kg) walked on the escalator at the same speeds for 10, 30, 60, 90, and 240 second bouts in randomized order. Oxygen consumption ($\dot{V}O_2$; mL min^{-1} kg^{-1}) was measured by a Cosmed K5 metabograph. The oxygen volume consumed for each bout ($VO2_{integ}$; mL kg^{-1}) was calculated by integrating net (above resting) $\dot{V}O_2$ over time, from bout start to the end of a 7-min recovery. Average net metabolic power ($P_{met;}$ W kg^{-1}) was then calculated as $VO2_{integ}$ divided by bout duration and multiplied by the energy equivalent of oxygen in aerobic respiration. Locomotor efficiency was then given by P_{mech} / P_{met} and regressed over bout duration with a linear mixed model.

RESULTS AND DISCUSSION

At all speeds, the positive mechanical power to raise and accelerate the body center of mass was more than 95% of P_{mech}; bout duration correlated negatively with P_{met}, and hence positively with efficiency (Table 1, Figure 1). The efficiencies were in line with previous research on walking up stairs [2] and in the range of those of isolated concentric muscular contractions.

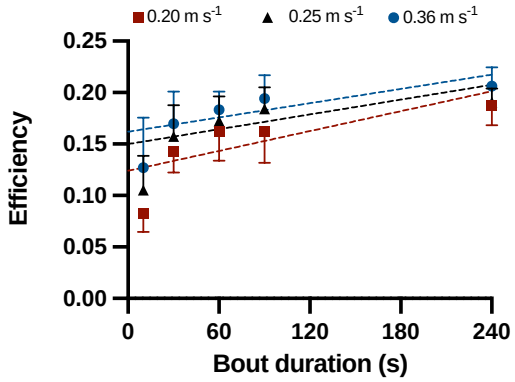

Figure 1 Efficiency versus bout duration and speed (mean±SD). Dashed lines: fixed effects from linear mixed model.

CONCLUSIONS

Short bouts of uphill stair walking are less efficient than longer ones, as they require a higher average metabolic power to produce the same mechanical power. Changes in the metabolic O_2 equivalent at the onset of exercise, the constant amount of energy consumed during the cardiodynamic phase of $\dot{V}O_2$ on-kinetics, and the relatively higher 'weight' of increased system entropy could have a role in these findings.

INTRODUCTION

Research on power output in running is limited. Unlike in cycling, there are no machines to which force is applied, making it difficult to measure power output. Existing portable devices estimate mechanical power output in running as a function of a runner's anthropometry, temporal-spatial parameters, and/or wind speed [1]. Our overall goal is to determine the mechanical power during running based on kinetic data. As a first step, we have performed long-duration measurements and uploaded them as a freely available dataset that allow us and the scientific community to estimate ground reaction forces based on plantar pressure. In this abstract, we present the experiments performed and give a brief overview of normalised individual runners' ground reaction forces and their temporal parameters.

METHODS

The study was approved by the Institute's Ethics Committee (#101525731). Seventeen persons (age: 29 ± 7 y, height 179 ± 9 cm, body weight 75 ± 13 kg) participated in the study. Data were collected simultaneously using a two-belt treadmill with integrated force plates (1000 Hz) and two pressure insoles with eight pressure sensors each (100 Hz). The experiment included three runs with a total duration of 40 minutes for each participant. The runs included two-minute warm-up and cool-down periods at a speed of 3 km·h^{-1}, three-minute running intervals at speeds of 4 km·h^{-1}, 6 km·h^{-1}, 9 km·h^{-1}, and 12 km·h^{-1}, and one-minute rest periods. Ground reaction forces were filtered using a 4th order zero-lag Butterworth filter with a cut-off frequency of 10 Hz and 30 Hz for the anterior-posterior forces and vertical forces, respectively. Only steps without a foot strike across the two force plates were selected for further analysis. Gait events were determined from the vertical force signals, with a force threshold of 50 N. In this abstract, only the results for 9 km·h^{-1} and 12 km·h^{-1} are displayed.

RESULTS AND DISCUSSION

The ground reaction forces measured in more than 500 hours of running showed different patterns across participants and running speeds (Figure 1).

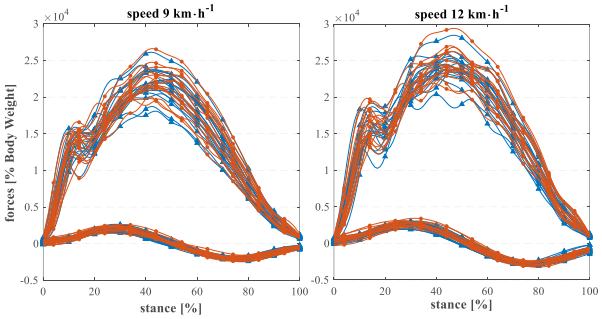

Figure 1 Left (blue '▲') and right (red 'o') mean values of normalised vertical and anterior-posterior ground reaction forces of participants (n = 17) running at speeds of 9 km·h^{-1} and 12 km·h^{-1}.

Participants completed a total of 31,874 steps at 9 km·h^{-1} and 11,572 steps at 12 km·h^{-1}. Due to cross-plate strikes, 47% and 61% of these steps were discarded, respectively. Table 1 summarizes the statistics for selected temporal parameters.

Table 1 Mean and standard deviation of the temporal parameters cadence, flight phase and stance phase across all valid steps.

	9 km·h^{-1}	12 km·h^{-1}
cadence (steps·min^{-1})	157 ± 9	166 ± 8
flight phase (ms)	89 ± 26	122 ± 18
stance phase (ms)	294 ± 31	240 ± 18

CONCLUSIONS

The data collected for this study is available as an open dataset at https://osf.io/kcqtf/ [2]. We are currently working on estimating ground reaction forces based on the measured plantar pressure. This will allow us in the future to determine the mechanical power during running based on the kinetic data.

HAS THE KNOWLEDGE OF BAREFOOT GAIT IN HEALTHY ADULTS CHANGED WITH TECHNOLOGICAL ADVANCEMENTS? – A SYSTEMATIC REVIEW

Alycia Fong Yan[1], Allan Chak Lun Fu[1], and Adrienne Hunt[1]
[1] Faculty of Medicine and Health, The University of Sydney, Sydney, Australia.
Email: alycia.fongyan@sydney.edu.au

INTRODUCTION

Despite the longevity and amount of research into human walking biomechanics, and technological advances in data acquisition, the current knowledge base used to teach gait analysis continues to refer to early theoretical work rather than drawing on original research. Since most published gait studies focus on a particular area of the body, outcome measures from a single study tend to be limited, and therefore tertiary educators seeking to use an evidence-based approach must source multiple individual studies to support the description of kinematics and kinetics across phases of gait and different joints in the body. Commensurate with advances in motion capture technology over the past 50 years, the conduct of research has become more rigorous, and so there now exists a vast and extensive pool of contemporary data from across the world that has the potential to enhance our understanding of healthy gait.The aim of this systematic review of human walking was to provide a thorough, evidence-based, and confident description of the kinematics and kinetics of healthy adult barefoot walking.

METHODS

A systematic search of the major databases from inception to June 2019 was conducted to collect all papers that investigated kinematics and/or kinetics of healthy, barefoot, human walking. Studies were included if they were a full original study investigating level, straight line walking. Participants needed to be healthy humans, aged 18-65 years, performing barefoot walking trials. Studies must have investigated kinematic and/or kinetic variables including angular displacement of all segments of the body, ground reaction forces (GRF), joint moments, and joint power in any of three planes. For inclusion in this review the data must have been presented in time series format or with respect to key time points in the gait (e.g., initial contact, foot flat, mid swing, terminal swing, heel off, toe off). Three independent reviewers screened the articles, analysed the quality, and extracted the data of the included papers. Due to the heterogeneity of the methodologies used and data presentation, a narrative synthesis was adopted. A rigorous quality assessment process was undertaken to ensure that the data were produced from valid and reliable measurements and provided an accurate and trustworthy representation of the results obtained. The process was based upon the JBI Critical Appraisal Checklist for Analytical Cross-Sectional Studies [1].

RESULTS AND DISCUSSION

161 papers met the inclusion/exclusion criteria. 26% were of sufficient quality to enable quantitative synthesis. The quality of studies included in this review was highly variable, with 12% of the eligible papers inaccessible to the reader due to unclear data presentation; data variability was reported in only 68% of the papers; and data normality was rarely described.
A clear consensus was reached for all characteristic sagittal plane movements of the hip, knee and ankle joints, the transverse plane of the pelvis and the hip joint, and the GRF in all three planes; however, it was challenging to determine the typical frontal and transverse plane movements for all other joints.
The authors could not draw any conclusions about the inter-relationships between the upper extremities and the head with other body parts during the gait cycle, or kinetics data in the frontal and transverse planes for all body regions, as no relevant studies were eligible for analysis.
The lack of clarity on the key events, such as stance and swing phase, made drawing fair and confident comparisons among studies, challenging. Lack of consensus in the frontal and transverse planes can be attributed to large variability, due to within or between participant differences, or as a result of different modelling selections, or a range of motion that crosses zero, since conflicting directions of the movement were reported. This was particularly evident for the foot and ankle.

CONCLUSIONS

Despite technological advancements in motion capture, healthy adult gait sagittal plane motion of the major joints and GRF are still the variables that can be described confidently. Improvement in the consistency of how gait analysis is conducted and reported may reduce the incongruency found in the frontal and transverse planes, and within the foot. This will enable future meta-analyses and multi-centre studies.

INTRODUCTION

The duty factor (*DF*) is defined as the fraction of the duration of a gait cycle for which each foot remains on the ground, and is inversely related to the peak ground reaction forces [1]. The difficulty of isolating *DF* from stride frequency (*SF*) during locomotion makes it hard to evaluate the impact of this parameter. An elegant experimental design suggested that reducing the *DF* maintaining the same average force and *SF* would imply the activation of more muscular fibres, with higher energy expenditure [2]. The asymmetries of unilateral skipping make an experimental model for decoupling *DF* from *SF* during locomotion, providing the basis to explore how muscles behave in these conditions. The aim of this work was to determine how *DF* changes alone, independently of *SF*, would affect the muscle activity, by analyzing the muscle activation patterns in the time-frequency domain during skipping gait at controlled speed.

METHODS

Fourteen volunteers (age: 25.3 ± 3.7 years, mass: 78.15 ± 13.8 kg, height: 1.76 ± 0.09 m) performed unilateral skipping at 9 km/h recording electromyographic activity (EMG) with a Delsys Trigno electromyograph at 2000 Hz on Biceps Femoris (BF), Vastus Medialis (VM), Tibialis Anterior (Tib), Soleus (Sol), Gastrocnemius Medialis (GasMed), Rectus Femoris (RF) and Gluteus Medius (GluM) of each leg. Also, the position of 18 markers located on the body was recorded at 100 Hz using 8 Vicon Bonita cameras to reconstruct an 11-segment body model. *DF* and *SF* was calculated by identifying the landing and takeoff times from the heel and fifth metatarsal markers. EMG signals were processed using a filter-bank generated from 11 Wavelets with center frequencies from 6.9 to 395.4 Hz to estimate EMG power (intensity) [3].

RESULTS

The *DF* in trailing leg was smaller than *DF* in leading leg (Table 1). In order to clarify the obtained results, Figure 1 shows an overview of the sum of the EMG intensity in one muscle per joint, at each of the four highest frequency bands (218, 271, 331 and 395 Hz). Wavelet analysis displayed greater intensity at high frequencies in GluMed of the trailing leg, while GasMed and RF showed the same activation patterns in both legs, despite the different *DF*.

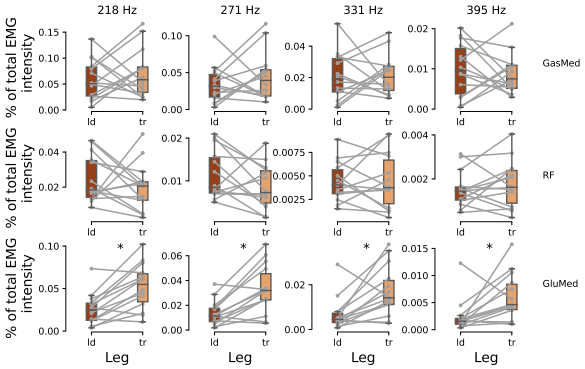

Figure 1: EMG intensity sum in frequency bands with center frequency of 218, 271, 331 and 395 Hz in leading leg (ld) and trailing leg (tr) during skipping. Asterisks (*) indicate significance at 0.05.

CONCLUSIONS

Changes in *DF* were related with greater intensity in high frequencies in GluMed, a muscle that execute high force during locomotion. Short *DF*s could trigger a switch to fast-twitch fiber recruitment in GluMed as strategy to perform high force development in short times during gait cycle. GasMed and RF maintained inaltered recruitment patterns despite the spatiotemporal constraint. This behaviour could be associated to gait selection or *SF* modification.

INTRODUCTION

Stable upright balance requires sensory and motor systems to effectively process stimuli from the surrounding environment and provide the corresponding downstream motor responses[1,2]. External perturbations can be applied to disturb the centre of mass (COM) and disrupt balance when the COM exceeds the base of support (BOS)[3]. External perturbations can be applied in the form of a physical or visual stimuli. To maintain stability, a reactive sequence of postural movements are required following physical perturbations while visual perturbations cause a perceived need to adjust balance.

The purpose of the present study was to evaluate the responses to visual and physical perturbations during quiet stance. It was hypothesized that standing balance will be more unstable in the anterior-posterior (AP) than mediolateral (ML) direction in response to physical and visual perturbations and perturbations in the AP direction will increase instability.

METHODS

The present study consisted of young adults (n=12; age = 18-40 years). All testing sessions took place in the FallsLab of the Toronto Rehabilitation Institute. The experiment used a 6m x 3m moveable platform, with four AMTI force plates, a 12-camera VICON motion tracking system, and the HTC Vive Pro Virtual Reality Head Mounted Display. The experiment consisted of 12 45-second quiet standing trials. There were five randomized conditions: no perturbations (None), AP visual shift (AP_VS) or ML visual shift (ML_VS), AP physical shift of the platform (AP_PS), and ML physical shift (ML_PS). Visual shifts of the virtual environment were applied at 2 m/s^2. Physical shifts of the physical platform were applied at 2 m/s^2. The perturbations were delivered at random times after 30 seconds of standing. Centre of Pressure (COP) path length was calculated by summing the Euclidean distance between successive data points over a 4 second analysis period starting at the onset of the perturbation.

RESULTS AND DISCUSSION

A Generalized Linear Mixed Model (GLMM) analysis was conducted on the length of the COP path length for the 12 healthy subjects (8F:4M, 24.6 +/- 1.1 years). Subject ID was considered as a random factor, and perturbation type (visual vs. physical) and perturbation direction (AP vs. ML) were examined as fixed factors. There was a significant effect of perturbation type ($p < 0.001$). Physical Perturbations in the ML and AP direction (19422.83cm +/- 11706.04cm; 4070.26cm+/-42455cm) induced larger COP path lengths compared to visual perturbations in the ML and AP direction (4396.7cm+/-5050.86cm;2793.40cm+/-2457cm). There was no significant effect of perturbation direction ($p=0.790$). ML direction did not produce significantly different COP Path Lengths compared to AP direction in physical ($p=0.419$) or visual ($p=0.256$) conditions. Mean Max COP excursions in the AP direction were analysed, and a significant effect of perturbation type was found ($p<0.001$). Physical perturbations resulted in larger COP excursions in the ML and AP perturbations (11.54cm+/-5.53cm;411.65cm+/-1770.9cm) when compared to ML and AP visual perturbations (2.25cm+/-1.34cm; 2.38cm+/- 2.12cm).

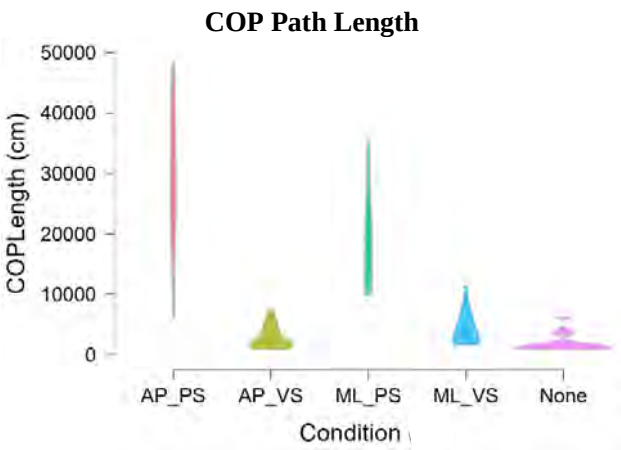

Figure 1. COP Path Length (cm) for all conditions for the 4 second analysis window. (AP_PS – Anterior Posterior Physical Shift, AP_VS – Anterior Posterior Visual Shift, ML_PS – Medio-lateral Physical Shift, ML_VS – Medio-lateral Visual Shift)

CONCLUSIONS

Physical perturbations resulted in larger COP path lengths compared to visual perturbations, and there was no significant difference between COP Path Lengths in the medio-lateral and anterior-posterior directions for each visual and physical perturbations. Physical perturbations also resulted in increased maximum COP excursion in the AP direction with greater effects observed in response to the physical perturbations.

INTRODUCTION

A fall is one of the main health problems in the elderly population, because it causes traumatic injury [1] and is associated with increased morbidity and mortality [2]. Compromised stability is considered a major fall risk factor for older adults. Since a dynamic stability in a biped model can be defined by a zero mement point method (ZMP), the stability analysis of human walking can be simplified with the ZMP method despite of its complexity. The aim of this study was to compare the effect of walking speed on the dynamic gait stability between the elderly and the young population using a ZMP method. It was hypothesized that increased walking speed in the elderly greater affects their giat stability than in the young.

METHODS

The subjects for the young (n= 24, a mean age of 22.2 ± 1.0 years, YG) and elderly group (n= 24, a mean age of 69.9 ± 1.0 years, EG) with no musculoskeletal disorders and fall experience were recruited for walking experiments. The experiments were approved by the Korea National Institute for Bioethics Policy Review Board. Each participant was monitored using a Helen Hayes full-body marker set. Each participant was asked to walk at a self-selected speed (SWS), 110 % of SWS and 120 % of SWS on 10 m flat ground. A three-dimensional motion capture system (Motion Analysis, USA) was used to record and analyze marker trajectories. Gait stability is defined by the percentage of ZMP values inside of base of support during one gait cycle. Results are shown as means ± standard error of the mean. Comparisons of ZMP values were conducted using a repeated measured ANOVA (SPSS 21.0, SPSS Inc.).

RESULTS AND DISCUSSION

An average SWS, 110 % and 120 % of SWS were 1.34 ± 0.06 m/s, 1.48 ± 0.07 m/s and 1.62 ± 0.07 m/s for the YG, and 1.19 ± 0.03 m/s, 1.31 ± 0.03 m/s and 1.44 ± 0.03 m/s for the EG, respectively. At 110% of SWS, the gait stabilities in the anterior-posterior (AP) direction were decreased by 2.1 % and 10.8 % for the EG and YG, respectively, and at 120% of SWS, those were decreased by 4.3 % and 3.9 % for the EG and YG, respectively. The gait stabilities at 110% of SWS in the medial-lateral (ML) direction were decreased by 9.0 % and 18.1 % for the EG and YG, respectively, and at 120% of SWS, those were decreased by 10.1 % and 8.3 % for the EG and YG, respectively. However, at the same walking speed of 1.34 m/s, there is a tendency of a greater decrease of gait stability in EG compared to YG (Figure 1).

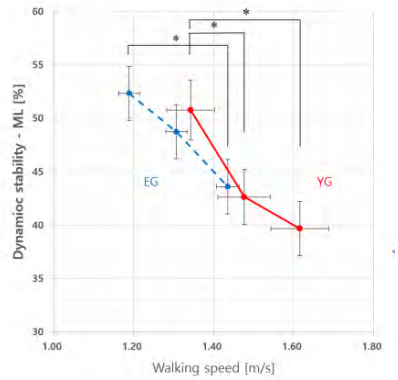

Figure 1. Gait stability in the ML direction at the different walking speed between young and elderly group. Data in the figure are shown as means ± standard error of the mean. (* p = 0.05).

CONCLUSIONS

Gait stability were similar in both the YG and EG at the SWS, but the pattern of change with increasing speed was greatly different. Namely, the gait stability gradually decreased through 120% SWS in the EG, but in the YG, the gait stability decrease rapidly at 110% of SWS and then the decrease rate reduced at 120 % SWS. Overall, it is anticipated that the gait stability of the YG is more affected by an increases of walking speed than that of the EG at the certain speed range.

INTRODUCTION

One of the functions of shoes is to improve postural stability and prevent injuries. Postural stability is affected by the mechanical properties of shoe midsole material. The trajectory of center of pressure (COP) is a parameter which evaluates dynamic balance control during gait. The "butterfly diagram" which depicts the COP trajectory during gait enables us to confirm visually the length and sway of COP, and step width [1,2]. The purpose of this study was to compare the postural stability during gait in different midsole materials and hardness by using the "butterfly diagram".

METHODS

Seven males (28.1±4.1 years, 1.72±0.05 m, 71.1±7.9 kg) who had no lower limb injuries participated in this study. The participants walked for 50 s at 4 km/h on a split-belt force-instrumented treadmill (Tec Gihan Co. Ltd, Uji, Japan, 1kHz) with two walking shoes conditions of different midsole and hardness. One was Softer midsole shoes （SS） with Ethylen-Vinyl Acetate (EVA) midsole and lower hardness. The other was Harder midsole shoes （HS) with Polyurethane (PU) midsole and higher hardness. Ground reaction force and COP coordinates during walking were collected by the force-instrumented treadmill. Butterfly diagram was produced using obtained COP coordinates (Figure 1). Displacements of anterior-posterior and lateral COP were calculated during single and double support stance phase. Step width was the difference of lateral COP coordinate between both legs.

RESULTS AND DISCUSSION

It is possible to compare the difference of COP displacement and step width between the shoe conditions visually. Lateral COP displacement of SS was significantly greater than of HS throughout the stance phase. On the other hand, there was no significant difference in lateral COP during the single support stance phase (Table 1). Therefore, HS may decrease the sway of lateral COP especially during the double support stance phase.

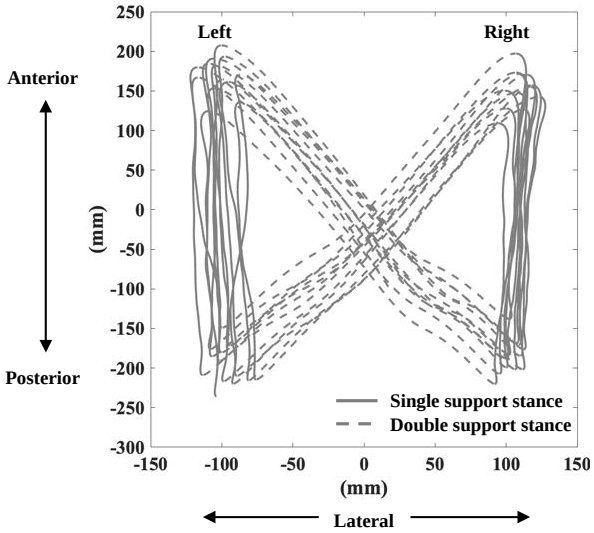

Figure 1: Typical result of the butterfly diagram.

CONCLUSIONS

Different midsole materials and hardness affects the COP displacement. Harder midsole made of PU decreases lateral COP displacement, which would provide more stability in walking.

INTRODUCTION

Use of augmented reality (AR) technology for rehabilitation has drastically increased in recent years. Evidence has shown that visual and auditory cues alter spatial and temporal gait parameters, respectively [1]. Through providing visual and auditory cues while walking, AR can be used to cue spatiotemporal gait adaptations with applications to clinical populations such as those with Parkinson's disease [2-4]. However, given the novelty of the technology it is unknown how cues delivered through AR drive gait adaptations. The purpose of this study is to assess the feasibility of visual and auditory cues delivered through AR on altering spatiotemporal gait outcomes in a healthy, young population.

METHODS

20 healthy participants (7 F/13 M; 25.5 + 4 yrs) were recruited to walk for 10 steps in four different cueing conditions using an AR headset: No Cues (NC) (i.e., natural gait), Visual (V), Auditory (A), and Visual + Auditory (VA). Each condition was completed three times in a random order for a total of 12 trials. An Inertial Measurement Unit (IMU) system with integrated footswitches was used to collect spatiotemporal gait data at 200 Hz. A System Usability Survey (SUS) was administered afterwards to determine the usability of our novel application and linear regressions were performed to determine the relationship between reported usability and gait variability.

RESULTS AND DISCUSSION

All cueing conditions exhibited a significantly faster cadence (V, A, VA = 0.67, 0.68, 0.68 steps/sec, respectively) compared to NC trials (0.63 steps/sec; p <0.05). Surprisingly, cadence variability was significantly higher for A trials (coefficient of variation (CV) = 0.11) compared to the other three groups (NC, V, AV = 0.1, 0.09. 0.09; p <0.05). V trials exhibited significantly decreased stride lengths (2.13 m) compared to NC (2.3 m; p < 0.05). Increased reported system usability was significantly correlated with decreased stance time across A trials (adj R^2 = 0.262, β = -0.549, p = 0.012).

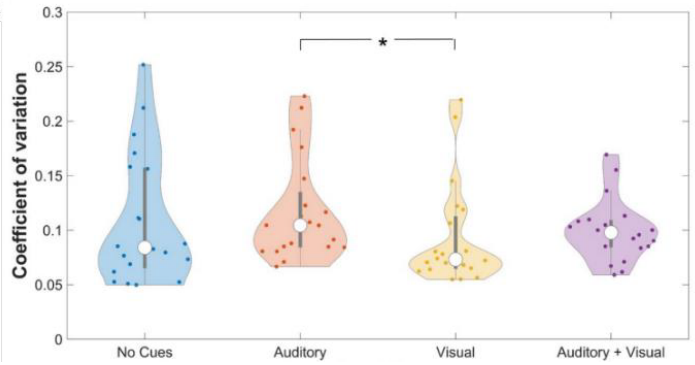

Figure 1 Violin plots demonstrating the mean and distribution of individual data points in each cueing condition for cadence variability.

CONCLUSIONS

Our findings reinforced that certain visual and auditory cues affect gait parameters, albeit in a direction opposite of what was hypothesized (e.g., greater cadence variability with auditory cues). These results provide insight into how healthy populations respond to cues delivered through AR, providing a foundation for future studies to implement AR with clinical populations such as those with Parkinson's disease.

EFFECTS OF ARTIFICIAL KNEE JOINT CONSTRAINT ON SHARED NEURAL DRIVE OF ANKLE PLANTAR FLEXORS DURING GAIT

INTRODUCTION

Synergistic muscles receive common descending drive from the CNS [1]. It is unknown how a joint range of motion constraint affects this shared neural drive between neighboring synergistic muscles. We aimed to investigate how an artificial knee joint constraint affects the shared neural drive of ankle plantar flexors during gait. As the gastrocnemius muscle (GAS) length depends on knee angle, we hypothesize that artificial knee constraint decreases the shared neural drive between GAS and soleus (SOL), which does not cross the knee joint.

METHODS

Fifteen healthy subjects walked overground at 1 m/s with an articulated knee brace limiting knee between 20° to 40° degrees (simulating a knee flexion contracture). Muscle activity of plantar flexors was collected through surface electromyography. Ten cycles corresponding to the middle 10 meters of a 30-meter corridor were used for data analysis (20 cycles in total). Shared neural drive was assessed using nonlinear method based on the ensemble empirical mode decomposition and instantaneous phase dependence of time series in bi-directional causality [2]. To estimate the intensity of shared neural drive, mutual predictability was assessed using approximate cross-entropy [3]. This method has been recently proposed to assess the synergistic action between pairs of synergistic muscles. [3].

RESULTS AND DISCUSSION

Artificial restriction of knee extension results in indicate that the direction of causality of shared neural drive is affected. ($p<0.05$) (Figure 1). Our results may be explained by potential changes in length-dependent and force-dependent feedback due to the restriction of knee extension during gait [4]. Our results agree with those of animal studies where the manipulation of muscle length and the connective tissue interface between neighboring muscles have been shown to change intermuscular coordination during locomotion [5].

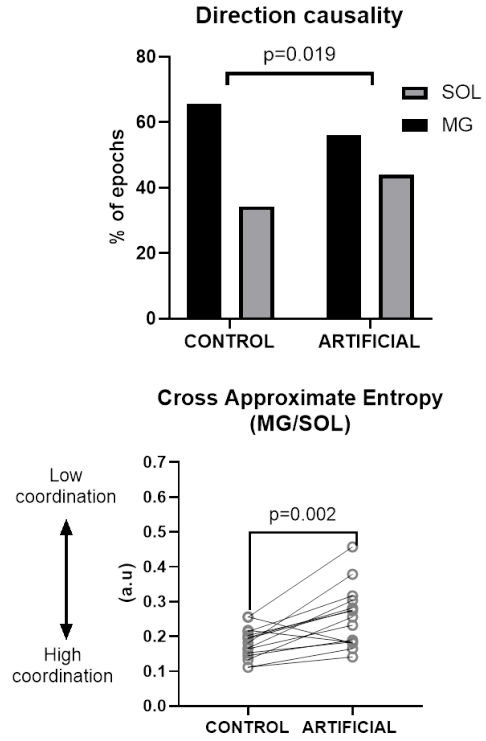

Figure 1. *Top. Direction of causality between medial gastrocnemius to soleus (MG) and Soleus to MG (SOL). Bottom. Mutual predictability between MG and SOl.*

CONCLUSIONS

The artificial restriction of knee extension changes the interaction from the gastrocnemius muscle to the soleus and their coordination. These results support the presence of excitatory length-dependent feedback from gastrocnemius to soleus during locomotion.

DETRENDED FLUCTUATION ANALYSIS OF RUNNING STRIDE TIME AT AND NEAR THE MAXIMAL LACTATE STEADY STATE

van Rassel, C.R. [1], Dimmick, H.L. [1], Ferber, R.[1], & MacInnis, M.J. [1]

INTRODUCTION

Fluctuations in running stride time (ST) may represent complex and rhythmic changes to the neuromuscular control of human gait [1]. Detrended fluctuation analysis (DFAα1) of ST has been used to quantify long range correlations (LRC) of the locomotor system. DFAα1 typically yields a scaling exponent between 0.5 and 1.0 and an alteration in ST-DFAα1 has been associated with acute fatigue, overreaching, and injury history [2]. Thus, ST-DFAα1 may provide utility as a running training metric. Maximal lactate steady state (MLSS), which represents the boundary between sustainable and unstustainable exercise, is commonly used to prescribe exercise intensity. Despite evidence that ST-DFAα1 may be altered during prolonged continuous exercise, it remains unknown whether similar fractal responses occur during constant-intensity exercise at/near the MLSS threshold. The purpose of this investigation was to determine the variation of ST-DFAα1 responses at and within 5% of MLSS and to determine the repeatability of ST-DFAα1 at MLSS.

METHODS

Sixteen (9M, 7F) recreational runners (mean [SD]; 30.1 [4.2] yrs, $\dot{V}O_{2max}$ 54.6 [6.3] ml·kg^{-1}·min^{-1}) performed an incremental exercise test and four, 30-min, constant-speed running trials at running speeds 5% below (B), at (M), and 5% above (A) MLSS, and a final repeat trial at MLSS (R). Participants were fitted with an inertial measurement unit (Blue Trident, Vicon, Oxford, UK; 1125 Hz, ±16 g) positioned between the posterior superior iliac spines, coincident with the inferior aspect of the iliac crest. Acceleration data were sectioned into three 8-min segments at the beginning (S1; 0.5-8.5min), middle (S2; 12.5-20.5min), and end (S3; 22-30min) of the 30-min running trials. Vertical axis acceleration data were low-band pass filtered before calculating ST as the sum time between consecutive peak accelerations. ST-DFAα1 was calculated for each 8-min section with window size 16 to N/9, where N is the number of STs within each respective segment. Differences in ST-DFAα1 across intensities and duration for the B, A, and M trials were examined using a linear mixed effects model (LMM), and repeatability of ST-DFAα1 at MLSS (R and M trials) was determined via LMM, intra-class correlation coefficients (ICCs) and Bland-Altman limits of agreement (LOA).

RESULTS AND DISCUSSION

Runners completed 30 min of running at B, M, and R, but not A (n=7) due to volitional exhaustion. 682 [35] strides were recorded per segment. There was no significant duration × intensity interaction effect ($p = 0.17$) or main effects for duration ($p = 0.66$) or intensity ($p = 0.76$) for ST-DFAα1 (Figure 1). On average ST-DFAα1 measures were lower during R compared to M trials, ICCs were moderate, and LOA were wide, suggesting that ST-DFAα1 measures between trials were not repeatable at MLSS (Table 1). As R was the final trial, it is possible that multiple bouts of prolonged treadmill running alter neuromuscular control of running gait, potentially indicating differences in fatigue or fitness, or the need for a "learning phase."

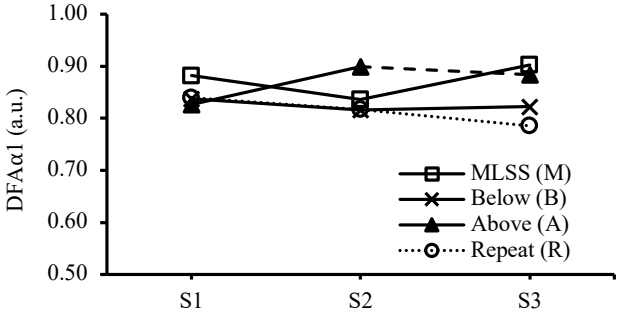

Figure 1 Mean ST-DFAα1 measures.

CONCLUSIONS

Although not significant, our preliminary analysis suggests that running intensities above MLSS may produce greater ST LRCs and that ST-DFAα1 measures between trials were not repeatable at MLSS.

INTRODUCTION

Foot strike patterns during running in long-distance runners have been typically classified into three patterns based on foot positionings in the sagittal plane and are related to their running performance [1]. In contrast, few studies have reported the usage trend of sagittal foot strike patterns in sprinters because most sprinters use the forefoot strike pattern [2]. To the best of our knowledge, no study has investigated the classification of forefoot strike patterns in sprinters. Utilizing the forefoot strike pattern classification may provide insight into understanding of how sprint performance differs among sprinters. Therefore, in this field study, we examined the usage trend of forefoot strike patterns based on foot positioning in the frontal plane during a 100-m sprint in male sprinters and then its associations with their 100-m sprint performance.

METHODS

Frontal video in 613 male sprinters who finished a 100-m sprint race were recorded from seven track and field events in the 2022 season using high-speed cameras placed behind the finish line. To ensure as much frontal video as possible, the video was acquired with one camera per sprinter. Of these, 417 male sprinters, who used the forefoot strike pattern and whose the corrected 100-m sprint time (see below) was less than 12.00 s, were included in the analyses of this study. The classification of the frontal forefoot strike pattern of the first leg stepping after the start was performed at a passage of 60 m (i.e., maximum speed phase) during a 100-m sprint. The frontal forefoot strike patterns were first classified into the non-inversion strike (NIVS) and inversion strike (IVS). NIVS was defined as a pattern in which the medial and lateral portions of the forefoot contacted with the ground almost simultaneously, whereas in IVS, the lateral edge of the forefoot contacted with the ground. Further, the NIVS pattern was subclassified into the flat strike (FS) and abduction strike (AS) and the IVS pattern was subcategorized into the inversion strike (IS) and abduction and inversion strike (AIS). FS was defined as a pattern in which the tip of the forefoot contacted the forward direction to the ground, whereas in AS, it contacted the outward direction to the ground. IS was defined as a pattern in which the lateral edge of the forefoot contacted the forward direction to the ground, whereas in AIS, it contacted the outward direction to the ground. To calculate the corrected 100-m sprint time for each sprinter, the official 100-m sprint time was corrected for the effect of wind speed using a windless conversion [3]. The Mann-Whitney U or Kruskal-Wallis test were used to compare the corrected 100-m sprint times between the different forefoot strike pattern groups.

RESULTS

The usage rates of NIVS and IVS patterns were 13.7 and 86.3%, respectively (Figure 1A). The corrected 100-m sprint time was significantly shorter in the NIVS group than in the IVS group (Figure 1B: $P = 0.002$). Additionally, the usage rates of four sub-patterns were the highest for the AIS (73.6%), followed by the IS (12.7%), AS (8.2%), and FS (5.5%). The corrected 100-m sprint time was significantly shorter in the FS and AS groups in the AIS group ($P < 0.05$). Furthermore, the corrected 100-m sprint time in the FS group was significantly shorter than that in the IS group ($P = 0.041$).

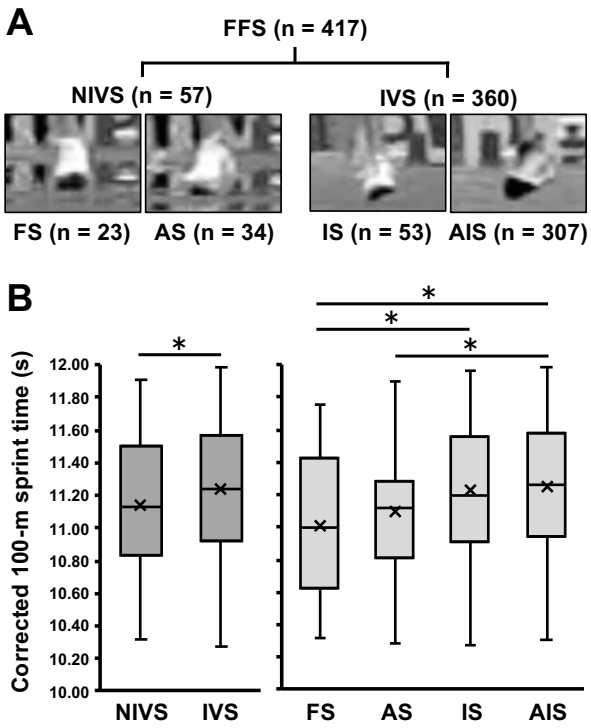

Figure 1. Frontal forefoot strike patterns and its associations with 100-m sprint performance in 417 male sprinters. A: classification and usage trends of forefoot strike patterns, B: comparisons of the corrected 100-m sprint time among the different forefoot strike pattern groups. *Significant difference ($P < 0.05$) between groups.

CONCLUSIONS

This study demonstrated that forefoot strike patterns based on the frontal plane can be classified into two or four patterns in male sprinters and may be related to their 100-m sprint performance. Therefore, these findings indicate that the frontal forefoot strike patterns may be an important biomechanical factor contributing to superior 100-m sprint performance in sprinters.

Can an Accelerometer Replace Lower Extremity Joint Moment upon Running?

Young-Seong Lee[1], JiSeon, Ryu[1], Sukhoon Yoon[1], Sang-Kyoon Park [1†]

INTRODUCTION

High impact occuridng from the ground upon running causes injuries to the lower extremities, and the relationship beteen the impact and injuries has been investigated through ground reaction force (GRF) and joint moment. Fore foot strike causes ankle injuries by increasing plantar flexion moment at the ankle joint in running and delivers high impact shock to the fore foot, therefore, it increases fracture rate of toes. Meanwhile, the rear foot stike increaes the knee joint's extension moment, and thus causes knee injuries and delivers high impact shock to the tibia, so it incresases the stress fracture rate of the tibia [1]. To investigate the impact characteristics, accelerometers are recently used. Very high correlations between the accelerometer attached to the tibia and the impact variables of vertical GRF was investigated, so the accelerometer is used as one of the impact variables[2]. However, research investigating relation-ship between the accelerometer attached to the lower extremity segmenaation and the joint moment is really insufficient. Accordingly, this research aims to examine relationships between joint moments and the peak accelerations on the tibia, thigh, and 5th lumbar (L5) during running.

METHODS

This research recruited 60 males in their 20s to 30s, and they conducted artificial fore foot strike and rear foot strike running. In doing so, they used a treadmill embedded with eight infrared cameras and GRF. Each accelerometer was attached to the distal tibia (8cm above the medial ankle), thigh (50% site from the greater trochanter of femur to the later epicondyle), and L5. The participants performed running on the treadmill through measurement of each participant's preferred velocity. They ran for 3 minutes depending on each strike pattern (RFS vs. FFS), and each participant's 20 steps were analyzed through one-minute video recording, respectively. Strike patterns were selected on the basis of the strike pattern scope proposed by previous researches, and the participants with improper strike patterns were excluded. The joint moment was computed through Visual 3D, and the 2nd lowpass filtering was carried out along with the accelerometer data (camera sf: 100Hz, GRF & Acc. sf: 1,000Hz). Correlation between the acceleration and joint moment were determined using the pearson correlation coefficient with a confidence level of $p < 0.05$.

RESULTS AND DISCUSSION

According to the research results, the plantar flexion moment of ankle joint showed a correlation with the vertical and resultant acceleration of the distal tibia upon rear foot strike (p<.05, table 1). The extension moment of hip joint revealed a correlation with the vertical and resultant acceleration of L5 upon fore foot strike and rear foot strike (p<.05, table 1). The result means that the accelerometer attached to the lower extremity segmentation affects the lower extremity joint moment during rear foot strike running. The reason why no correlation was revealed between the accelerometer attached to the thigh and knee joint moment is skin movement artifact. Therefore, it is judged that accelerometers need to be attached to the site close to bones, not skin, when attaching an accelerometer.

CONCLUSIONS

Our findings suggest that peak accelerations by using accelerometers are significantly correlated with joint moments at the ankle and hip joint during rear foot strike running. However, some consideration would be required when applying this approach to forefoot strike running due to weak correlation.

Foot medial longitudinal arch deformation and plantar load distribution pattern during running

Akira KIUCHI, Tomoya HIRANO, Natsumi FURUTA and Kazuo FUNATO
Graduate School of Sport System, Kokushikan University / Tokyo, Japan
Email: s1dd002x@kokushikan.ac.jp

INTRODUCTION

As one of the important foot functions, medial longitudinal arch (MLA) play spring-like action far braking and accelerating of movement. During the stance phase, MLA changes in response to load, absorbing shock at foot contact and generating propulsive force during push off phase [1]. The load applied to the foot during contact is called plantar load, and to date has been evaluated using a plantar pressure measurement plate. One of the problems in evaluating plantar load is how to divide the foot into sections and quantify the load at each plantar region. It is difficult to quantify and evaluate how much load is applied to any section of the foot, because the anthropometry of the foot differs from person to person.

To overcome this problem, automated and objective footprint masking based on anatomical structures of the foot was developed [2]. The running has a high incidence of foot-related injuries, and the evaluation of plantar load based on the foot anatomical structures and the shock absorption of MLA are considered to predict and prevent sports injuries. Therefore, the purpose of this study was to quantify changes in MLA and the plantar load distribution during running.

METHODS

Eight healthy male subjects participated in this study (Age 20.8±3.4 years; Height 174.2±4.7 cm; Mass 69.9±5.6 kg). Plantar pressure measurement plate (Novel GmbH®, 100Hz), motion capture system (Oxford, 100Hz) and force plate (Kistler, 1KHz) were synchronized. Using this system, subjects performed running trial at 2.78m/s. Plantar load distribution was divided into five sub-area based on anatomical measurement points [2]. MLA angle was calculated as the angle between the distal first metatarsal, navicular tuberosity and calcaneus, and first metatarsophalangeal joint (MTPJ) angle as the angle between the hallux, distal and proximal first metatarsal.

RESULTS AND DISCUSSION

Plantar loads were observed on the medial and lateral hindfoot and the lateral forefoot at foot contact, followed by the medial forefoot and the midfoot after 10% of the normalized time from foot contact to toe off (Fig. 1A). Lateral forefoot and total plantar loads showed maximum values at 40%, followed by a gradual decrease (Fig. 1A). The medial forefoot load tended to increase after 40%, reaching a maximum value at 50% and then gradually decreasing (Fig. 1A). The load shift from the lateral to medial forefoot observed in this study may be a function of the foot's ability to increase foot stiffness during push off (Fig. 1A). MLA angle showed the greatest amount of change around 40%, when the maximum load value was shown (Fig. 1A, B). At this point, a large load was applied to the forefoot, and MLA seems to play a role in absorbing the load to the foot (Fig. 1A, B). Hick's [3] windlass mechanism is that dorsiflexion of MTPJ tightens the plantar aponeurosis and, thereby, pulls the calcaneus and metatarsal heads towards each other and stiffens the foot. In this study, there was also a tendency for MLA angle to decrease with MTPJ dorsiflexion (Fig. 1B, C). In addition, ground reaction force (GRF) tended to increase in the anterior direction after 60%, when MTPJ was dorsiflexed (Fig. 1C, D). From these results, it is assumed to dorsiflexion of MTPJ increased the stiffness of the foot and forward propulsion.

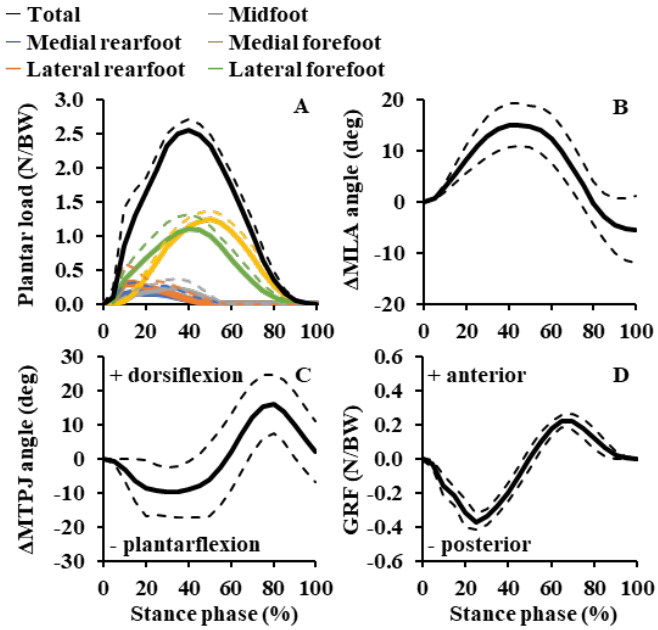

Figure 1 Temporal changes (A) 5 sub-area plantar loads distribution (B) MLA angle (C) GRF (D) MTPJ angle during running

CONCLUSIONS

MLA is a flexible structure that absorbs plantar load during foot contact, and it was assumed that the dorsiflexion of MTPJ during push off contributed to the increase in foot stiffness to support forward propulsion from the forefoot.

Biceps Femoris Shortens Actively during the Late Swing Phase of High-speed Running

Junhee Yoon[1,3], Hae-Dong Lee[2,3]
[1] Department of Physical Education Graduate School, Yonsei University / Seoul, Korea.

INTRODUCTION

Hamstring strain injury (HSI) commonly occurs in sports involving high-speed running [1]. HSI primarily happens in the late swing phase due to the hamstring muscle-tendon unit (MTU) reaching its maximum length [2]. Recent studies showed that accuracy in predicting muscle behavior through joint kinematics could not be guaranteed because of the interaction between muscle and elastic tendon within an MTU [3]. Thus, in the swing phase of high-speed running, the hamstring muscle behavior may act differently from the MTU behavior.

This study investigated the fascicle and MTU behavior and the activation of the biceps femoris long head (BFlh) during the swing phase of high-speed running.

METHODS

Nine recreationally active males (age 24 ± 1.7 years; height 178.7 ± 6.1 cm; weight 78.8 ± 6.3 kg) ran at 70, 80, and 90% of their maximum running speed on a treadmill. Kinematics of the hip and knee joints were collected during running. Muscle activation of BFlh was also recorded using surface electromyography (sEMG). The fascicle length of BFlh was monitored using a B-mode real-time ultrasound imaging system.

During the swing phase, one-way repeated measures ANOVA was performed to investigate the differences in the hip and knee joint angle, fascicle behavior, MTU behavior, and muscle activation of BFlh between each speed.

RESULTS AND DISCUSSION

The MTU length changes of the BFlh during the swing phase increased significantly as the speed increased ($p < .05$), from 70% to 80%. There was no significant difference in fascicle length change during the swing phase when the running speed increased. Unlike MTU behavior, the fascicle was actively lengthened with weak activation during the early to the middle swing phase but actively shortened with strong activation during the late swing phase.

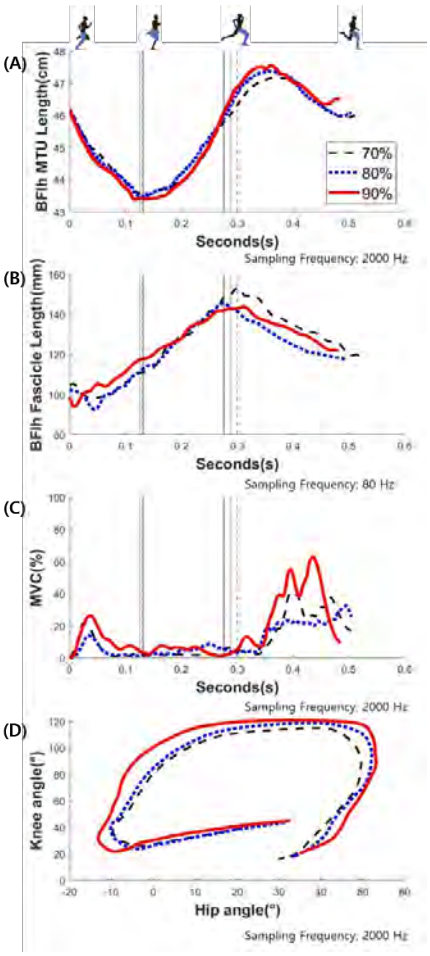

Figure 1 Sample raw data for a representative subject. (A) BFlh MTU behavior, (B) BFlh fascicle behavior, (C) BFlh muscle activation, and (D) hip angle to knee angle during the swing phase. Vertical lines represent the phase divisions 70% (broken line), 80% (dotted line), and 90% (solid line).

CONCLUSIONS

In this study, the BFlh fascicle actively shortens during the late swing phase. Also, during the swing phase, fascicle behavior was asynchronous with the MTU behavior in BFlh. The MTU length and muscle activation significantly increased as the speed increased, but the fascicle length behaved isometrically.

INTRODUCTION

Previous studies have reported contradicting results about biomechanical factors contributing to running-related injuries.[1] We sought to prospectively identify runners at risk for injury using ground reaction force (GRF)-time characteristics. We hypothesized that runners with a subsequent musculoskeletal injury would have more GRF characteristics outside statistical boundaries of non-injured runners.

METHODS

Thirty-three National Collegiate Athletic Association Division I endurance runners (22 F, 11 M) provided informed consent in this IRB approved multi-institutional study. GRFs were measured for multiple foot contacts at 1000Hz using over-ground force plates (Kistler) or instrumented treadmills (Treadmetrix and Bertec). Athletes ran at 7 min/mi (3.83 m/s). Data were filtered with a low-pass 4th-order Butterworth recursive filter (50Hz treadmill, 75Hz over-ground) using custom Python and R scripts. Nine (out of 33) athletes experienced a musculoskeletal injury. We selected ten GRF variables for each leg in the vertical and anterior-posterior directions. These included contact time, braking time, average vertical GRF during braking and propulsion (Avg $_V$GRF Brake, Avg $_V$GRF Prop), average anterior-posterior GRF during braking and propulsion (Avg $_{AP}$GRF Brake, Avg $_{AP}$GRF Prop), change in vertical velocity during braking and propulsion (Δv_V Brake, Δv_V Prop), change in anterior-posterior velocity during braking and propulsion (ΔvAP Brake, ΔvAP Prop). We established boundaries for all non-injured athletes as Median +/- Scaled Median Absolute Deviation (MADN) [2] (Table 1).

Table 1: Median (MADN) GRF variables in uninjured runners.

Median (MADN)	*Braking*	*Propulsion*
Avg GRF_V (BW)	1.951 (0.140)	1.329 (0.147)
Avg GRF_{AP} (BW)	-0.200 (0.024)	0.219 (0.027)
Δv_V (m/s)	0.955 (0.123)	0.328 (0.134)
Δv_{AP} (m/s)	-0.195 (0.022)	0.210 (0.029)
Time (ms)	Braking: 98 (9)	Contact: 198 (12)

We used a robust distance measure (RDM) [2] to determine if a GRF variable was within the boundaries of non-injured runners (Fig 1). Cliff's method was used to test the probability that an injured runner would have more variables outside the non-injured boundaries.[2]

RESULTS AND DISCUSSION

The median number of variables outside the boundaries was 3 for non-injured and 4 for injured athletes. We found no statistically significant difference (p=0.17) between injured and non-injured legs, which may be due to low power from the small sample size.

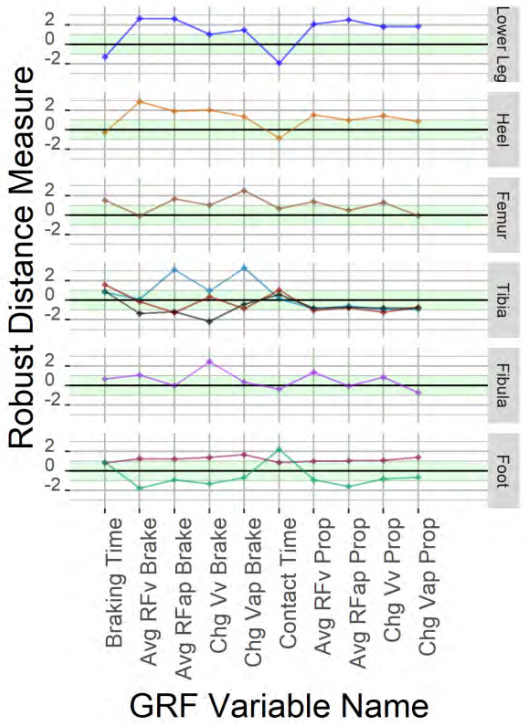

Figure 1: Robust Distance Measures (RDM) of GRF variables for nine injured athletes. Green indicates Median +/- MADN. Individuals are ordered by soft tissue injury (top 2 rows) and by bone stress response location. (+ = higher force/velocity/time).

CONCLUSIONS

Our new method identifies GRF variables that may contribute to running-related injuries.

INTRODUCTION

Between-limb asymmetry of running biomechanics is often examined as a running related injury risk factor and consideration for return to training after injury. Additionally, higher levels of asymmetry have been associated with reduced mechanical efficiency which would impact running performance [1]. While expected levels of asymmetry have been characterized for level ground (LG) running across a range of speeds in healthy runners [2], the amount of expected asymmetry during incline (INC) and decline (DEC) running is unknown. Determining the effect of graded surfaces on asymmetry would inform return to run prescription and training program design. Furthermore, establishing expected values for healthy runners will inform future studies that aim to examine the effect of asymmetry on injury risk and performance. Therefore, the purpose of this study is to determine the effect of graded running on joint work asymmetry at the hip, knee, and ankle.

METHODS

Eleven healthy, recreational runners (7 females, age: 25 years, mass: 63 kg, height: 170 cm) completed thirteen 30s running trials at 5 speeds across 3 grades (LG, 7.5° INC and 7.5° DEC). Kinematic data were collected at 200 Hz using an 8-camera motion capture system (Motion Analysis Corp.) and kinetic data were collected at 1000 Hz using a force-instrumented treadmill (Bertec). Each participant's slowest speed (1:30 min/mile slower than self-reported 5k pace; average 3.20 m/s) was utilized for analysis, as this was the estimated speed at which participants performed the majority of their training volume. Sagittal plane hip, knee, and ankle power were calculated using inverse dynamics in Visual 3D (C-Motion, Inc.). Stance phase positive and negative work were calculated for each joint by integrating the positive and negative portions of the power-time curves, respectively (Figure 1). Symmetry angle was utilized to calculate between-limb asymmetry for each variable [3]. Repeated-measures ANOVAs were performed using SPSS (IBM) to determine the effect of grade on joint work asymmetry.

RESULTS AND DISCUSSION

Across grades, asymmetry was lowest at the ankle (<3.5%), followed by the knee (5.5-10.25%) and hip (6.79-19.25%), which is consistent with previous LG studies [2]. Inter-subject variability of joint work asymmetry was high (Table 1). No significant effect of grade was detected for between-limb asymmetry of negative or positive ankle and knee work or negative hip work ($p > 0.05$). However, positive hip work asymmetry was significantly higher in the DEC condition compared to INC ($p = 0.003$). Since positive hip work is minimal in DEC running (Figure 1), small absolute differences in hip work result in a large relative asymmetry.

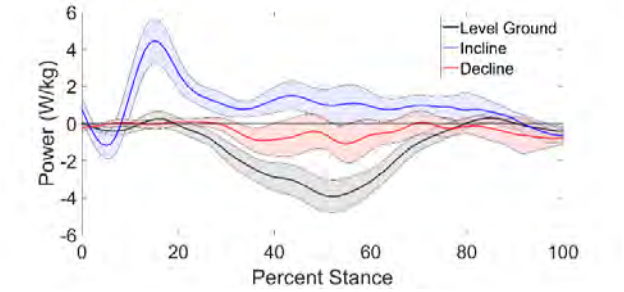

Figure 1 Hip power across grades for one exemplar participant. Work is calculated as the area under the power-time curve (J/kg). Shaded areas represent ± 1 standard deviation.

CONCLUSIONS

Joint work asymmetry changes minimally in response to graded running. While positive hip work asymmetry is higher in DEC running, this appears to be due to the minimal amount of positive hip work performed while running downhill and is not likely clinically significant.

INTRODUCTION

Uphill running is characterized by an increased demand for work performed and is often incorporated in a runner's training regimen. Previous studies have reported an increase in ankle joint work and power with grade during stance phase, while joint moment remained unchanged [1, 2]. This suggests that an increase in joint angular velocity is the source of increased power, and thus increased work. Indeed, it has been shown that the shortening velocity of the gastrocnemius muscle-tendon unit (MTU) increases with grade [3], leading to an effective increase in joint angular velocity. While the effect of grade has been well documented, the role of speed on the mechanical properties of the ankle joint is still unclear. Therefore, the purpose of this study was to clarify the effect of speed on ankle joint mechanics during incline treadmill running.

METHODS

Seven healthy, recreational runners (2M, 5F; age: 24.5 years, height: 176.8 cm, mass: 67.7 kg) completed 30s running trials at 4 speeds with a grade of 7.5˚ incline on a force-instrumented treadmill (Bertec). Speeds were relative to each participant's self-reported 5k pace (Speed 4), where Speeds 1, 2, and 3 were 1:30, 1:00, and 0:30 min/mile slower, respectively. Kinematic data were collected using an 8-camera motion capture system at 200 Hz (Motion Analysis Corp.), and force data were collected at 1 kHz. Peak plantar flexion (PF) and dorsiflexion (DF) angular velocity was calculated from joint kinematic data. Ankle joint power was calculated using an inverse dynamics approach in Visual3D (C-motion), and work was defined as the time-integral of power (Figure 1). The effect of speed on dependent variables was assessed with a one-way repeated measures ANOVA using SPSS (IBM Corp.).

RESULTS AND DISCUSSION

Both peak positive and negative power increased with speed ($p < .001$), while there was no significant effect of speed on net work ($p = .235$). Peak PF and DF angular velocity increased with speed ($p < .001$; $p = .022$, respectively). Post-hoc pairwise comparisons with Bonferroni correction are summarized in Table 1.

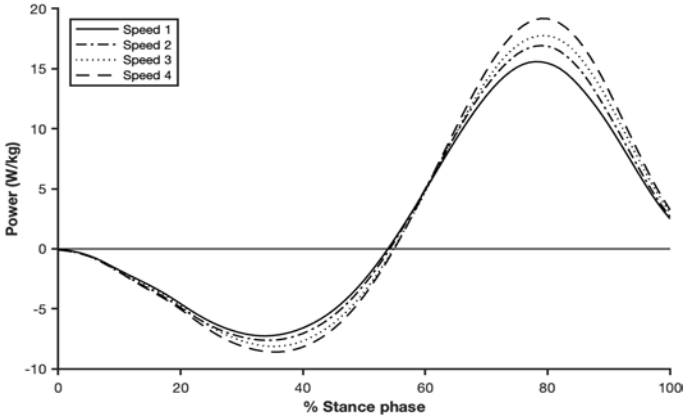

Figure 1 Ankle joint power (W/kg) during stance (average of 7 subjects).

CONCLUSIONS

No change in ankle joint net work was observed, while peak positive and negative power increased. This increase in power may be attributed to the observed increase in joint angular velocity, suggesting greater stretch and recoil of tendinous tissue. Future work should clarify further the contribution of the whole MTU to joint power, specifically about the ankle joint.

The effects of foot torsional stiffness on foot kinematics and impact force during running

INTRODUCTION

Foot torsional stiffness evaluates foot complex motion in three planes and viscoelasty of the midfoot. Previous studies have shown that abnormal foot torsional stiffness exhibits abnormal foot kinematics during gait, which is associated with a history of overuse injuries [1,2]. However, no study examines the influence of foot torsional stiffness on foot kinematics and kinetics during running. The purpose of this study was to investigate the relationship among foot torsional stiffness, multi-segment foot kinematics, and kinetics during running.

METHODS

Twenty-nine healthy adults participated in this study and 12 subjects (7 females and 5 males) who ran with rearfoot strike were analyzed. We simultaneously measured midfoot passive resistance torque and forefoot frontal plane motion relative to rearfoot from forefoot maximum pronation to supination (Figure 1). Foot torsional stiffness was calculated by dividing the torque change by segmental excursion between forefoot 5° of eversion to 5° of inversion. This range corresponds to the forefoot frontal plane range of motion measured during the stance phase of gait [3]. Subjects ran barefoot at 3.3 m/s ± 10% along the 10-m runway and collected ground reaction force and three-dimensional kinematics of the shank, rearfoot, and forefoot. We calculated the peak fore-/rearfoot angle and excursion in the absorption and propulsive phases. We also calculated the impact peak, active peak, initial loading rate, and second loading rate as variables of impact force [4]. The relationships among foot torsional stiffness, kinematics, and kinetics were explored using Pearson's correlation coefficients ($\alpha = 0.05$).

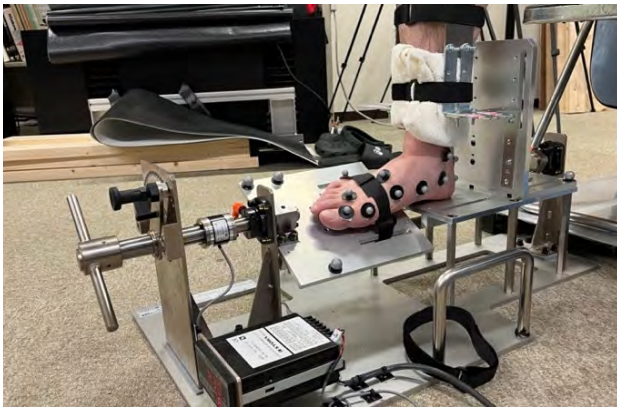

Figure 1 Measurement of midfoot passive resistance torque and three-dimensional foot kinematics.

RESULTS AND DISCUSSION

The foot torsional stiffness was significantly correlated with peak rearfoot inversion ($r = 0.65$, $p = 0.02$) in the propulsion phase and active peak ($r = 0.62$, $p = 0.03$), respectively. High foot torsional stiffness was associated with greater rearfoot inversion. The medial longitudinal arch elevation that occurs in the propulsive phase would increase the foot stiffness, which makes it possible to generate propulsive force efficiently. Considering rearfoot inversion is part of foot supination, it is possible that the foot with high foot torsional stiffness contributes to generating propulsive forces efficiently by elevating the arch in running. Moreover, high foot torsional stiffness was also associated with a higher active peak. Because the foot arch is depressed by the load at foot flat where active peak occurs, the value of active peak is considered to be an index of shock absorption by foot arch [4]. Thus, high foot torsional stiffness may prevent efficient shock absorption. Foot torsional stiffness depends on soft tissues such as intrinsic foot muscles, ligaments, and plantar aponeurosis across the midfoot. These soft tissues contribute to shock absorption in early to mid-stance, while they also contribute to energy return and the rigidity of the medial longitudinal arch in late stance. In particular, intrinsic foot muscles contract concentrically or eccentrically according to the magnitude of the load, which provides proper rigidity of the foot. Increasing the stiffness of the foot in propulsive phase allows the foot to transmit force to the ground efficiently and potentially reduces excessive strain on the soft tissues of the foot [5].

CONCLUSIONS

Foot torsional stiffness affects the foot kinematics and impact force during running as well as walking. High foot torsional stiffness appears to be effective for generating propulsion, while it may be inefficient from the point of view of shock absorption. This finding suggests that evaluating foot torsional stiffness may help in the selection of footwear and foot orthoses for rearfoot strikers.

The Influence of Fast Running Speed on Joint Coupling Angle between Ankle and Knee Joints in Unilateral Patellofemoral Pain

Chia-Li Hsu[1], Tunpisith Jeamsupakorn[2,5], Chich-Haung Richard Yang[2,4,5], Kuan-Lin Liu[2,3]

INTRODUCTION

Patellofemoral pain (PFP) is the most common condition that often increases compression forces and loads over the patella during dynamic activities such as stairs ascending and descending, jumping, running, and squatting [1]. A common cause is multifactorial, including biomechanical problems, muscle dysfunction, and overuse injury [2]. Changes in neuromotor control in running patterns could be a precursor to persistent symptoms, such as pain, in runners with PFP. An increase in running speed may contribute to moderate alterations in the frequency of joint coupling movement patterns [3]. We aimed to examine whether changes in the joint coupling angle of the knee and ankle joints during fast appear in individuals with PFP compared to healthy controls.

METHODS

15 recreational runners with PFP (age 36.5±9.9 years, BMI 22.3±2.9 kg/m^2) and 15 healthy controls (age 27.4±8.4 years, BMI 22.4±2.5 kg/m^2) were recruited. The PFP group has reported unilateral anterior or retropatellar knee pain during functional activity, pain on patellar palpation, and symptoms lasting at least 3 months on and off, with pain VAS of at least 3/10. We collected data during fast running (120% of self-selected speed) on the treadmill at a fast speed. Using vector coding technique to calculate the joint coupling angle between ankle and knee joint in the sagittal plane at fast running speed. The result was shown in the mean joint coupling angle of both groups, SPM1d t-test and p-value bar graph. In the mean joint coupling angle graph, the left y-axis is the degree of joint coupling angle, the right y-axis is the coordination pattern (proximal (knee) phase, in phase, distal (ankle) phase, and anti-phase) [4].

RESULTS AND DISCUSSION

In fast running speed during the initial stance phase of running, the PFP group showed increased knee flexion while ankle dorsiflexion (Anti-phase distal dominance). Then, from the mid-stance to the terminal stance of the running cycle, the PFP group showed decreased knee flexion while ankle dorsiflexion with knee extension while ankle plantar-flexion (In proximal phase dominance). In the terminal stance phase, the PFP group showed increased knee flexion while ankle plantar flexion to knee extension while ankle plantar flexion. In the early float phase, the PFP group showed an increase in knee extension during ankle dorsiflexion. During the swing phase, the PFP group showed a decrease in knee flexion while ankle dorsiflexion for knee extension during ankle flexion. During the late float, the PFP group showed a decline in knee extension in the late phase to increase knee extension during ankle dorsiflexion. (Figure 1). These findings have shown a significant impact on the understanding the neuromuscular control of knee and ankle coupling angles during fast running in runners with PFP.

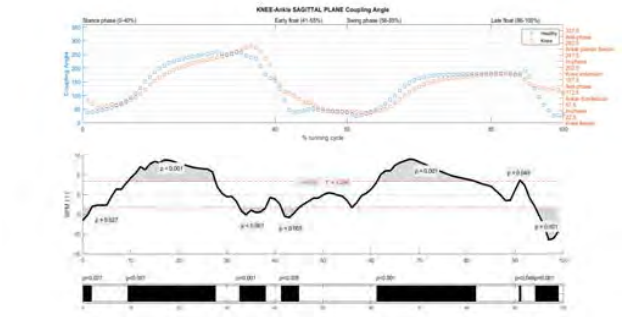

Figure 1. Knee-Ankle coupling angle in the sagittal plane during fast speed running

CONCLUSIONS

Individuals with PFP may employ a compensatory motor strategy in the knee and ankle coupling angle to adapt their functional movements, such as fast running. These findings could provide a further understanding of impairments in movement control to improve optimal rehabilitation for these populations.

INTRODUCTION

Power output onto the ground is necessary during the human accelerated sprinting. Previous studies indicated that the contractile component of the muscles is responsible for the power output during low-velocity running, whereas the stored elastic energy in the series elastic elements enhances power output during high-velocity running [1, 2]. Based on these concepts, it was expected that the lower limb muscle activation pattern would vary with increasing running velocity during sprint acceleration. This study aimed to determine the electromyogram (EMG) of the lower limb muscles during the acceleration stage of sprinting.

METHODS

Four male sprinters (Table 1) performed 70-m sprinting from starting blocks in the indoor track. EMGs for lower limb 16 muscles (rectus femoris [RF], vastus medialis [VM] and lateralis [VL], biceps femoris [BF], gastrocnemius medialis [GM] and lateralis [GL], soleus [SOL], and tibialis [TA] muscles of both right and left lower limbs) were recorded at each step using telemetric surface EMG system (Noraxon, USA, Inc., Scottsdale, AZ, 2kHz). EMG signals were filtered using a band-pass filter (20–450 Hz) and smoothed using root mean squared analysis (Time window: 25 ms). The maximum muscle activation obtained during the sprinting was used to normalize EMG. Ground reaction forces in each step were measured using a 50-m force plate system (Tec Gihan Co. Ltd, Uji, Japan, 1 kHz). The integral EMG (iEMG) and the ratio of iEMG during the braking and propulsive phases (iEMG ratio) were calculated.

Table 1: Characteristics of participants

	Age (years)	Height (m)	Mass (kg)	100-m personal best (s)
Sprinter A	21	1.69	68.9	10.36
Sprinter B	27	1.82	70.0	10.62
Sprinter C	22	1.73	64.3	11.30
Hurdler D	21	1.67	65.5	10.81
Mean	23.5	1.73	67.2	10.77
SD	2.6	0.59	2.3	0.34

RESULTS AND DISCUSSION

The iEMG was the highest immediately after the block clearance and gradually decreased with increasing velocity until a certain activation level in the acceleration stage was achieved and maintained (Figure 1). Participants reached 80% of their maximum running velocity (80%V_{max}) at 7-10 steps. Greater iEMG was observed in the propulsive phase, compared with braking phase until 80%Vmax. This suggest that concentric force production by the lower limb muscles can be important for initial accelerating the human body. In contrast, with increasing running velocity above 80%V_{max}, iEMG gradually decreased in the propulsive phase and increased in the braking phase. In this high-velocity acceleration stage, the elastic energy stored in a series elastic element would enhance the power output, possibly resulting in a decrease in iEMG in the propulsive phase.

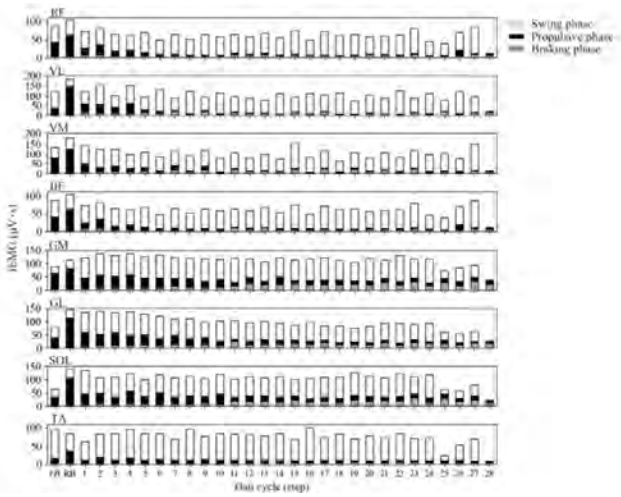

Figure 1 Results of iEMG of support leg across each step during sprinting for sprinter A. FB and RB indicated the front and rear block clearance, respectively. Over 80%V_{max} was reached at step 10.

CONCLUSIONS

From the block clearance to 80%V_{max}, iEMG in the propulsive phase accounts for the majority of the total iEMG in the stance phase. As the running velocity increased, the rate of iEMG in the braking phase increased.

KINEMATICS OF MAXIMAL VELOCITY RUNNING: FACTORS TO FURTHER ENHANCE STEP LENGTH AND FREQUENCY

Takeo Matsubayashi[1], Mai Kameda[1], Takafumi Kageyuki[1] and Amane Zushi[1]
[1] Department of Sport Science and Research, Japan Institute of Sports Sciences, Tokyo, Japan.

INTRODUCTION

Kinematics of maximal velocity running and its relation to maximal runing velocity have been investigated in several studies. However, it is not fully understood how it relates to the two components of running velocity independently, i.e., step length (SL) and step frequency (SF). To enhance maximal running velocity, one have to improve either or both SL and SF depending on their trainability. Therefore, it is important to understand the running kinematics required to improve each component separately. The aims of this study were 1) to examine the relation between SL, SF, and running kinematics, and 2) to elicit what kind of running motion would be required to improve SL and SF.

METHODS

Japanese male track and field athletes (n=102, including sprinters, hurdlers, long jumpers, decathletes; maximal running velocity, 10.17±0.32 m/s) participated in this study. Their maximal velocity running was captured using a 250-Hz optical motion capture system. Spatiotemporal and kinematic parameters, e.g., contact time (CT), flight time (FT), contact length (CL), segment/joint angles and angular velocities in the sagittal plane, were obtained from two consecutive left and right steps of each athlete. Multiple regression analysis was used to examine the relation between SL, SF, and the running kinematics: it can elicit the effect of one explanatory variable with those of the others standardized, allowing the kinematics related to SL and SF to be examined independently. Regression models were developed with each spatiotemporal and kinematic parameter as a dependent variable and with SL, SF, and leg length as explanatory variables. Leg length was included to standardize the effect of body dimensions. The effects were determined based on the statistical significance (α=0.05) of the standardized partial regression coefficients (β).

RESULTS AND DISCUSSION

SL and SF were both found to be negatively related to CT (β=-0.44 and -0.98 for SL and SF, respectively), implying that an increase in maximal running velocity should be accompanied by a reduction in CT, irrespective of whether SL or SF is improved. However, it should be noted that the effect of SL was smaller than that of SF. This may reflect the inherent demand of longer CT for longer SL: longer SL should be accompanied by longer FT (β=0.34), which may require a greater impulse during the stance phase, and longer CT would be preferred for this. This is also supported by the positive relation between SL and CL (β=0.28), suggesting that a slightly longer CT can be achieved with a longer CL. Correspondingly, the kinematics of the stance-leg knee joint was found to be related to SL (Figure 1 top). Longer SL was accompanied by a more extended stance-leg knee joint (β=0.25) and a more forward swung stance-leg shank segment (β=0.34) at toe-on; the knee joint was largely flexed after toe-on (β=0.30), although its maximum flexion angle was not marked (β=0.03, $p>0.05$). This stance knee joint motion may play an important role in achieving a longer CL. SL was also found to be related to the forward lean angle of the trunk at toe-on (β=0.32) and toe-off (β=0.28). Due to this forward leaned trunk, the extended knee joint was not associated with a larger center-of-mass (CoM) -toe distance at toe-on (β=0.09, $p>0.05$). On the other hand, the distance at toe-off was larger for longer SL (β=0.44). As for SF, it was found to be negatively related to CL (β=-0.27) and CoM-toe distance at toe-on (β=-0.47), which was mainly due to a more forward leaned trunk at the toe-on (β=0.46, larger effect than SL, Figure 1 bottom). Smaller CoM-toe distance at toe-on suggests that a breaking impulse may be smaller, and this may be a key to keeping SL unshortened. SF was also related to the angular velocity of the swing-leg knee flexion (β=0.54), suggesting that a lower moment of inertia would allow faster forward recovery of the swing leg and higher SF.

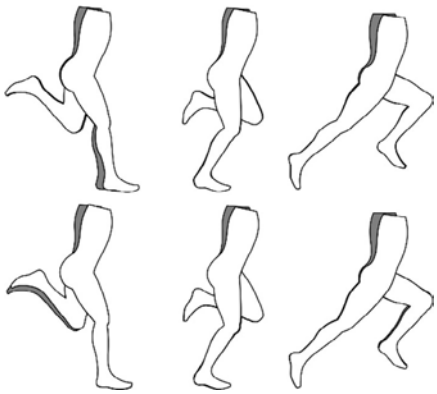

Figure 1 Running motions related to longer SL (top) and higher SF (bottom) respectively, plotted over the average running motion derived from the present data (dark silhouette).

CONCLUSIONS

The current study successfully elicited the motions related to greater SL and SF separately: longer SL was mainly related to longer CL and larger stance-leg knee movement, whereas higher SF was related to smaller CoM-toe distance at toe-on with forward leaned trunk and faster swing leg knee flexion. Acquisition of these motions would help to enhance maximal running velocity with improved SL and/or SF.
